There are no validated diagnostic criteria for MAS, and early diagnosis is often difficult. A recent consensus conference has developed expert-based *classification* criteria for MAS, although these have not been validated as *diagnostic* criteria in clinical trials. Thus, in a patient with persistently active underlying rheumatologic disease, a fall in the ESR and platelet count, particularly in combination with persistently high C-reactive protein and increasing levels of ferritin, should raise a suspicion of impending MAS. The diagnosis of MAS is usually confirmed by the demonstration of hemophagocytosis in the BM. Assessment of the levels of sCD25 and sCD163 in serum may help with the timely diagnosis of MAS. Although mild elevation of sCD25 has been reported in many rheumatic diseases, including JIA and SLE, a several-fold increase in the levels of sIL2Rα in these diseases is highly suggestive of MAS. The application of the HLH diagnostic criteria to systemic JIA patients with suspected MAS is problematic. Some of the HLH markers, such as lymphadenopathy, splenomegaly, and hyperferritinemia, are common features of active systemic JIA itself and therefore do not distinguish MAS from a conventional systemic JIA flare. Patients with systemic JIA often have increased white blood cell and platelet counts, as well as serum levels of fibrinogen as a part of the inflammatory response seen in this disease. Therefore, when they develop MAS, they reach the degree of cytopenias and hypofibrinogenemia seen in HLH only at the late stages of the syndrome when medical management becomes challenging. This is even more problematic for the diagnosis of MAS in patients with SLE in whom autoimmune cytopenias are common and difficult to distinguish from those caused by MAS.

Early recognition of this syndrome and immediate therapeutic intervention to produce a rapid response are critical. Prompt administration of more aggressive treatment in these patients may, in fact, prevent development of the full-blown syndrome. To achieve rapid reversal of coagulation abnormalities and cytopenias, most clinicians start with intravenous methylprednisolone pulse therapy (30 mg/kg for 3 consecutive days) followed by 2 to 3 mg/kg/day divided into four doses. After normalization of hematologic abnormalities and resolution of coagulopathy, steroids are tapered slowly to avoid relapses of MAS. Commonly, however, MAS appears to be corticosteroid-resistant, with deaths being reported even among patients treated with massive doses of steroids. Parenteral administration of cyclosporine A has been shown to be highly effective in patients with corticosteroid-resistant MAS. The utility of biologic drugs in MAS treatment remains unclear. Although tumor necrosis factor-inhibiting agents, biologics that neutralize IL-1 and IL-6, have been reported to be effective in occasional MAS patients, other reports describe patients in whom MAS occurred while they were receiving these agents. Recently, there have been reports on chronic complications with these agents such as lung disease. Based on some success with IVIG administration in virus-associated HLH, this treatment might be effective in MAS triggered by viral infection. If MAS, however, is driven by EBV infection, rituximab, a monoclonal antibody that depletes B lymphocytes (the main type of cells harboring the EBV virus), may be considered.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS IN THE CONTEXT OF IMMUNE-ACTIVATING THERAPIES (RX-HLH)

The HLH syndrome develops in some patients receiving immune-activating therapies, such as T cell–engaging antibodies, chimeric antigen receptor (CAR) T cells, or immune checkpoint inhibitors. In this context, this syndrome is usually referred to as cytokine release syndrome (CRS). However, its pathophysiology appears quite similar to F-HLH and should be recognized as iatrogenic HLH, or Rx-HLH.

Diagnosis and Treatment

The anti-IL-6 antibody tocilizumav has been used with rapid resolution of CRS in patients after CAR T cell immunotherapies.[86] A CART cell associated toxicity working group suggests that CRS should be managed with anti-IL-6 and corticosteroids for organ toxicities higher than grade 3. If the patient has no clinical or laboratory improvement within 48 hours, additional therapy with etoposide (75 to 100 mg/m^2 should be considered). Treatment interruption or corticosteroids alone have been used with successful outcomes in CRS induced by immune checkpoint inhibitors.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS IN THE CONTEXT OF IMMUNE COMPROMISE (IC-HLH)

HLH can occur in a variety of immune-compromised patients including primary immune deficiency (PID) or patients receiving immunosuppressive therapy, mostly in the context of unresolved infection. For instance, patients with inflammatory bowel disease (IBD), usually treated with azathioprine or mercaptopurine, have been reported to develop (usually relatively mild) HLH after infection with EBV or CMV. In these contexts, the pathophysiology is not well understood. While it may be related to the underlying disease, HLH appears to be a dysregulated response to infection in the context of immunosuppression.

A variety of PIDs have been reported to present with HLH (detailed in Table 53.7). Patients with PID and HLH often have unresolved, severe infections. Patients with severe combined immunodeficiency (SCID) most often have viral infections, while those with chronic granulomatous disease (CGD) present with bacterial infections. Thus, the presence of HLH associated with unusual or unusually severe infection should suggest undiagnosed immune deficiency.[87]

Diagnosis and Treatment

The diagnosis is based on a history of immunosuppression (primary or secondary to drug use) or unusually severe infection as the initial presentation of a PID. Some of the IC-HLH can be included in the HLH disease category and as thus, will gain from immunosuppression while others should be considered as HLH mimics (some PIDs). IBD patients should be treated with drug withdrawal, treatment of infection, and a moderate dose of corticosteroids +/- etoposide.

Future Directions

Although HLH appears to be a disease of excessive immune activation, the ideal form of immune suppression and anti-inflammatory therapy remains unknown. Although somewhat responsive to corticosteroids and clearly responsive to etoposide or anti-T-cell serotherapy, such as ATG or alemtuzumab, HLH remains difficult to treat. However, newer, targeted therapies, based on insights from animal models, were developed and are being tested in clinical trials. Anti-IFN-γ, emapalumab, is the first targeted therapy approved and is now being examined for frontline use in HLH and in specific subsets (R-HLH, M-HLH). A JAK1/2 inhibitor (ruxolitinib) is being investigated currently in several clinical trials. Anti-cytokine treatment is common in R-HLH (IL-1 or IL-6 blocking agents), though these patients are increasingly diagnosed with chronic complications such as lung disease. The blockade of IL-18 is being investigated for patients with HLH driven by the inflammasome. It is likely that such targeted therapies will eventually supersede current approaches.

CHAPTER 54

LYSOSOMAL STORAGE DISEASES, FOCUSING ON GAUCHER DISEASE: PERSPECTIVES AND PRINCIPLES

Atul Mehta, Mia Horowitz, Joaquin Carrillo-Farga, and Ari Zimran

LYSOSOMAL STORAGE DISEASES

Lysosomal storage diseases (LSDs) are genetic disorders caused by deficiencies in single lysosomal hydrolases. Deficiencies result in cellular and organ damage due to subsequent accumulation of a specific substrate for that particular enzyme, hence the term “storage” disease. However, the diverse role of the lysosome in cellular metabolism means that the pathological consequences of enzyme deficiency extend beyond substrate accumulation.

Although individually rare, the true prevalence of these disorders is likely to be much higher. Overall, 60 or so monogenic disorders have a combined frequency of approximately 1:7000 live births, and are probably increased due to consanguinity rates among different populations. All are autosomally inherited except for Fabry, Danon and mucopolysaccharidoses II (MPS II), which are sex-linked. The classification is in accordance with the biochemical nature of the primary storage material and pathogenic mechanisms (Table 54.1).[1,2]

Hers was the first to describe enlarged and abnormally shaped lysosomes resulting from primary accumulation of storage material in a patient with Pompe disease (α-glucosidase deficiency), thus delineating the first LSD.[3] Many LSDs have an early age of onset, associated with genetic mutations which lead to absent, or very low, enzyme levels and a correspondingly severe clinical course. However, several also have an attenuated form with later age of onset, genetic mutations associated with reduced or mutant enzyme production and reduced (but not absent) catalytic activity. LSDs are characterized by broad systemic involvement of multiple tissues and organs (typically involving bone, viscera, connective tissue, skin, kidney, and heart). Crucially, the majority have extensive neurological involvement manifesting as intellectual disability, dementia, seizures, movement disorders and sensory organ abnormalities.

Accumulation of storage material compromises the functional capacity of the lysosome and initiates a cascade of secondary downstream pathologic events. These include impaired autophagy (see Chapter 10), apoptosis and signal transduction, which precipitate cellular death and neurodegeneration. There is deficient supply, recycling and transport of key membrane and intracellular receptors, and macromolecules leading to synaptic failure and energy depletion. Cellular damage induces inflammation as an initial protective response but chronic induction is deleterious. Abnormal calcium homeostasis disturbs intracellular fusional and signaling events, and alters the potential of hydrogen (pH) to cause trafficking defects affecting storage and egress of cholesterol, sphingomyelin, and glycosphingolipids (GSLs). Macrophage activation, possibly mediated by cytokine release, has been demonstrated in Gaucher disease (GD) and other LSDs.[4] Accumulation of lysosphingolipids (i.e., GSLs that do not have N-acylated fatty acids) may be of pathogenic significance in Krabbe, Gaucher, and Fabry diseases.

Gaucher disease is important for hematologists because the presenting signs are splenomegaly and bleeding tendency (mainly due to thrombocytopenia but also platelet dysfunction and coagulopathies), because early diagnosis is important so therapy begins before irreversible bony complications occur, and because comorbidities include MGUS with increased risk of myeloma, lymphoma and MDS. Gene therapy trials are ongoing and adding relevance.

The biochemical composition of the accumulated macromolecules distinguishes the main categories of LSD: the glycosphingolipidoses (GPS), the mucopolysaccharidoses (MPS) and carbohydrate storage diseases. The pattern of storage of the accumulated lipid substrate in LSDs often mirrors the normal distribution of the molecule in the body, giving rise to organ-specific pathology. Thus, accumulation of GSLs in the central nervous system (CNS) leads to neurodegeneration, whereas storage in visceral cells leads to organomegaly, skeletal abnormalities, pulmonary infiltration, and other manifestations. In the MPS disorders, the accumulating lipid substrates (also known as glycosaminoglycans [GAGs]) are found predominantly within connective tissues to cause cartilage and bone abnormalities. The CNS may also be affected, particularly in diseases (e.g., MPS type I) where the GAG heparan sulfate accumulates. In contrast, in Maroteaux-Lamy disease (MPS type VI), only dermatan sulfate, which is not usually found in the brain, accumulates, and CNS manifestations do not occur; while in MPS IV, the accumulation of keratan sulfate leads to a predominant skeletal phenotype. (See box on Illustrative Mucopolysaccharidoses Case History.)

Lysosomal Protein Biosynthesis and Sorting

All lysosomal enzymes are translated on the endoplasmic reticulum (ER)-bound polyribosomes and contain a leader sequence. They enter the ER through the ER-specific translocons, and then lose the leader sequence. During translation the protein sequence, already within the ER is glycosylated on asparagine residues, which are part of the consensus sequence: Asparagine-X-Serine/Threonine (N-X-S/T; “X”

ILLUSTRATIVE MUCOPOLYSACCHARIDOSES CASE HISTORY

A male infant whose parents were first cousins was born healthy at full term. He presented at age 2 months with an inguinal hernia and a congenital hydrocoele. He developed four episodes of bronchiolitis and chest infection requiring antibiotics in the first 6 months of life. At 7 months hepato-splenomegaly was incidentally noted but initial general investigations did not yield a diagnosis. He was reviewed by a specialist pediatrician at 17 months when delay in attainment of motor, language and cognitive milestones was noted. He had coarse facial features with hepatosplenomegaly, corneal clouding, lower thoracic and lumbar kyphosis, umbilical hernia ultimately leading to a suspicion of an MPS disorder. Specialist testing and enzymology showed zero activity for alpha iduronidase, and a diagnosis of MPS 1 (Hurler syndrome) was made. Enzyme replacement therapy (ERT) was commenced immediately. Allogeneic stem cell transplant (SCT) from a fully matched sibling donor was performed at age 24 months.

Comment: If specialist referral had been undertaken at 7 months the diagnosis would have been made earlier, specific treatment including ERT and SCT would have been undertaken earlier and there would have been earlier supply of enzyme to the developing brain, CNS and systemic tissues leading to amelioration of the damage caused by the enzyme deficiency.

TABLE 54.1 Classification of Lysosomal Storage Disorders[1,2]

Disease	Prevalence	Deficient Enzyme	Subtypes
Sphingolipidoses, sphingolipid activator defects	>1/20,000 people		
Gaucher disease	1:40,000	beta glucocerebrosidase Saposin C	Types 1, 2, 3
Fabry disease	>1:20,000	alpha galactosidase A	Classic late onset Heterozygous
Tay-Sachs	<1:100,000	beta hexosaminidase A	Infantile and adult onset types
Sandhoff		beta hexosaminidase B	Infantile and adult onset types
Krabbe		beta galactosylceramidase	
Niemann-Pick types A and B		Acid sphingomyelinase deficiency	
Metachromatic leukodystrophy	<1:200.000	Arylsulfatase A Saposin B	
GM1 gangliosidosis		beta galactosidase	Types I, II, and III
Mucopolysaccharidosis (MPS)			
MPS I	>1:100,000	alpha-L-iduronidase	Severe (Hurler), milder (Scheie)
MPS II	<1:100,000	Iduronate-2-sulfatase	Hunter, and milder phenotypes
MPS III		Heparan-N-sulfatase and other enzymes	
MPS IV		N-acetylgalactosamine 6-sulfatase and beta galactosidase	Sanfilippo 4 subtypes: Morquio 2 subtypes
MPS VI		N-acetylgalactosamine 4-sulfatase	Maroteaux-Lamy
MPS VII	<1:300,000	beta glucuronidase	Sly
MPS IX		Hyaluronidase	Natowicz
Other enzyme deficiencies			
Glycogen storage disease type II	<1:100,000	Acid maltase	Pompe milder adult forms
Glycoproteinoses (e.g., aspartylglucosaminuria, fucosidosis, alpha/beta mannosidosis, Schindler disease)			
Lipidoses		Acid lipase	Wolman cholesterol ester storage disease
Defective post-translational processing of lysosomal enzymes			
Multiple sulfatase	<1:300,000	Formyl glycine generating enzyme	
Mucolipidosis II and III		N-acetylglucosamine-1-phosphotransferase	
Lysosomal membrane and transport defects			
Cystinosis	<1:300,000	Cystine transporter	
Sialic acid storage disease		Sialic acid transporter	
Cobalamin F disease		Cobalamin transporter	
Danon		Lysosome associated membrane protein 2 (LAMP-2)	
LIMP-2 deficiency[a] Action myoclonus renal failure syndrome		Lysosomal integral membrane protein 2	
Niemann-Pick types C1 and C2		Niemann-Pick types C1/C2 protein	
(CLN) Types 1–10; Batten = CLN3			
Defects in lysosome biogenesis			
Chediak-Higashi syndrome	<1:300,000	LYST Lysosomal traffic regulator	
Griscelli syndrome types 1–3			
Hermansky-Pudlak syndrome types 1–9			

[a] LIMP 2 (lysosomal integral membrane protein 2) aids trafficking of GCase from the ER to lysosomes; is involved in the pathogenesis of hand, foot, and mouth disease, caused by enterovirus-71 and possibly by coxsackievirus A16; mutations in the *LIMP2* gene can serve as a modifier in Gaucher disease (GD).

can be any amino-acid except proline). These N-linked glycan trees (dubbed N-glycans) consist of nine mannose residues and[5] three glucose residues. The enzymes are then folded, and, if recognized by the ER quality control machinery as correctly folded, they exit the ER in specific trafficking vesicles (called COPII vesicles) toward the Golgi network. They undergo further modifications on their N-linked glycan trees, which lose the glucose residues and three to four mannose residues. Most lysosomal enzymes are phosphorylated by the enzyme N-acetylglucosaminyl-1-phosphotransferase on a terminal mannose and as such are recognized by the mannose 6-phosphate receptor, which shuttles them, on specific late endosomal vesicles to the lysosomes. Mutations in the gene encoding this enzyme lead to severe LSD (I-cell disease), characterized by the abnormal secretion of all lysosomal enzymes whose lysosomal targeting depend on the M6P recognition signal.

If recognized as misfolded by the ER quality control machinery, lysosomal proteins undergo several folding attempts. If unsuccessful, the misfolded protein is translocated from the ER to undergo polyubiquitination and proteasomal degradation. This is known as ER-associated degradation (ERAD; Fig. 54.1).[6] Persistent retention of misfolded molecules in the ER provokes ER stress and induces the Unfolded Protein Response, known as UPR.[7] UPR monitors the conditions in the ER by sensing insufficiency in protein folding capacity and translating this information into gene expression by a signal transduction.

Several lysosomal enzymes and proteins (including the hexosaminidase A alpha and beta chains, mutated in Tay-Sachs disease and in Sandhoff disease, respectively) undergo proteolytic cleavage in the lysosomes as the last stage of their maturation process.

A large number of mutant lysosomal enzymes undergo ERAD and, therefore, lysosomal diseases may be regarded as misfolding or conformational diseases.

Genetics of Lysosomal Storage Diseases

Lysosomal genes are regarded as "housekeeping," that is, they are expressed in the majority of cell types and are essential for cellular function, such that complete absence of most of the enzymes is incompatible with life; Fabry disease is an important exception. All LSDs are inherited in an autosomal recessive fashion except for Fabry, MPS II and Danon, which are X-linked. One lysosomal gene, SMPD1 encoding acid sphingomyelinase (ASM), is known to be "paternally imprinted" (i.e., preferentially expressed from the maternal chromosome).[8] Diverse mutations underly individual LSDs, and the majority of these are unique ("private") to individual pedigrees. Broad genotype-phenotype relationships have been established. GD is a good example—major organizational disruptions of the gene are associated with a more severe phenotype.[9,10]

In general, heterozygous "carriers" of single mutations in a lysosomal gene do not develop clinical symptoms of the disorder, except in the X-linked disorders. For example, in Fabry disease X-inactivation patterns can lead to clusters of cells without enzyme activity, and heterozygous females often develop disease-related pathology primarily as a result of unbalanced X chromosome inactivation.[11] Heterozygous carriers of glucocerebrosidase gene (*GBA1*) mutations have a much increased risk of developing Parkinson disease (PD).

Some LSD-specific populations have recurrent mutations caused by founder effects and/or consanguinity. This facilitates the use of DNA-based screening methods for their detection. This has been translated into clinical use in the Ashkenazi Jewish population and has led to the establishment of a DNA-based "Jewish Genetic Disease" screening panel. Evolving cost-effective, high-throughput sequencing methods are likely to open other populations and disorders to these screening approaches. However, DNA-based methods will generate large numbers of GVUS (genetic variants of uncertain significance) and should not be used to predict clinical outcomes in patients unless the biochemical consequences of the mutations are fully established. An example of a mutation which was formerly a GVUS, but has recently been demonstrated to undoubtedly be associated with late-onset hypertophic cardiomyopathy in Fabry disease, is c.472 G>A; however, detailed studies have shown that although this variant is a necessary requirement for Fabry cardiomyopathy in affected individuals, it is not sufficient and other disease mechanisms are important for disease manifestations to develop.[12]

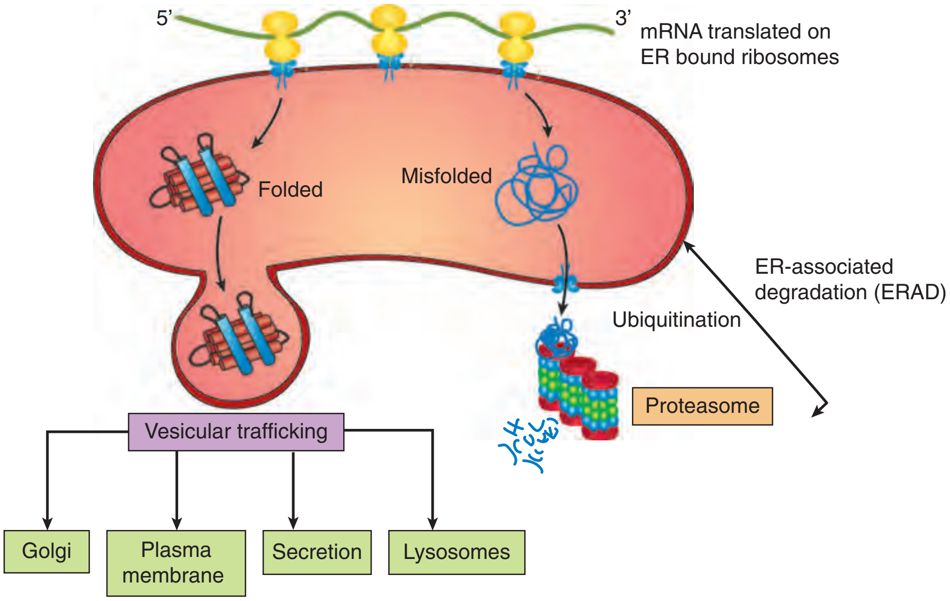

Figure 54.1 THE ER-ASSOCIATED DEGRADATION (ERAD) PROCESS. Proteins in the secretory pathway are synthesized on ER bound ribosomes. Following their entry to the ER and loss of their leader peptide, they undergo glycosylation on asparagines. Recognition of the peptide as correctly folded allows its shuttling to the secretory pathway via the Golgi apparatus. When recognized as misfolded, the proteins undergo several chaperone-mediated attempts to refold them. If unsuccessful, the misfolded molecules are retro-translocated from the ER to the cytoplasm, where they are polyubiquitinated and undergo proteasomal degradation, known as ERAD.

Diagnosis of Lysosomal Storage Diseases

The key to diagnosis is clinical suspicion of the disease. Clinical and laboratory diagnosis should be coordinated—once there is clinical suspicion, laboratory diagnosis is usually straightforward. These are multi-system disorders with few signature manifestations which occur among all ethnicities. The carrier rate among Ashkenazi Jews is about 1 in 15 for GD, 1 in 30 for Tay-Sachs, and 1 in 80 to 100 for Niemann-Pick type A.

Accurate clinical history and physical examination are crucial. The history must include a detailed family history and inquiry about consanguinity within the pedigree. Delay in diagnosis is a common problem and often leads to inappropriate investigations, delay in instituting specific treatment, and avoidable complications. A particular pitfall in diagnosis for pediatric and adult hematologists is that LSDs may have features that are shared by hematologic conditions (e.g., anemia, thrombocytopenia, hepatosplenomegaly, bone lesions). A survey of hematologists in the USA who have a clinical history of classic type 1 GD revealed that the overwhelming majority were initially considered to have a hematologic malignancy. The majority of Gaucher patients make their initial presentation to a hematologist and report a delay in diagnosis.[13]

Screening Programs

Screening programs aim to reduce diagnostic delay by institution of coordinated community diagnosis. Newborn screening (NBS) is already performed worldwide for certain metabolic diseases where early intervention is widely available and effective at preventing long term complications (e.g., dried blood spot [DBS] tests for phenylketonuria and hypothyroidism). Many states in the USA and countries in Europe and worldwide have embarked on these programs. Most of the laboratories engaged in LSD NBS carry out first-tier testing by measurement of lysosomal enzymatic activities in DBS on NBS cards using either tandem mass spectrometry (MS/MS) or fluorimetry (either digital microfluidics [DMF-F] or a standard plate reader).[14] Confirmatory enzymatic and DNA analysis is performed on positive samples. An emerging problem is that the programs are generally associated with a significant false positive rate. Furthermore, for some conditions (e.g., Fabry) neonatal screening based on gene sequencing has revealed prevalence rates which are far higher than previously suspected (e.g., 1:3200 for Fabry), but the majority of detected variants are of uncertain significance (GVUS), raising important ethical and procedural issues.

Targeted screening is the approach whereby clinical algorithms are used to identify subjects and family members considered to be at increased risk of suffering an LSD who can then be offered accelerated laboratory diagnosis. Such clinical algorithms have been devised for GD based on expert guidance.[15] A multi-national multi-center targeted screening study of 500 subjects with splenomegaly attending hematologists in Europe yielded a diagnosis of GD among 15 subjects.[16] Other examples of successful targeted screening programs include screening for Fabry disease among subjects with left ventricular hypertrophy and premature “cryptogenic” stroke.

Laboratory Diagnosis

DBS samples are increasingly used, replacing anticoagulated whole blood and, in some cases urine, and referred to specialty laboratories so that common pitfalls in laboratory diagnosis are avoided. Full clinical details and family history should be provided. Tissue biopsy is not indicated. Blood film morphology may give important clues (see below). Specific enzyme activity will then be measured in white blood cells, lymphocytes (such as T cells), plasma or DBS. Cultured fibroblasts are required to measure the activity of certain enzymes, for example, neuraminidase. Mass spectrometric assays allow simultaneous analysis of activity of several enzymes from DBS. Positive and negative controls are often included. Deficient activity in a clinically normal individual may also indicate “pseudodeficiency” due to the presence of a polymorphism—for example, as is commonly found with arylsulfatase A. A false-negative result may indicate a laboratory error but could rarely occur due to deficiency of a sphingolipid activator protein (SAP, e.g., the GM-2 activator protein or saposins A–D). Enzymatic activity from a heterozygous female will be normal or only marginally reduced if the condition is X-linked. Confirmatory DNA analysis should always be performed Laboratory diagnosis should also include confirmatory tests, for example, measurement of substrate level and relevant biomarkers.[17]

Baseline and Sequential Assessment

A genetic counselor can help with the interpretation of the results, the organization of pedigree analysis, and guidance with respect to treatment. A biomarker is a laboratory analyte that reflects the presence and/or extent of a biological process, and should be directly linked to the clinical manifestations and treatment outcome. Quantifiable biomarkers, which are specific, sensitive, reliable, and reproducible, are of great value in the management of several LSDs.[18,19]

The diversity of clinical manifestations means that multidisciplinary clinical assessment should be conducted to document structure, function, and patient-reported elements at diagnosis and at specified time intervals thereafter, irrespective of whether or not specific treatments are applied. Specific therapy should improve the disease manifestations, yet in many LSDs the impact of the intervention is much more limited, and may only amount to structural or functional reduction in the natural rate of decline. Reliable data on untreated individuals is crucial. Regulatory and funding authorities increasingly regard patient-reported outcome (PRO) as good measures reflecting the quality of life (QOL) and the overlay of psychological, social, societal concerns and stressors which are unique to LSD patients.

Specific Treatment

General Principles

The fundamental underlying principle behind the treatment of most LSDs is to replace the missing or defective protein, or to augment its activity, for example, by stem cell or organ transplantation, (protein) enzyme replacement therapy (ERT), gene therapy, substrate reduction therapy (SRT), or chaperone therapy (CT). “Proof-of-principle” was first documented by Neufeld and colleagues, who showed in an elegant series of studies that metabolic cross-correction of MPS cells could be achieved by co-culture of these cells with normal cells, or by replacing the media in MPS cells with “conditioned” media obtained from normal cells.[20] The identification of the mannose 6-phosphate (M6P)-targeting system for lysosomal enzymes and the finding that the secreted forms of many lysosomal enzymes could be rapidly internalized by cell surface M6P receptors and delivered into the lysosomal compartment further raised the prospect of ERT.[21]

A small biotechnology company (Genzyme, Cambridge, MA) began to commercially prepare β-glucocerebrosidase, the enzyme deficient in GD, from human placentas. The purified enzyme was chemically modified to expose terminal mannose residues, leading to preferential uptake by macrophages, the primary cellular site of pathology in type 1 disease (GD1). The results of biweekly intravenous ERT in GD1 included dramatically reduced organomegaly and improved hematologic findings, and substantially improved QOL.[22] Human recombinant enzymes for different LSDs are now produced in various sources, including Chinese Hamster Ovary (CHO) cell lines, transformed human cells, plants, and chicken eggs. Generic and bio-engineered preparations are increasingly being manufactured.

The physiological state requires that a small amount of protein is delivered on a constant basis. ERT has several drawbacks, among them the need for repeated intravenous infusions because of a short half-life, the inability to cross the blood-brain barrier (BBB), immunogenicity and excessive cost. The two major different approaches are cell therapy and the use of small molecules.

Cellular Therapy, Including Gene Therapy

Cell therapy is aimed at engraftment of cells (autologous or allogeneic) which can produce endogenous enzymes (see Chapter 103). Advantages of hemopoietic stem cells (HSCs) include their potential to self-propagate and to differentiate into multiple stem and progenitor cell lineages, which could potentially repopulate diverse organs and tissues. Furthermore, the application of this technology in subjects with non-malignant metabolic diseases does not impose a need to eliminate host hematopoiesis; and advances in molecular techniques increasingly offer ways of bioengineering the grafted cells. However, intensive immunosuppressive pre-conditioning with chemotherapeutic agents, with its associated high morbidity and potential mortality, is still required to achieve effective engraftment; and an allogeneic donor raises the specter of graft-versus-host disease. Donor availability is improved with the availability of cord blood banks, and haploidentical and even sibling carrier donors; but despite improved transplantation techniques which have reduced the risks of stem cell transplantation, the possibility of confounding the Hippocratic injunction to "do no harm" remains high.

Results of hematopoietic stem-cell transplantation (HSCT) for LSDs have been variable. The capacity of HSCs to repopulate different tissues is not uniform throughout the body, and is limited with respect to the skeleton (cartilage and bone) and the CNS. Permanent tissue damage is not reversible and transplantation is best undertaken early in the course of the disease. Liver transplantation has offered interesting perspectives which may have lessons for future gene therapy strategies using adenoviral constructs which infect hepatocytes. The procedure has been undertaken to treat end-stage cirrhosis complicating GD and long-term results show excellent recovery of liver function and continued absence of substrate accumulation in the liver. However, skeletal remodeling does not occur, and subjects continue to require ERT to treat systemic disease outside the liver. Ex vivo gene therapy approaches (see Chapter 104) for a range of LSDs are being investigated whereby the genetic construct is introduced into autologous HSCs which are then transplanted. A pilot study (prematurely closed to recruitment in January 2022) has reported autologous infusion of lentivirus transduced HSCs in five male patients with Fabry disease with up to 3 years of follow-up; all patients produced α-gal A to near normal levels within one week and three patients have discontinued ERT. However, safety concerns have led to discontinuation of the trial in January 2022. (Also see box on Fabry Disease: Specific Treatment).

The long-term results of this and other studies are awaited with interest, amid continuing concern about future risk of side-effects related to the chemotherapeutic conditioning regimen. Exciting developments have also been reported with regard to the potential for cellular therapy with induced neural stem cells.[23]

Small Molecule Therapy

Small molecules have important advantages over ERT. They can be taken orally, they have the potential to cross the BBB and access the CNS, antibody formation is not anticipated, production costs are lower, and small molecules are likely to have a higher volume of distribution in the body and to thereby access tissues such as bone, kidney, lungs, and the myocardium.

Two important approaches are SRT and PC. Eliglustat (see below) is established as an important alternative to ERT for many patients with type 1 GD. Neurologic pathology in Niemann-Pick disease (NPD), more specifically NPD type C (NPDC), is associated with the secondary accumulation of a particular glycolipid, GM2 ganglioside. Miglustat inhibits glycolipid biosynthesis and results in reduction of GM2 storage and partial neurologic improvements.

FABRY DISEASE: SPECIFIC TREATMENT

1. Team meetings—Essential to gather all relevant baseline data and for lead physician to record it. Cardiac (including echo, MRI, LV mass, 24 h ECG), renal (GFR, 24 h proteinuria, albumin/creatinine ratio, ultrasound) and pain (including pain scores, nerve conduction if relevant) data essential; also record baseline assessment of GI, skin, ophthalmology, hearing/audiometry and quality of life.
2. Whom to treat—Males and females with demonstrable organ damage; or severe pain/reduced quality of life unresponsive to other interventions. ERT is safe in children.
3. When to treat—Commence treatment early before there is established or irreversible organ damage.
4. How to treat—a. Usual to start with ERT as it will treat all mutations. Agalsidase beta IV 1 g/kg given over 2–4 h every 2 weeks (Fabrazyme, Sanofi—available world-wide); agalsidase alfa IV 0.2 mg/kg given over 40 min every 2 weeks (Replagal, Takeda/Shire—not licensed in the US); penunigalsidase alfa IV every 2 weeks (Protalix/Chiesis, Israel—License pending)
   b. Adults—Chaperone therapy—Migalastat (Amicus therapeutics) 123 mg orally once daily on alternate days is equally effective as ERT if the mutation is amenable. Compliance is essential.
5. Where to treat—ERT must be commenced in the clinic under supervision. Infusion reactions are commoner with agalsidase beta and usually easily managed with hydrocortisone and anti-histamine. Home treatment by a nurse or self-infusion is commonly practiced throughout Europe.
6. How to monitor—Clinical review with full data set of blood tests including assessment for neutralizing antibodies every 6 months. Complete assessment of organ function (must include cardiac, renal, pain and quality of life assessment) every 12 months.
7. Investigational treatments—Substrate reduction therapy—Venglustat (Sanofi), Lucerastat (N-butyldeoxygalactonojirimycin, Idorsia, Switzerland)
   - Gene therapy—Sangamo, Freeline
   - Apabetalone (RVX-208, Resverlogix), a selective BET (bromodomain and extra-terminal) inhibitor that can regulate disease-causing genes.
8. Who should be considered for investigational therapy?
   All patients should be considered, as there are significant unmet needs with all available treatments.
   Particularly consider those:
   - unresponsive to or allergic to licensed therapies;
   - unable to access them;
   - special considerations—e.g., severe disease phenotype;
   - strong preference for oral treatment but with a mutation unamenable to Migalastat;
   - strong preference for a single as opposed to repeated treatments;
   - personal choice.

Pharmacological chaperones (PCs) are usually specific inhibitors of the corresponding misfolded mutant proteins, and facilitate their delivery to lysosomes by enhancing residual activity; they are currently undergoing clinical trials for several LSDs. Migalastat is licensed for use in Fabry patients with "amenable" mutations. It is a PC which stabilizes and facilitates trafficking of amenable mutant forms of alpha galactosidase A from the endoplasmic reticulum to lysosomes and increases its lysosomal activity. Oral migalastat is the first pharmacological chaperone approved for treating patients ≥ 18 years in the US and Canada or ≥ 16 years in other countries with Fabry disease who have a migalastat-amenable alpha galactosidase A mutation. In patients with migalastat-amenable alpha galactosidase A mutations, relative to placebo, migalastat treatment significantly reduced the mean number of GL-3 inclusions/KIC and plasma lyso-globotriaosylsphingosine levels at 6 months. Among evaluable patients, migalastat maintained renal function and reduced cardiac mass after ≤24 months' therapy. Renal function was maintained during 18 months of migalastat or ERT; however, migalastat significantly reduced cardiac mass compared with ERT. Migalastat is generally well tolerated. Given that it can be administered orally and that limited therapeutic options are available, migalastat is an important treatment option for Fabry disease in patients with migalastat-amenable alpha galactosidase A mutations. Numerous other small molecule approaches are being evaluated in the various LSD animal models, including targeting inflammatory pathways and stem cell-based therapies. A combination of approaches, targeted at individual diseases and organs, may well be optimal.

General Aspects of Treatment

The advent of treatment for LSDs is a recent phenomenon. Specialty centers are best able to assess patients and families in a multidisciplinary fashion.[21] Each patient should have a designated "lead" specialist, who not only provides specialist input into their own discipline (e.g., a hematologist working within a center for GD; pediatricians trained in metabolic medicine), but will also coordinate care across a team of specialist physicians and health care professionals. Centers of excellence focus on providing holistic care, not only to the index patient, but to families and care providers. Specialty centers should work alongside patient advocacy groups and the pharmaceutical industry to organize active research programs, extending beyond the clinical trials. It is a mandatory requirement for manufacturers of many LSD drugs to provide post-marketing information regarding the long-term safety and efficacy of their products, and this is often done through Registries.

HEMATOLOGIC ASPECTS OF INDIVIDUAL LYSOSOMAL STORAGE DISORDERS

The immense clinical diversity of LSDs means that hematologists across the entire spectrum of the specialty (pediatric, malignant, transplantation, coagulation and hemostasis, transfusion medicine, general and laboratory) are likely to encounter these conditions. In large teaching hospitals, hematologists often practice clinical and laboratory medicine, and may be consulted about appropriate investigations in patients with a systemic disease presenting as a diagnostic conundrum.

The next section considers selected presenting features in more detail; and then focuses on one disease in particular, GD, which is the province of the hematologists.

Splenomegaly

The spleen is an integral part of the reticuloendothelial, immunological, and hepatobiliary systems. Splenomegaly will lead to anemia, thrombocytopenia, and leukopenia, which raise concerns about hematologic malignancy; hence hematologists and hepatologists will encounter affected patients. In the neonatal period and during childhood, LSDs (particularly the MPS disorders and some GSLs including GD) must be considered as part of the differential. Among adult and adolescent patients, splenomegaly in the absence of cirrhosis leads to suspicion of an infiltrative or storage disorder, and hematologists must be aware of rare causes, including LSDs. GD is discussed in more detail below. Splenectomy will improve peripheral blood counts but will accelerate deposition of substrate in other organs and tissues (e.g., liver, bone), leading to further complications.

Niemann-Pick disease types A and B (NPDA/B) present with thrombocytopenia, anemia, leukopenia, and splenomegaly. Some patients with NPDB have excessive bleeding without significant thrombocytopenia or coagulopathy. Frequent and prolonged epistaxis can be particularly problematic, and in some extreme cases may require cauterization, packing, and blood transfusions.

As with GD, a primary cellular site of pathology in NPDA/B is the monocyte-macrophage system, and the characteristic pathological cells are referred to as Niemann-Pick cells. These can be distinguished from Gaucher cells by an experienced pathologist, but are frequently misclassified. NPDC is caused by primary defects in cholesterol transport, and many patients present with mild hematologic findings including splenomegaly, albeit less severe than in NPDA/B (see Fig. 54.2B).

Wolman disease (cholesterol ester storage disease) presents in adults with liver disease (classically as non-alcoholic fatty liver disease) and splenomegaly. It is under-diagnosed, results from acid lipase deficiency, and is supremely responsive to ERT.

Excessive Bruising/Bleeding

Thrombocytopenia due to splenomegaly occurs in several childhood and adult LSDs. However, splenomegaly usually causes asymptomatic thrombocytopenia, with platelet counts ranging from 50 to 120 × 10^9/L, and, if unexplained, should alert the physician to seek a definitive diagnosis. Massive splenomegaly, for example in GD, can cause thrombocytopenia and may be associated with spontaneous bruising, and excessive bleeding from mucous membranes (menorrhagia, epistaxis), or in response to trauma, after surgery or delivery. Marrow infiltration, or disturbed function of hemopoietic stem cells, is reported in some LSDs (e.g., GD), and may be a contributory factor. Excessive bleeding with moderate to severe thrombocytopenia should raise suspicion of platelet dysfunction. Platelets release lysomal granules containing glycohydrolases capable of degrading glycoproteins, glycolipids and glycosaminoglycans upon activation. Hermansky-Pudlak syndrome (see Table 54.1) is an autosomal recessive disorder characterized by prolonged bleeding with oculocutaneous albinism, a storage pool deficiency of platelets, and lysosomal accumulation of ceroid lipofuscin; it is rare worldwide but is one of the commonest inherited disorders in Puerto Rico.

Thrombosis

Thrombosis and fibrinolysis with excessive consumption of platelets and coagulation factors is an important pathophysiologic component of LSDs. Tissue infarction may result in osteonecrosis in GD; sub-clinical thrombotic events, in part induced by inflammation, are likely to be involved in the neurologic pathology of many LSDs. Fabry disease warrants particular mention. Adults with mild missense mutations develop late-onset organ damage often restricted to a single organ, for example, the heart, kidney, or the CNS. Stroke, both thrombotic and hemorrhagic, often in the posterior fossa, is a frequent presenting feature among adults with Fabry disease. Structural abnormalities of blood vessels and disturbed regulation of blood flow are likely to be important contributory factors, but Fabry patients often have renal and cardiac disease, which will independently increase the risk of stroke.

Abnormal Morphologic Appearances: Bone Marrow and Peripheral Blood

It is frequently quoted, in articles and textbooks, that in lysosomal diseases "vacuoles in leukocytes" can be found. This assertion suggests that these changes are non-specific or of little diagnostic value. In a study of more than 1000 cases of LSDs, in the past 50 years, the *Journal of Cardiac Failure (JCF)* has found distinctive morphologic changes in peripheral blood or bone-marrow cells that, in many cases, suggest the specific diagnosis and, in some cases, are completely diagnostic.

The morphologic changes consist of macro-molecules that have not been degraded in the lysosome due to specific enzyme deficiencies. Fig. 54.2 depicts 16 of the most characteristic cells. The diagnosis, in all cases, has been confirmed by enzyme and molecular methods. Romanowsky-stained blood or bone-marrow smears are

an easy, cheap and rapid method for the initial evaluation of many LSDs. Detailed explanation of the findings in each of the different LSDs is complex and beyond the scope of this chapter.

GAUCHER DISEASE

GD is an autosomal recessive disease resulting from decreased activity of the lysosomal enzyme beta-glucocerebrosidase, leading to accumulation of glucosylceramide mainly in macrophages throughout the body. It is important for hematologists because the presenting symptoms are typically hematological (including splenomegaly, anemia, thrombocytopenia, hyperferritinemia, gammopathy). The diagnosis is frequently made by finding Gaucher cells in bone marrow aspiration (albeit a suboptimal way to diagnose GD—see below), because of the need for hematological consultations before surgery and delivery, and because of an increased incidence of hematological malignancies (particularly multiple myeloma) and idiopathic thrombocytopenic purpura (ITP). Recent ex vivo gene therapy trials (see Chapter 104), involving autologous HSCT, have further engaged hematologists with GD.

GD has been traditionally classified to three clinical forms, based on absence (type 1; GD1) or presence (types 2 and 3) of neurological signs (see box on The Three Clinical Forms of Gaucher Disease). While these sub-types may be regarded as a continuum, specific differences between them are useful in genetic counseling. Therapy is available only for the systemic complications of GD1 and GD3 and not for the neuropathic forms of GD (nGD).

Genetics and Biochemistry

Glucocerebrosidase is encoded by the *GBA1* gene, located on chromosome 1q21, close to a pseudogene, *GBA1P*, which shares 96% identity with the *GBA1* active gene.[9] The consequent occurrence (fortunately rare) of complex gene/pseudogene rearrangements may create pitfalls in molecular diagnosis, particularly when performed by next-generation sequencing (NGS) analysis.[24] More than 860

THE THREE CLINICAL FORMS OF GAUCHER DISEASE

• Type 1:	Non-neuronopathic, adult, chronic
• Type 2:	Acute neuronopathic, infantile: classic/neonatal
• Type 3:	Sub-acute (juvenile) neuronopathic 3a: neurological > visceral 3b: neurological < visceral 3c: cardiac variant

different mutations have been identified in the *GBA1* gene, including exonic missense, splice-junction, complex/recombinant alleles, deletions, insertions, and termination mutations. These explain, in part, the great phenotypic heterogeneity which is a hallmark of GD. A mild mutation on one of the alleles (such as N370S; according to the new nomenclature it would be termed: c.1226 A>G p.Asn409Ser, but we keep the traditional or "legendary" one throughout the chapter) will ensure GD1, which will be milder when the second allele also has a mild mutation. The combination of two severe mutations (any mutation that has been detected in a patient with nGD) will cause GD3 or GD2; two null alleles are incompatible with life. These basic genotype-phenotype correlations are important for genetic counseling and management.

In addition to the GC storage in macrophages, there are many other pathophysiological processes (partially delineated in the first part of this chapter) including inflammation, complement activation, protein misfolding, impaired autophagy, and other processes leading to lysosomal dysfunction and together[25] contributing to the diversity of disease manifestations.

Epidemiology

With a prevalence of ~1:40,000 to 1:150,000 (based on different NBS studies), GD is often considered the commonest LSD (although late-onset Fabry is probably commoner). GD1 is particularly common among Ashkenazi Jews who have a carrier rate of approximately 1:15 and population prevalence of 1:850, the majority of them are homozygous for the N370S mutation. Two additional ethnical predilections are a subset of patients with GD3b in Northern Sweden ("the Norbotnian type") all homozygous for the L444P mutation, and GD3c mainly in Palestinian Arabs near Jenin ("the cardiac variant") homozygous for the D409H allele.

Clinical Manifestations

Type 1 (GD1)

GD1, also known as "adult type" or chronic, non-neuronopathic form, usually presents with splenomegaly (from minimal enlargement detected incidentally to massive enlargement extending across the midline to the right lower quadrant) and bleeding tendencies, mainly mucosal bleeding (i.e., epistaxis, ecchymosis, menorrhagia) or bleeding after surgery, dental procedures, or postpartum. Massive hepatomegaly may occur in splenectomized patients; but predominant hepatomegaly suggests a primary hepatic comorbidity. Hypersplenism manifests as thrombocytopenia followed by anemia and then leukopenia. An elevated platelet count is seen in splenectomized patients. The younger the age, the more severe the clinical course, and in young children, there is often linear growth retardation. The bleeding tendency is exacerbated by platelet dysfunction, a coagulopathy (probably due to low level activation of the coagulation pathway); and in Ashkenazi Jewish patients, an association with partial deficiency of Factor XI is common.

Bone involvement is common and may be asymptomatic or extensive and debilitating; the skeletal complications tend to develop later in the course of the disease, and they are far more severe in splenectomized patients or among untreated patients with severe mutations, who do not have access to GD-specific therapies. Bone crisis is an acute onset of excruciating pain, usually above or below the knee, commonly accompanied by swelling and redness, with or without systemic signs of inflammation including fever, leukocytosis and elevated erythrocyte sedimentation rate (ESR) or c-reactive protein (CRP). These bone crises are commonly mistaken for acute osteomyelitis, particularly before GD has been diagnosed, and many patients undergo surgical drainage to exclude infection, which, not infrequently, leads to bacterial contamination. Bone crises were traditionally related to reduction in blood flow ("aseptic infarction"), and hence to lack or reduced tracer uptake in bone scintigraphy, when performed within a few hours from the onset of pain, unlike the expected increased uptake during infection). However, magnetic resonance imaging (MRI) studies done during the acute events reveal that at least in some cases there is evidence of subperiosteal bleeding. Bone crises by themselves are predictors for osteonecrosis (avascular necrosis; AVN) in the future[26]; AVN usually develops in the hip joints (unilateral or bilateral; Fig. 54.3) but also in other large joints including the knees and shoulders. Pathological fractures may occur in the ribs and vertebrae due to osteoporosis. Devastating bone complications have become much rarer since the introduction of ERT, in part due to the fact that splenectomy is no longer indicated.

Lung involvement usually arises due to interstitial infiltration by pathological/alveolar macrophages, but intravascular shunts and pulmonary hypertension may occur. While symptomatic lung disease is rare (mainly splenectomized previously untreated patients, and in GD3), pulmonary function tests commonly show airways obstruction, with reduced expiratory flow, reduction in lung volumes and alveolar-capillary diffusion abnormality.

Fatigue is a frequent symptom which does not necessarily correlate with overall disease severity nor with anemia, but still impacts significantly on QOL. It has been related to underlying inflammation, possibly ER-stress, and it is not always responsive to ERT or SRT, but theoretically might improve with PCs.

Types 2 (GD2) and 3 (GD3)

Neuronopathic GD (nGD) includes GD2, known as the "acute infantile" type, and GD3—the sub-acute juvenile neuronopathic type, represent the more severe GD forms, which also demonstrate diverse phenotypes. The distinction between "milder" GD2 and very severe GD3 may be challenging in young children. A common and pathognomonic sign is oculomotor apraxia, or supra-nuclear gaze palsy, predominantly horizontal, which in GD2 becomes a fixed convergent squint early in the course of the disease. Its universal absence in GD1 supports our preference to keep the classification of GD to three distinct forms.

GD2 is subdivided into a classic form (a fatal disease presenting during early infancy with survival of up to 2 to 3 years without complete life support), and a neonatal form (presenting at birth with hydrops fetalis, ichthyosis and death within 48 hours). GD3 has three sub-types: GD3a with a dominant neurological disease and relatively minor visceral involvement, GD3b with minimal neurological symptoms and massive visceral and skeletal disease, and more recently GD3c, the cardiac variant, with severe calcifications of the left heart valves and aorta, leading to death during late childhood to early adulthood, without significant visceral or neurological abnormalities.

The definitions of the exact form of nGD are based on clinical symptoms, and may not be based on the molecular diagnosis. With the launch of clinical trials specific for nGD, it became important to establish well-defined criteria to allow uniform patients' recruitment.[27]

GD2

Patients with GD2 typically present with severe, progressive neurological deficits in the first weeks of life. Stridor and apnea are common, necessitating tracheostomy by age 2 years; swallowing dysfunction, aspiration (requiring percutaneous endoscopic gastronomy [PEG] feeding), opisthotonos, progressive myoclonic epilepsy, and failure to achieve gait are other symptoms.

GD3

This nGD form is more heterogeneous; the gaze palsy (sometimes hard to notice at an early age) may be the isolated neurological finding

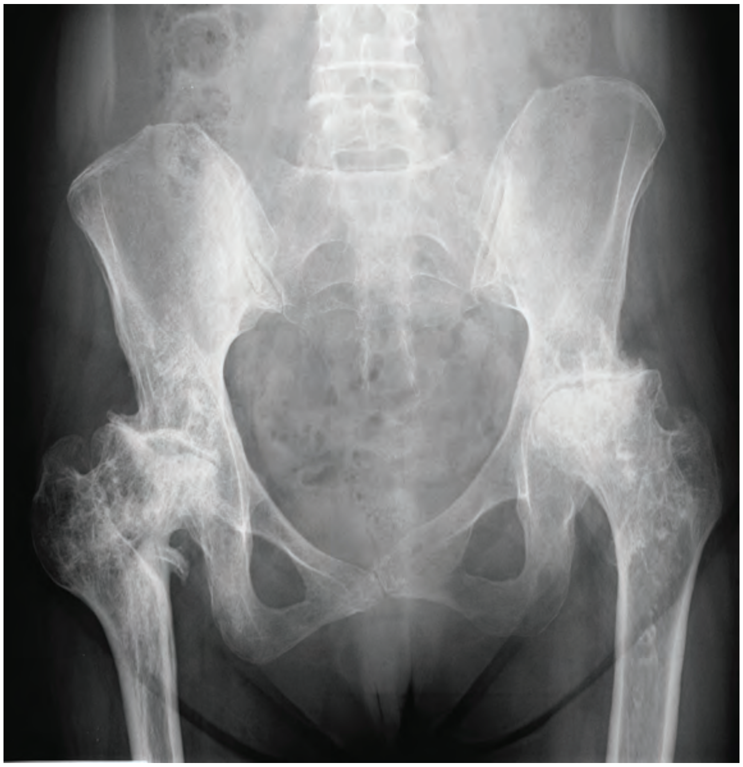

Figure 54.3 BILATERAL OSTEONECROSIS OF THE HIP JOINT. Bilateral osteonecrosis (AVN) in a 48-year-old woman with Gaucher disease (GD)1; the AVN occurred sequentially within 3 years after splenectomy, two decades earlier, in the pre-ERT era.

(GD3b) or be part of dominantly neurological abnormalities including motor and coordination deficits (ataxia), epilepsy (generalized seizures or myoclonic), stridor, dysarthria, cognitive impairments and more—GD3a. Most GD3 patients do not deteriorate rapidly. The most common genotype is homozygosity of L444P, and it is also the most frequent type of GD in Asia. A rather typical and very debilitating symptom is thoracic kyphosis (usually without scoliosis) and with no evidence of vertebral body collapse, usually developing between the age of 6 to 16 years. In GD3b, all the visceral and hematological manifestations that were described in GD1 are also present but usually with more severe prevalence of lung involvement.

Laboratory Findings

The diagnosis of GD is based primarily on the enzymatic assay demonstrating reduced glucocerebrosidase activity combined with the detection of DNA mutations, preferably by a whole *GBA1* gene sequence. There is no need to perform a bone marrow examination to diagnose GD.

Complete blood count (CBC) typically shows various degrees of thrombocytopenia (most patients), anemia (normocytic, normochromic found in ~30%) and less commonly leukopenia. The WBC differential count is normal, but lymphocytosis is frequently found in splenectomized patients. Platelet function and neutrophil function may be abnormal. Other causes of anemia (such as iron deficiency, that may be related to bleeding tendency, or vitamin B12 deficiency) should be excluded.

The biochemical panel is frequently normal; there may be a slight elevation of liver enzymes, as well as low levels of high-density lipoprotein (HDL) cholesterol, a non-specific GD biomarker, as are elevated serum ferritin levels (occasionally GD patients have been wrongly suspected of having hemochromatosis), angiotensin-converting enzyme (ACE) (not part of routine biochemistry panel), and tartrate-resistant acid phosphatase (no longer in use). GD-specific biomarkers are performed in referral centers and include chitotriosidase, CCL18, and glucosylsphingosine (LysoGb1); since the latter is the most sensitive, specific, reproducible and can easily be done via DBS[19], we rely on it, and perform the other two mainly during clinical trials.[28]

Both polyclonal and monoclonal gammopathies are frequently detected; monoclonal gammopathies are related to increased risk of multiple myeloma (see Chapter 91), and recent studies have identified that the clonal immunoglobulin in GD is actually reactive against the lysolipids.[29] There is also an increased prevalence of autoantibodies, some of which may trigger autoimmune diseases (see below).

Imaging Findings

Imaging is important at diagnosis for baseline assessment of the disease burden and for the decision on whether to initiate therapy. Imaging is used mainly to assess organ volume and skeletal involvement. Organ volume can be measured by ultrasonography (widely available, no radiation, no need for sedation in children and inexpensive; but operator-dependent and not as accurate as an MRI, which is the preferred methodology in clinical trials). Intrasplenic and less commonly intrahepatic focal lesions, may be detected and mimic malignancies.

Plain X-ray imaging has largely been replaced by MRIs, but is still done for specific indications (e.g., exclusion of fracture or assessing bone age in children). Frequent radiological features include the famous Erlenmeyer flask deformities of the distal femurs, osteopenia or osteoporosis and lytic lesions within long bones, even in the absence of bone pain. Lytic lesions are also relatively common in panoramic x-rays of the mandible. The bone marrow burden score is an MRI-based semi-quantitative assessment of the lumbar spine and entire femora, allowing prediction of skeletal complications when done before specific therapy, and for sequential monitoring.

Differential Diagnosis

Delayed awareness is a major concern in GD, and therefore GD must be included in the differential diagnosis (DD) of any patient at any age group who presents with splenomegaly and/or thrombocytopenia. Massive splenomegaly increases the likelihood of GD, particularly when imaging identifies intrasplenic focal lesions, as are any combination of findings (i.e., low platelets plus bone pains, splenomegaly plus elevated ferritin levels), medical history of gall-stones and family history of PD.[15] (See box on Gaucher Disease: Diagnosis and Specific Treatment.)

GD should be considered in the DD of patients presenting with bone crisis (DD from bacterial osteomyelitis), osteoporosis (especially in adult male or young subjects), history of pathological fractures, and short stature in the pediatric age group.

Myoclonic epilepsy and gaze palsy must include nGD (usually GD3a) in the DD, as well as those with severe kyphosis without scoliosis (GD3b); hydrops fetalis and ichthyosis should bring neonatal GD2 to the DD.

GAUCHER DISEASE: DIAGNOSIS AND SPECIFIC TREATMENT

1. Presenting disease features—Typically include bleeding tendency, fatigue, splenomegaly, bone pains and in children linear growth retardation. Common laboratory findings—thrombocytopenia, anemia, elevated serum ferritin, low HDL-cholesterol, abnormal liver function tests and (in adults) polyclonal or monoclonal gammopathies. Less common features—history of cholelithiasis, delayed menarche, family history of Parkinsons, intrasplenic lesions and osteoporosis/osteopenia. In young children you must exclude neurological involvement, particularly anormal eye movements.
2. Specific diagnosis—Document reduced enzymatic/glucocerebrosidase activity, mutant genotype by whole gene (GBA) sequence, and elevated biomarker—LysoGb1 (glucosylsphigosine). All three tests can be done on dry-blood-spot; avoid bone-marrow examination.
3. When to treat—Start before the development of irreversible organ damage (mainly bones). Selected asymptomatic GD1 patients can be monitored and treated upon symptom onset or progressive disease parameters.
4. How to treat—In all children and most adults, bi-weekly infusions of ERT should be the first specific therapy. Dose—varies between countries and centers; most US doctors begin with 60 units/kg, whereas 15–30 units/kg are typically prescribed in Israel, UK, and Australia. The three enzymes are imiglucerase (Sanofi/Genzyme), Velaglucerase-alfa (Takeda), and taliglucerase-alfa (Pfizer/Protalix).

   Oral therapy with SRT, eliglustat 84 mg (Sanofi), is approved as first-line therapy for adult GD1 patients who are CYP2D6 extensive, intermediate or poor metabolizers (twice daily or once-a-day accordingly). Contraindications are cardiac, renal, or hepatic problems and current or contemplated pregnancy. Compliance is important, and drug-drug interactions requires attention. Another SRT, miglustat (Actelion) is approved for patients with mild to moderate GD1 for whom ERT is not suitable, but it is not widely used.

   Investigational treatments include gene therapy (in vivo and ex vivo) and pharmacological chaperones. Ambroxol, a cough medicine available over-the-counter, acts as a GBA-chaperone, may improve myoclonic epilepsy and other neuronopathic features in nGD, and is in clinical trials for GBA-related Parkinson's.
5. Where to treat—Commence ERT in the clinic under supervision. Infusion reactions are commoner with taliglucerase-alfa and least common with velaglucerase-alfa. Home therapy by a nurse or self-infusion is commonly practiced (less popular in the US).
6. How to monitor—Comprehensive assessment in a referral center is recommended. Perform blood tests including biomarkers and imaging studies every 6 months for treated patients and every 12 months for untreated, stable patients.
7. Who should be considered for investigational therapy?
   - Patients who cannot receive or are unresponsive to ERT/SRT
   - Patients with neuronopathic GD
   - Altruistic patients wishing to advance medical knowledge

The ultra-rare GD3c should not be forgotten in the consideration of rheumatic heart disease, particularly in patients of Palestinian descent, who present with mitral stenosis and/or aortic stenosis and insufficiency.

Symptomatic Therapy

Patients who have undergone splenectomy and suffered bony complications before the era of ERT often require pain management and surgical (mainly orthopedic) procedures. When indicated (i.e., massive splenomegaly and refractory hypersplenism, splenic torsion, concern about malignancy) hand-assisted laparoscopic splenectomy is safe and feasible.[30] Arthroplasties, particularly total hip replacement in patients with osteonecrosis of the femoral head, have been shown to be safe, and achieve long-term implant survival, improve function, and QOL.[31]

Specific Treatments

Not all patients with GD, particularly N370S homozygous, require treatment.[32] The most common indications for commencing treatment include marked splenomegaly, significant cytopenias, bony manifestations, impaired QOL, and growth retardation. The currently available treatments do not cross the BBB, and improvement of the neurological symptoms of nGD is not achievable. New treatment approaches are being intensively investigated, including PCs, new SRTs, and gene therapy.

Enzyme Replacement Therapy

Background

ERT for LSDs was first suggested by Christian de Duve in 1964, a year before the identification of glucocerebrosidase deficiency as the etiology of GD by Roscoe Brady, who a year later presented the concept of ERT.[22] It took more than 25 years before Brady's first ERT was approved for GD1 in 1991, following a seminal clinical trial of 9 months in 12 patients.[33] Historically, the introduction of the first placental-derived ERT, alglucerase, was a dual success: Medically, its safety and efficacy has revolutionized the management of patients with GD1, and led to the development of ERT for several other LSDs; and financially, the great marketing success, opened the doors for making drugs available for patients with rare diseases in general.

ERT does not only stop the deterioration of GD, but actually reverses many of the disease's manifestations (such as organomegaly, hypersplenism, bone pains, growth retardation, etc.), so when given to patients before they develop irreversible bony complications, their morbidity is pretty much restricted to the need for bi-weekly intravenous infusions. Alglucerase was replaced in 1994 by the CHO-derived human recombinant imiglucerase, which was for 16 years the single ERT available. Imiglucerase has one amino-acid substitution (Arg495His) due to a cloning artifact in the original cDNA used for its production. In 2010 and 2012, two additional ERTs became commercially available: velaglucerase-alfa, produced in a human cell-line using proprietary gene-activation technology, has an amino-acid sequence identical to the wild-type enzyme, and a higher alpha-mannosyl content than imiglucerase (which is important for targeting to macrophages); and taliglucerase alfa, the first human enzyme produced from transduced carrot cells, that contains the same amino-acid substitution as imiglucerase. These ERTs were developed as novel proteins, whereas at least three "non-comparable biotherapeutics"[34] are currently available in a few countries: Abcertin™, Asbroder™ and Glurazyme™ (from Korea, Mexico and Russia, respectively), all sharing the same generic name "imiglucerase biosimilar," none of which has been approved by Food and Drug Administration (FDA)/European Medicines Agency (EMA) and are not discussed in this chapter.

Results of Treatment

Despite minor differences, the three FDA-approved ERTs can be discussed as a class, and in the majority of the patients, the impact on the key disease's symptoms is similar: improvement of hematological parameters, reduction in organomegaly, even if huge at baseline, amelioration of bone pain, prevention of osteonecrosis, growth spurts in children, and general improvement in QOL (currently expressed as GD-specific patient reported outcome; PRO; 34). The response to ERT tends to be more dramatic when the degree of abnormality is more prominent; children tend to respond faster than adults, and in the majority of the patients the detection of anti-ERT antibodies does not change the response. For female patients who may conceive while on ERT, the risk of postpartum hemorrhage decreases, and ERT, even if detected in breast milk, does not harm the babies.

There is still debate about the optimal dosage regimen; the majority of centers in the US begin with the high-dose of 60 units/kgBW/EOW, and may later reduce the dose upon stabilization, typically after 2 to 3 years. In Israel, UK, and a few other countries, most of the patients begin with lower doses (15 to 30 units/kg/EOW) and increase the dose if the response is sub-optimal. Because the human-derived velaglucerase-alfa has the wild-type sequence, and has demonstrated better in vitro internalization into macrophages, when the "mutant" ERTs were used (imiglucerase or taliglucerase alfa), we usually switch these patients to the same-dose of velaglucerase alfa before increasing the dose (usually doubling to 60), as we prefer the minimal effective dose to the maximally tolerated one.

Most patients in Europe and Israel receive their ERT at home, either by home care nurses or by self-administration. This practice has become particularly important during the COVID-19 pandemic.

The overall safety profile of ERT is excellent; most of the adverse events (AEs) are mild and transient; anaphylaxis and severe allergic reactions are rare (their risk is higher with taliglucerase alfa, probably due to the existence of D-xylose and fucose, two sugars derived from the plant cells); mild hypersensitivity reactions are often treated with premedication, but here too, we have found that a switch to the human-derived ERT usually resolves the need for premedication.

Unfortunately, the high cost of ERT has not changed dramatically with the introduction of additional enzymes products, and many patients in underdeveloped countries are still unable to receive this standard of care, except a few lucky ones who receive compassionate treatment.[35] None of the ERTs are capable of crossing the BBB, and hence they only impact the non-neuronopathic symptoms in nGD; there seems to be no impact on GD-related comorbidities, and usually not on "gaucheromas" (masses composed mainly of Gaucher cells, at times causing massive lymphadenopathy with protein losing enteropathy), or on pulmonary involvement.

Substrate Reduction Therapy

SRT was first proposed as a treatment for GD by Radin in 1975. The technique exploits the fact that all patients with GD have a degree of residual enzyme activity and the partial inhibition of substrate production would lead to its reduced accumulation.

Miglustat (N-butyl-deoxynojirimycin) is a low-molecular-weight glucose analogue that inhibits glucosylceramide synthase, the enzyme that catalyzes the first step in the biosynthesis of glucosylceramide and other GSLs. Miglustat was the first oral SRT to receive market authorization in 2000; its use resulted in decreased organomegaly and improvement in hematologic parameters in GD1, but not to the extent achieved with ERT, and with significantly more AEs, particularly gastrointestinal and peripheral neuropathy; hence, its use has been limited to patients with mild to moderate GD1 for whom ERT is not suitable.

Eliglustat, a ceramide analogue with a better tolerability and efficacy profiles, was the second SRT approved in 2014. In contrast to miglustat, eliglustat was approved as first-line oral treatment for certain adult patients with GD1, who have a suitable CYP2D6 status (extensive, intermediate or poor metabolizers) due to its metabolism in the liver. Although it has been claimed to be as good as ERT, the findings from the clinical trials suggest inferiority to ERT and a more problematic safety profile, including cardiac AEs (in at least 5% of the patients), palpitations and syncope.[36] Drug-drug interactions, several contraindications/precautions (hepatic, renal and cardiac diseases, pregnancy, and suitability for children and older patients), and the need for good compliance are additional disadvantages. Taking into consideration also the partial inhibition of hundreds of different glycolipids (SRT class effect), our policy is to use eliglustat for patients unwilling or unable to receive ERT.[37] Eliglustat is particularly suitable for stabilized patients (young adults, excluding females planning a family) without underlying diseases and co-medications, who wish to receive an oral alternative to ERT.

Associated Diseases: Parkinson and Malignancies

When a patient with a chronic disorder develops an additional disease, one should distinguish between two independently sorting diseases (GD-unrelated) and those that occur in significantly higher incidence compared to the general population (GD-related), but all are considered comorbidities. There may be a mutual impact of two unrelated diseases due to common symptoms, such as bleeding tendency due to the GD-unrelated partial deficiency of Factor XI, also common among Ashkenazi Jews, and there may be common symptoms of a GD-related diseases such as bone pains and/or anemia in multiple myeloma, which contributes to delayed diagnosis of the other disorder (Fig. 54.4). Both related and unrelated comorbidities should be differentiated from atypical manifestations or complications of GD, as well as delayed occurrence of drug-related medical problems, such as peripheral neuropathy with SRT or metabolic syndrome with ERT.[38]

When GD-related, specific therapy may or may not ameliorate the comorbidity, when GD-unrelated there will be no effect; if drug-related, it has not been present prior to advent of specific therapy, and it will be sustained (and possibly worsen over time) while on therapy but may ameliorate or disappear upon withdrawal of therapy.

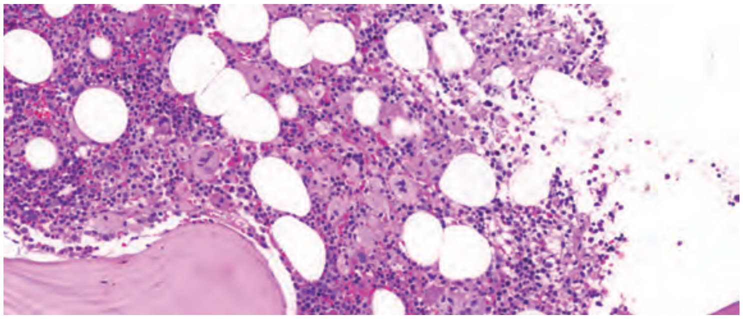

Figure 54.4 GAUCHER DISEASE (GD)1 AND MULTIPLE MYELOMA. Bone marrow biopsy from a 62-year-old female with GD1. She was noted to develop a progressive rise in her paraprotein and had developed new onset vertebral collapse. A diagnosis of myeloma was confirmed.

CONSIDER THE EXISTENCE OF A COMORBIDITY

In the untreated patient:

1. when hemoglobin level is significantly lower than the platelet counts
2. when the degree of hepatomegaly is greater than that of the splenomegaly

In the treated patient:

3. when there is no response to specific therapy (ERT/SRT)
4. when there is a change in the pattern of response

GD-related comorbidities include cholelithiasis, several autoimmune diseases (i.e., ITP, uveitis, Hashimoto thyroiditis and celiac disease), but the most important ones are plasma-cell dyscrasias (MGUS and multiple myeloma) and PD.[39,40] (See box on Consider the Existence of a Comorbidity.)

Prognosis

The majority of the patients with GD1 are expected to have a normal lifespan, especially those who are mildly affected, non-splenectomized, and those who receive ERT/SRT prior to the development of irreversible complications. A single paper from 2008, based on a drug company registry, claimed that patients with GD1 live on the average 9 years less compared to the expected survival of the American population[41]; this biased paper suffers major pitfalls including the comparison of the GD global population (including under-developed countries) to the US general population, the inclusion of children with nGD who died at ages 0 to 10 years, and the lack of molecular diagnosis in 46% of the 102 deceased patients. Importantly, malignancies did not contribute to the shortened lifespan.

Patients with GD2 have a grave prognosis with death usually by the age of 2 years, whereas no data are available regarding life expectancy of patients with GD3, which is shorter and inferior for GD3a and GD3c. Sudden death has been reported in a large cohort of GD3 patients from Egypt.

New Therapeutic Modalities, Including Gene Therapy

New treatment options address nGD, improved treatments for GD1 and the prevention of GD-related comorbidities. PCs include ambroxol, which is already being used off-label as well as in different trials for patients with nGD or *GBA1*-related PD. New PCs are being investigated, ideally non-inhibitory drugs, and several candidate molecules are in early stages of research.[42] Arimoclomol is a heat-shock-protein (HSP70) amplifier, stimulating the endogenous correction of misfolded proteins into a functional conformation; it has potential activity in several disorders including ALS, NPC, GD1, GD3, and more.

Gene therapy clinical trials, both in vivo and ex vivo, are already ongoing in humans; one-time in vivo injection of AAV9-based gene therapy to the cisterna magna in nGD or intravenously for patients with GD1, and ex vivo lentivirus-based gene therapy also for GD1, with a potential also to impact the CNS via CD34+ derived microglia cells that can migrate into the brain. If successful, these pioneering modalities will improve the prognosis and QOL of patients with GD.[43] (See box on Illustrative Case of Gaucher Disease.)

ILLUSTRATIVE CASE OF GAUCHER DISEASE

A 25-year-old female, ultra-orthodox Ashkenazi Jew, mother of two, was referred to our clinic at the 20th week of her third pregnancy, to rule out GD. She is known to have low platelet counts since age 8, but has never been evaluated. Splenomegaly has never been mentioned; menarche age 14 years, with no story of bleeding tendency, early satiety or bone pains. Low platelet count was noted upon arrival to delivery room at her first pregnancy; the delivery was complicated by massive bleeding and required blood transfusions. At her second pregnancy the thrombocytopenia (lowest counts were around 50,000/μL) was related to ITP, and treatment with steroids was given with no effect; platelet infusions and intravenous iron were administered during and after delivery, respectively. In her discharge report she was advised to consult a hematologist. Routine gynecological ultrasound during her third pregnancy revealed an enlarged spleen, when she was referred to our clinic. The diagnosis of GD was confirmed by DBS demonstrating reduced glucocerebrosidase activity, elevated LysoGb1 and the N370S/N370S genotype. Intravenous administration of ERT was initiated immediately, and at this time, her platelet count increased to 95,000/μL; the delivery was uneventful. At the last follow-up visit, at 14 weeks of her fourth pregnancy, the platelet counts normalized, and hopefully she will enjoy for the first time an epidural analgesia during labor.

Comment: Delayed diagnosis is common even among Ashkenazi Jews in Israel; an earlier diagnosis of this rather typical patient should have led to earlier initiation of treatment, and to the prevention of unnecessary blood transfusions or steroid therapy, which may increase the risk for osteonecrosis. A recent evaluation of the effect of ERT on the pregnancy and obstetric outcome in a unique group of multiparous women with GD1 who had pregnancies with and without ERT, has demonstrated that early PPH and RBC transfusions were significantly lower when ERT was used.[44]

CONCLUSIONS AND FUTURE DIRECTIONS

There have been huge advances in our understanding of LSDs and GD in particular, which have been translated into groundbreaking treatments. There remain, however, very significant unmet needs for patients—including the need to access the CNS, more convenient treatments with greater activity, and the need to improve access to these treatments for major populations worldwide who cannot afford the current options. There is a universal need for hematologists to raise awareness of these diseases and reduce delays in diagnosis. The fundamental role of lysosomes in cellular homeostasis implies that a better understanding of the physiology will lead to identification of the downstream consequences of enzyme deficiencies and substrate accumulation and elucidation of the underlying pathological processes. These include inflammation, complement activation, abnormal autophagy, the unfolded protein response, aberrant intra- and extra-cellular signaling, calcium metabolism and many other processes, many of which are amenable to therapeutic intervention. NBS will uncover many new patients and focus energies on the need to better define genotype-phenotype relationships, which in turn will allow us to improve targeting of existing and new treatments. Hematologists know too well that this is essential if we are to successfully introduce treatments with significant treatment-related morbidities (e.g., gene and cellular therapies); while all physicians as well as society as a whole should require that patients with these rare diseases receive cost-effective and ethical care, which is on a par with that provided to patients with more common ailments.

CHAPTER 55

EPSTEIN-BARR VIRUS AND ASSOCIATED LYMPHOPROLIFERATIVE CONDITIONS

Nader Kim El-Mallawany, Lisa R. Forbes, Rayne H. Rouce, and Carl E. Allen

The initial clinical descriptions of primary Epstein-Barr virus (EBV) infections are credited to Filatov and Pfeiffer at the end of the 19th century. Pfeiffer coined the term *glandular fever*, which described an illness consisting of fever, malaise, sore throat, and lymphadenopathy. In 1920, Sprunt and Evans introduced the term *infectious mononucleosis (IM)* to describe a series of patients with fatigue, fever, lymphadenopathy, and prominent mononuclear lymphocytosis (Fig. 55.1). Serologic diagnosis of IM became available in the 1930s with the heterophile agglutination test developed by Paul and Bunnel and later modified by Davidson.

The identification of EBV as the causative agent of IM was impeded for many years by the inability to transmit the disease to animals or to grow the virus ex vivo. In 1958, Denis Burkitt described a lymphoma in Ugandan children, and investigators suspected an infectious etiology because the geographic distribution of disease coincided with the malaria belt of equatorial Africa.[1] In 1964 Epstein, Achong, and Barr described herpesvirus-like particles in tumor biopsies from Ugandan children with Burkitt lymphoma (BL). Werner and Gertrude Henle developed an indirect immunofluorescent antibody assay to this new virus, now called *Epstein-Barr virus*, and showed that African children with BL, as well as 90% of American adults, had antibodies against EBV. In 1965 the Henles documented seroconversion to EBV of an individual who presented with clinical symptoms of IM. This initial observation was corroborated by larger studies confirming the association of EBV and IM.

EBV has subsequently been linked to a heterogeneous group of diseases.[2] EBV was the first human virus implicated in oncogenesis, and the biology of the virus has been studied extensively on a cellular and molecular level.[2] Because primary EBV infection is a self-limiting disease in almost all immune-competent individuals, clinical strategies have focused on the diagnosis and treatment of rare, potentially fatal EBV-associated diseases. Over the past two decades, successful immunotherapeutic approaches have been developed for EBV-associated malignancies, using either monoclonal antibodies or the adoptive transfer of EBV-specific T cells.[3–7]

BIOLOGY OF EPSTEIN-BARR VIRUS

EBV belongs to the family of herpesviruses, which has almost 100 members. Membership is based on the architecture of the virion that is 120 to 300 nm in size and contains (1) a core of linear, double-stranded DNA, (2) an icosadeltahedral capsid with 162 capsomers, (3) an amorphous material between the capsid and envelope designated tegument, and (4) an envelope containing viral glycoproteins. Besides EBV, designated human herpesvirus 4 (HHV-4), seven other herpesviruses have been isolated from humans: herpes simplex viruses 1 and 2, cytomegalovirus (CMV), varicella-zoster virus, HHV-6, HHV-7, and the Kaposi sarcoma–associated herpesvirus (KSHV; HHV-8). Herpesviruses are further divided into subfamilies to reflect evolutionary relatedness and similar biologic properties. EBV and KSHV belong to the human gamma herpesvirus subgroup and have a limited tissue tropism to B and T lymphocytes and certain types of epithelial cells. Several variants of EBV have been identified by genomic polymorphisms. Initially, two EBV types were distinguished by sequence changes in EBV nuclear antigens 2 and 3 (EBNA2 and EBNA3). However, using polymorphisms in the latent membrane protein 1 (LMP1), further subtypes have been described. EBV strains vary by geography and have not been linked to a particular EBV-associated disease.

PRIMARY EPSTEIN-BARR VIRUS INFECTION

Primary EBV infection usually occurs through the oropharynx, where mucosal epithelial cells and/or B cells become infected (Fig. 55.2). Infection of B cells by EBV is initiated by binding of the dominant viral glycoprotein gp350/220 to CD21, the C3d complement receptor; subsequent cell entry is mediated by a complex of three viral glycoproteins, gH, gL, and gp42. Gp42 binds to human leukocyte antigen (HLA) class II, which functions as a coreceptor, and gH is most likely involved in virus-cell fusion. The entry of EBV into epithelial cells may occur through multiple mechanisms because the majority of epithelial cells are CD21 negative. After viral entry, the capsid is dissolved and the EBV genome is transported into the nucleus, where it circularizes. Infection of epithelial cells results in lytic or abortive infection. In contrast, B-cell infection results predominantly in latency; however, lytic infection also occurs, resulting in the release of infectious virus into the saliva and other secretions. During primary infection, EBV establishes lifelong latency in B cells, and it is estimated that 1 to 50 cells per 1×10^6 B cells in the peripheral circulation are infected with EBV. The number of latently infected B cells within a person remains stable over years; however, intermittent reactivation of EBV in B cells into the lytic cycle at mucosal sites is probably responsible for the observed shedding of infectious virus into the saliva of asymptomatic carriers (see Fig. 55.2).

Although EBV can infect any B cell and express the full spectrum of latency proteins, typically only infection of naïve B cells results in persistent infection (see Fig. 55.2). EBV infection pushes the naïve B cell into a memory state independent of an antigen-dependent germinal center (GC) reaction by upregulation of cytosine deaminase, which induces both class switching and somatic hypermutation. The former also requires the expression of EBV-encoded LMP1, a constitutively activated CD40 molecule, or CD40 ligation, most likely provided by GC T helper (Th)3 cells that can provide T-cell help for B-cell differentiation by provision of CD40 ligand, interleukin (IL)-4, and IL-10 while preventing antigen-dependent effector T cell–mediated B-cell elimination by expression of transforming growth factor (TGF)-β. This reaction occurs within the lymph node and also involves downregulation of latency proteins and expression of latency type II. On exit from the lymph node, expression of latency proteins is completely inhibited. In this way, infected B cells can evade immune elimination. By contrast, primarily infected memory B cells enter and remain in latency type III and are rapidly eliminated by effector T cells and therefore do not contribute to virus persistence.

LATENT EPSTEIN-BARR VIRUS INFECTION

During latent infection, EBV persists episomally in resting memory B cells. Initially, it was thought that EBNA1 and LMP2 were expressed in memory B cells; however, more recent studies indicate that the

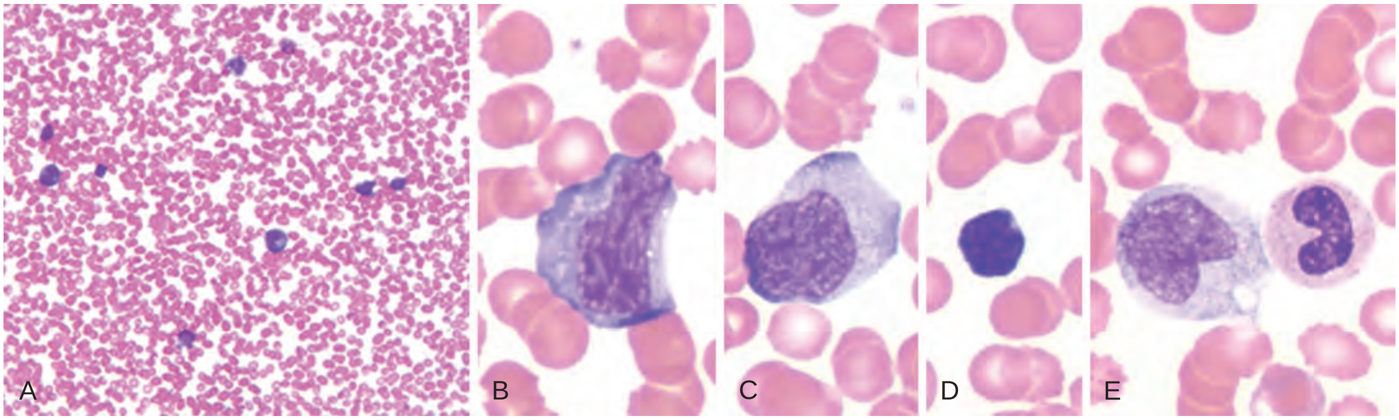

Figure 55.1 PROMINENT MONONUCLEAR LYMPHOCYTOSIS IN MONONUCLEOSIS. Low power (A) illustrates the leukocytosis, mainly due to activated lymphocytes (B and C), which are contrasted with a normal small lymphocyte (D) and a monocyte and granulocyte (E). The large reactive lymphocytes are frequently confused with monocytes because of their morphologic resemblance and the term *mononucleosis*. Monocytes usually have a finer, lacy chromatin and a gray cytoplasm with small granules and vacuoles when compared with the large activated lymphocytes.

majority of infected cells do not express viral proteins and of the almost 100 viral proteins, only EBNA1 is expressed during memory B-cell division (see Fig. 55.2).[2] This extremely limited expression of viral proteins allows EBV to persist long term despite a robust cellular EBV-specific immune response.

Three other distinct types of EBV latency have been characterized in a heterogeneous group of malignancies (Fig. 55.3). Latency type III, which can be readily produced by infecting B cells in vitro with EBV, is expressed in lymphoblastoid cell lines (LCLs). These cells express the entire array of nine EBV latency proteins: EBNA1, -2, -3A, -3B, and -3C, EBNA leader protein (LP), and the two viral membrane proteins LMP1 and LMP2. This pattern of EBV gene expression characterizes the EBV-associated lymphoproliferative disorders (EBV-LPDs) that occur in individuals severely immunocompromised by solid organ or hematopoietic stem cell transplantation (SOT, HSCT), congenital immunodeficiency, or human immunodeficiency virus (HIV) infection. Latency type II is the hallmark of EBV-positive Hodgkin lymphoma (HL), various EBV-associated non-Hodgkin lymphomas (NHLs), as well as nasopharyngeal carcinoma (NPC), which express EBNA1, LMP1, and LMP2. In addition, BARF1 is expressed in subsets of latency type II–associated malignancies. In latency type I, classically found in EBV-positive BL,

Figure 55.2 INFECTIOUS LIFE CYCLE OF EPSTEIN-BARR VIRUS. *EBV*, Epstein-Barr virus; *EBNA*, Epstein-Barr nuclear antigen; *LMP*, latent membrane protein.

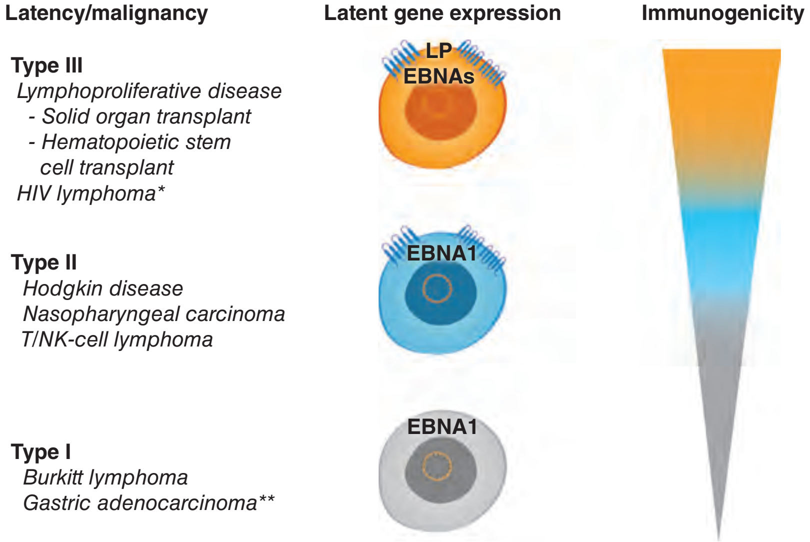

Figure 55.3 EPSTEIN-BARR VIRUS (EBV)–LATENT GENE EXPRESSION AND IMMUNOGENICITY OF COMMON EBV-ASSOCIATED MALIGNANCIES. *EBNA*, Epstein-Barr nuclear antigen; *LP*, leader protein; *NK*, natural killer. For an explanation of symbols, see Fig. 55.2. *Not all lymphomas are latency type III. **Gastric adenocarcinoma can also express latency type II genes.

only EBNA1 is expressed. However, variants in which all EBNAs are expressed in the absence of LMP1 have also been described. Latency type I or latency type II is found in EBV-associated gastric adenocarcinoma. Although grouping EBV-associated malignancies according to their dominant gene expression profile provided a useful framework for understanding EBV-driven oncogenesis, more recent studies using comprehensive gene expression array profiling have demonstrated expression of lytic cycle genes in BL or expression of lytic cycle and latency III genes in NPC.[8,9]

The EBV proteins expressed during type III latency are involved in the transformation and growth of EBV-infected B cells. EBNA1 binds to the origin of replication of the latent viral genome and is responsible for the maintenance of the EBV episome in host B cells. EBNA2 upregulates the expression of the viral proteins LMP1 and LMP2 and cellular proteins that contribute to transformation. EBNA3A and EBNA3C are essential for EBV-induced B-cell transformation, and although EBNA3B is not essential for transformation, it is highly conserved and therefore must provide a survival function in vivo. EBNA-LP cooperates with EBNA2 in the induction of viral and cellular genes. LMP1, a viral oncogene, behaves like a constitutively activated CD40 molecule and is essential for EBV-mediated B-cell transformation. LMP2 mimics an activated B-cell receptor (BCR), allowing for long-term B-cell survival in the absence of antigen. In addition, it prevents the reactivation of EBV into the lytic phase of infection.

Besides EBV proteins, small nonpolyadenylated viral RNAs termed *EBERs 1* and *2* and the BamHI-A rightward transcripts microRNAs (BART-miRs) are expressed in all forms of latency. In addition, the expression of at least 17 distinct EBV-derived microRNAs has been reported. The EBERs are the most abundant viral RNAs in latently infected cells. They enhance the oncogenic phenotype of EBV-transformed cells but are nonessential for EBV-mediated transformation. The expression pattern of the microRNAs depends on the latency type, and it is therefore likely that they play an important role during the life cycle of the virus.

IMMUNE RESPONSE TO EPSTEIN-BARR VIRUS

Healthy individuals mount vigorous humoral and cellular immune responses to primary EBV infection.[10] Although antibodies to the viral membrane proteins neutralize virus infectivity, the cellular immune response is essential for controlling virus-infected cells during both lytic and latent phases.

Humoral Immune Responses

Heterophile Antibodies

Heterophile antibodies, originally described by Paul and Bunnell, are present in 90% to 95% of EBV infections at some point during the illness. However, in infants and children younger than the age of 4 years with primary EBV infection, heterophile antibody responses may not be detected. Heterophile antibodies are immunoglobulin M (IgM) antibodies, which agglutinate erythrocytes from different species including bovine, camel, horse, goat, and sheep. EBV-induced heterophile antibodies have no reactivity against guinea pig kidney cells in contrast to naturally occurring antibodies (Forssman antibodies) or antibodies present in patients with serum sickness and other conditions.

In addition to heterophile antibodies, cold agglutinins directed preferentially against the anti-I antigen on red cell membranes are frequently detected in the sera of patients with IM; however, hemolytic anemia is rare. Other antibodies (including anti-I, anti-N, Donath-Landsteiner antibodies, platelet antibodies, and anti–smooth muscle antibodies) have been described in association with EBV infection

Epstein-Barr Virus–Specific Antibodies

EBV-specific antibody responses are detected with immunofluorescence assays developed in the first decades of EBV research. EBV antibodies are directed against (1) EBNA, (2) early antigen (EA), (3) the membrane antigen expressed on the surface of cells late in the lytic cycle, and (4) the viral capsid antigen (VCA) expressed within cells late in the lytic cycle. Each antigen is a composite of several distinct viral proteins, and attempts have been made to replace the aforementioned assays with tests using specific viral proteins; however, no single test has attracted widespread use.

VCA-IgM and IgG antibodies are usually present at the onset of clinical symptoms because of the prolonged viral incubation period (Table 55.1). VCA-IgM antibodies are a good marker for an acute infection because they rapidly disappear within 4 to 8 weeks.

TABLE 55.1 Frequently Determined Epstein-Barr Virus–Specific Antibodies

Antibody Specificity	Positive in IM (%)	Time of Appearance in IM	Persistence	Comments
Viral Capsid Antigen (VCA)				
VCA-IgM	100	At clinical presentation	4–8 weeks	Highly sensitive and specific; of major diagnostic utility
VCA-IgG	100	At clinical presentation	Lifelong	Useful for documentation of past EBV infection
Early Antigen (EA)				
Anti-D	70	Peaks 3–4 weeks after onset	3–6 months	Correlates with disease severity; seen in patients with NPC
Anti-R	Low	2 weeks to several months after onset	2 months to >3 years	Occasionally seen with unusually severe cases; seen in patients with African Burkitt lymphoma
EBNA	100	3–4 weeks after onset	Lifelong	Presence excludes primary EBV infection

EBV, Epstein-Barr virus; *IM*, infectious mononucleosis; *NPC*, nasopharyngeal carcinoma.
Modified from Schooley RT. Epstein-Barr virus (infectious mononucleosis). In: Mandell GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Diseases*. Philadelphia: Churchill Livingstone; 2000:1599.

VCA-IgG antibodies persist for life and are commonly used to document prior EBV infection. IgG antibodies against EA are present at the onset of the clinical illness in approximately 70% of patients. EA antibodies are divided into methanol-sensitive (anti-D) and methanol-resistant (anti-R) antibodies, and the majority of EA antibodies detected are anti-D antibodies. The presence of anti-D antibodies is consistent with recent infection, because titers disappear after recovery. IgG antibodies to EBNA appear late in the course of almost all cases of EBV infection and persist throughout life; their presence early in a suspected case of primary EBV infection excludes the diagnosis. Aberrations in this pattern of serum reactivity are observed in many EBV-associated diseases and will be discussed under the specific disease sections. For example, the absence of EBNA antibodies despite previous EBV infection is one of the serologic markers suggestive for chronic active EBV (CAEBV) infection.

Cellular Immune Responses

In normal individuals, primary EBV infection often results in a massive expansion of activated, antigen-specific T cells. Using tetramer technology to enumerate antigen-specific T cells, it has been documented that the $CD8^+$ T-cell response may be dominated by T cells specific for a limited number of epitopes, as seen with T-cell responses against other herpesviruses. T cells specific for epitopes derived from immediate early and several early EBV proteins of the lytic cycle are dominant during the acute phase of IM, and long-term persistence of EBV-specific, $CD8^+$ T cells has been documented after primary EBV infection. As many as 5.5% of the circulating $CD8^+$ T cells in a healthy virus carrier may be positive for a single EBV epitope, illustrating how persistent EBV infection can influence the composition of the host's T-cell pool. Besides EBV-specific $CD8^+$ T cells, EBV-specific $CD4^+$ T cells play an important role in the control of EBV infections, and EBNA1-specific $CD4^+$ T cells have been implicated in the control of newly infected B cells. As for $CD8^+$ T-cell responses, there is a marked hierarchy of immunodominance, with the majority of $CD4^+$ T cells being specific for EBNA1 and to less extent EBNA3C.

EPSTEIN-BARR VIRUS VACCINE DEVELOPMENT

At present there is only limited experience with human EBV vaccines.[11] Vaccine studies have been conducted in healthy donors in the prophylactic setting using recombinant vaccinia virus encoding the major viral glycoprotein gp350 (1), recombinant gp350 protein (2), or an EBNA3A peptide. While vaccination with gp350 induced neutralizing antibodies and in one study prevented the clinical picture of IM, these vaccines did not significantly reduce the incidence of EBV infection. Also, no reduction in the incidence of EBV infection was observed with the EBNA3A peptide vaccine. In addition, a recombinant gp350 protein was evaluated in patients with chronic kidney disease prior to kidney transplantation. Although the vaccine-induced transient neutralizing antibodies, it did not reduce the incidence of EBV-LPD post transplant. Newer vaccines consisting of gp350-ferritin complexes that induce significantly higher titers of neutralizing antibodies in preclinical models have been developed but require testing in humans.[12]

Vaccine strategies for EBV-associated malignancies should seek to elicit or boost the EBV-specific cellular immune response against EBV latency. Individuals likely to benefit from this approach are EBV-seronegative patients scheduled to undergo SOT or patients who have an EBV-associated malignancy with a low tumor burden or are in remission.[12] A variety of vaccine studies have been conducted in patients with EBV^+ NPC.[13] In two studies patients with advanced disease were vaccinated with either dendritic cells (DCs) loaded with peptides derived from LMP2 or DC transduced with an adenoviral vector encoding full-length LMP2 and an inactive form of LMP1. Administration of DC vaccines was safe, and a transient increase in the frequency of LMP2-specific T cells was observed on the DC/peptide vaccine trial. However, the clinical benefit in both studies was limited. Thus future studies will need to explore DC vaccines with greater potency administered to subjects with less tumor burden.[12] In another phase I clinical study, after frontline therapy, patients with NPC were vaccinated with a modified vaccinia virus Ankara encoding the c-terminal portion of EBNA1 and LMP2 (MVA-EL). Induction of $CD4^+$ and $CD8^+$ antigen-specific T-cell responses was observed in the majority of patients after vaccination, and a phase II clinical study is in progress.[13] Lastly, a recombinant adenovirus vaccine encoding LMP2 was evaluated in patients with NPC. Although vaccine administration was safe, no data are available if the vaccine boosted LMP2-specific T-cell responses.[12] Ultimately, although development of an effective EBV vaccine has remained an elusive achievement, numerous studies have been undertaken in pursuit of this goal.[14–24]

Although the aggregate number of patients around the world with EBV-associated lymphomas and lymphoproliferative disorders (LPDs) is modest, when EBV-associated gastric carcinoma and NPC are considered, global estimates of EBV-associated malignancies approach 200,000 cases per year.[25] Acknowledging the burden of these malignant complications from EBV, in addition to the toll of IM in adolescents and young adults infected by the virus, a case for vaccine development gains traction. As precedent for effective vaccination against other oncogenic viruses such as human papillomavirus and hepatitis B has been established, EBV should be considered a target for wide-scale vaccine development.[11,26,27]

INFECTIOUS MONONUCLEOSIS

Epidemiology

EBV infections occur worldwide, and, in most populations, 90% to 95% of adults have antibodies against EBV. Depending on geographic and socioeconomic factors, there is a wide variation in the age of primary EBV infections. Early, asymptomatic primary EBV infection occurs more often in individuals from lower socioeconomic groups, particularly those living in low- and middle-income countries. In higher socioeconomic groups in high-income countries, the age of primary infection is more often delayed until the second decade of life and clinically apparent IM is more prevalent.

Humans are the only source of EBV, which is present in the saliva of patients with IM. A majority of EBV-positive adults shed virus into their saliva, and this percentage is increased in immunocompromised patients such as SOT recipients. EBV is viable outside the body for 2 weeks at 4°C but is susceptible to drying; the virus has not been recovered from environmental sources, suggesting that close contact is needed for viral spread. The incubation period of EBV is estimated to be 30 to 50 days.

Clinical Manifestations

Primary EBV infection in infants and young children is either asymptomatic or accompanied by mild, nonspecific symptoms and signs such as fever, upper respiratory tract infection, pharyngitis with or without tonsillitis, and cervical lymphadenopathy. In contrast, approximately 30% to 50% of adolescents and young adults present with the clinical picture of IM.[28] Frequently, a prodrome consisting of fatigue, malaise, and low-grade fever is present for 1 to 2 weeks. Prominent pharyngitis with exudative tonsillitis is often the cardinal sign of IM; other signs and symptoms are listed in Table 55.2. The adenopathy in IM most commonly affects the posterior cervical lymph nodes, although diffuse adenopathy can occur. The enlarged lymph nodes are not fixed, may be tender to palpation, and lack overlying skin erythema. Hepatomegaly is uncommon; however, splenomegaly develops in 15% to 65% of patients and is more prominent in the second to fourth week of the illness. Skin manifestations include a faint, morbilliform rash reminiscent of rubella and less commonly erythema multiforme and erythema nodosum. Most patients with primary EBV infection have symptoms for 2 to 4 weeks and recover without significant complications or sequelae.

Complications of Infectious Mononucleosis

Although the majority of patients with IM fully recover without severe complications, any organ system can be affected in this clinical syndrome of primary EBV infection.

TABLE 55.2 Clinical Manifestations of Infectious Mononucleosis

Manifestation	Percentage (Range)
Symptoms	
Sore throat	82 (70—88)
Malaise	57 (43–76)
Headache	51 (37–55)
Anorexia	21 (10–27)
Myalgias	20 (12–22)
Chills	16 (9–18)
Abdominal discomfort	9 (2–14)

Hematologic Complications

Patients with IM may present with a wide range of hematologic findings besides the atypical lymphocytosis (Fig. 55.4). These include anemia, neutropenia, thrombocytopenia, and rare cases of aplastic anemia.

Anemia

Autoimmune hemolytic anemia occurs in approximately 3% of patients with IM. It presents in the first 2 weeks of the illness, and the majority of patients recover within 1 to 2 months. Patients usually have a positive direct Coombs test. Most common anti-I antibodies are present; however, anti-I, anti-N, and Donath-Landsteiner antibodies have also been reported. In addition to hemolysis, IM-associated anemia can be caused by transient erythroblastopenia.

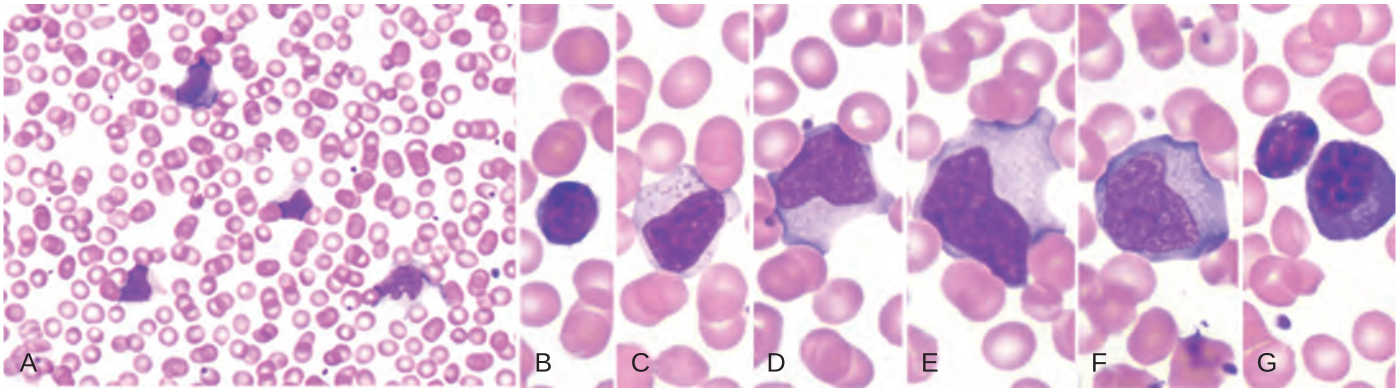

Figure 55.4 PERIPHERAL BLOOD SMEAR IN INFECTIOUS MONONUCLEOSIS. (A) Low power shows moderately high white blood cell count and high number of reactive, or "atypical" lymphocytes. (B–G) Higher power illustrates spectrum of lymphoid morphology, including small resting lymphocyte (B) for comparison, large granular lymphocyte (C), atypical forms (D–F), also referred to as "reactive" lymphs, and circulating plasma cell (G).

Neutropenia

Mild, self-limiting neutropenia is a common finding during the first 4 weeks of the disease. However, severe neutropenia associated with fatal bacterial infections has been reported.

Thrombocytopenia

Mild thrombocytopenia (50,000 to 150,000/mm^3) is a common finding in patients with IM. It usually occurs within the first 2 weeks of presentation and resolves within 2 months. Severe thrombocytopenia with overt bleeding is rare; however, death from intracranial hemorrhage has been described. The etiology of the thrombocytopenia is not completely understood, and a variety of explanations have been suggested. Because bone marrow examination shows normal or increased numbers of megakaryocytes, peripheral platelet consumption is most likely due to the presence of antiplatelet antibodies or platelet pooling and destruction within an enlarged spleen.

Splenic Rupture

Splenic rupture occurs predominately in males, with an incidence of 1/1000 to 1/3000. The incidence of rupture is highest in the second and third week of illness and can be the first sign of IM. Clinical symptoms include abdominal pain or pain referred to either shoulder. Because abdominal pain is an unusual symptom of uncomplicated IM, a splenic rupture should be strongly considered in IM cases when abdominal pain is reported. Although it is a life-threatening complication, with current management the mortality rate is very low.

Neurologic Complications

Neurologic complications develop usually during the first 2 weeks of IM and may be the only manifestation of IM. EBV infection can cause a wide spectrum of neurologic diseases, including encephalitis, meningitis, Guillain-Barré syndrome, acute transverse myelitis, and peripheral neuritis. Most patients with neurologic complications recover completely.

Other Organ Involvement

Although symptomatic heart disease with IM is uncommon, in one cohort of patients, nonspecific ST- and T-wave abnormalities were found in 6% of patients. Renal involvement manifested as microscopic hematuria, and proteinuria is seen in 10% to 15% of patients; however, significant renal dysfunction is rare. Airway compromise due to hypertrophy of the adenoids and tonsils or mucosal inflammation and edema is uncommon but potentially fatal.

Diagnosis

Atypical lymphocytosis is the cardinal hematologic finding in IM (see Fig. 55.4). It develops during the first week of the illness and peaks between the second and third week. Atypical lymphocytes represent 60% to 70% of the total white cell count, which usually ranges between 12,000/mm^3 and 18,000/mm^3. In general, the atypical lymphocytes are large and vary in size. Nuclei are large and eccentrically placed; the cytoplasm is basophilic, and vacuoles are often present. The variable morphologic pattern of atypical lymphocytes in IM distinguishes them from the monotonous appearance of immature leukemic blasts. Atypical lymphocytosis is not pathognomonic for IM and is associated with other diseases such as acute viral hepatitis, CMV infections, mumps, toxoplasmosis, rubella, roseola, and drug reactions.

The diagnosis of EBV infection depends on serologic testing. Tests for heterophile antibodies, including the monospot test and slide agglutination tests, are routinely available. The results of these tests are often negative in children younger than monopod 4 years of age, but they identify 90% of cases in older children and adults. Of the available EBV-specific serologic tests, VCA-IgM antibodies are most commonly determined to diagnose primary EBV infection in heterophile-negative IM cases; determining antibodies against EA may also be helpful (see Table 55.1). VCA-IgG antibodies are positive during acute infections as well as the convalescent period. The presence of anti-EBNA antibodies excludes an acute infection. Isolation of EBV from throat washings is feasible; however, it is of little diagnostic value because 10% to 20% of healthy adult EBV carriers may shed the virus.

Differential Diagnosis

In the majority of cases, the diagnosis of IM is straightforward. The differential diagnosis includes streptococcal and nonstreptococcal pharyngitis, acute infections with CMV, HHV-6, hepatitis viruses, and toxoplasma. Depending on the presentation, other diseases may be considered such as HIV, rubella, and leukemia or lymphoma.

Treatment

Supportive therapy should include rest and analgesia in the acute stage of IM. Contact sports should be avoided until the patient has fully recovered and the spleen is no longer palpable. The use of corticosteroids is not indicated for uncomplicated IM; however, a trial of corticosteroids may be warranted in patients with marked tonsillar inflammation and hypertrophy resulting in impending airway obstruction. Although acyclovir reduces EBV shedding into oral secretions, treatment of IM with acyclovir has resulted in no clinical benefit.

INHERITED IMMUNODEFICIENCY DISORDERS AND PREDISPOSITION TO EPSTEIN-BARR VIRUS–ASSOCIATED NEOPLASMS

A variety of inherited immunodeficiency disorders have been associated with a genetic predisposition to EBV-associated complications. Patients with dysfunctional cytotoxic T-cell function are particularly susceptible to EBV-related lymphoproliferation and subsequent lymphoma due to inability to "prune" EBV$^+$ B cells. The clinical syndromes driven by EBV are heterogeneous and include non-malignant B-cell hyperplasia, CAEBV infection, hemophagocytic lymphohistiocytosis (HLH), and overt lymphomas. X-linked lymphoproliferative disease (XLP) was historically the classic immunodeficiency disorder associated with vulnerability to life-threatening complications of EBV infection, but since the turn of the century a number of novel immunodeficiency disorders have been identified through technological advances in genetic testing and the enhanced capacity to identify clinically relevant gene mutations.[29,30] XLP is notable in that patients are specifically susceptible to EBV and typically are unaffected by other microorganisms. Other immunodeficiency disorders (e.g., X-MEN disease, ITK, coronin 1A, CD27, CD16, CD70, and MCM4 deficiencies) are characterized by susceptibility to viral infections in general, and patients frequently experience severe complications from EBV. EBV-related complications can also occur in immunodeficiency disorders in which patients are generally susceptible to both viral and nonviral infections (e.g., activated PI3Kδ syndrome, Chédiak-Higashi syndrome, and deficiencies of STK4, ZAP70, CTPS1, and GATA2). Another group of immunodeficiency disorders notable for predisposition to EBV-associated complications is characterized specifically by susceptibility to developing lymphoma (e.g., Wiskott-Aldrich syndrome, ataxia telangiectasia, and autoimmune lymphoproliferative syndrome). This section will highlight XLP1 and XLP2 and discuss the ever-expanding range of uncommon and even rare immune deficiency disorders that have been associated with lymphoproliferative complications of EBV infection (Table 55.3).

TABLE 55.3 **Primary Immunodeficiencies Associated With Lymphoproliferative Complications of Epstein-Barr Virus Infection**

Immune Deficiency Syndrome	Affected Gene	Immune Defect Related to EBV Immunity
Impaired T-Cell and NK–Cell Cytotoxicity		
XLP1	*SH2D1A*	Impaired T/NK-cell cytotoxicity
XLP2	*BIRC4*	Impaired T/NK-cell cytotoxicity, BIRC4 encodes XIAP
Chédiak-Higashi syndrome	*LYST*	Impaired T/NK-cell cytotoxicity
Griscelli syndrome	*RAB27A*	Impaired T/NK-cell cytotoxicity
Familial HLH-2	*PRF1*	Impaired T/NK-cell cytotoxicity
Familial HLH-3	*UNC13D*	Impaired T/NK-cell cytotoxicity
Familial HLH-5	*STXBP2*	Impaired T/NK-cell cytotoxicity
CD16 deficiency	*FCGR3A*	Impaired spontaneous NK-cell cytotoxicity
Defects in Cell Proliferation, Differentiation, and Signaling		
Coronin1A deficiency	*CORO1A*	Defective actin polymerization and T-cell activation
Activated PI3Kδ syndrome	*PIK3CD*	Impaired CD8$^+$ T-cell and NK-cell effector function
Activated PI3Kδ syndrome	*PIK3R1*	Impaired CD8$^+$ T-cell and NK-cell effector function
IL-2 inducible T-cell kinase deficiency	*ITK*	Impaired T-cell function
X-linked immunodeficiency with magnesium defect, EBV, and neoplasia	*MAGT-1*	Defective TCR glycosylation and impaired cytolytic function
CD27 deficiency	*CD27*	Impaired T/NK-cell function
CD70 deficiency	*CD70*	Impaired B-cell signaling
NF-κB1 haploinsufficiency with common variable immunodeficiency	*NFκB1*	Impaired T- and B-cell function
STAT1 gain of function	*STAT1*	Impaired T-, B-, and NK-cell function
STIM1 deficiency	*ORAI1*	Defective Ca^{2+} sensing and T-cell activation
RASGRP1 immunodeficiency	*RASGRP1*	Defective T-cell development and B-cell differentiation
CTPS1 immunodeficiency	*CTPS1*	Impaired lymphocyte function and differentiation
STK4 deficiency	*STK4 (MST1)*	T-cell lymphopenia and defective antigen-induced T-cell stimulation and increased apoptosis
DOCK8 deficiency	*DOCK8*	Impaired cytoskeletal rearrangement, immune cell trafficking and survival
ALPS	*TNFRSF6*	Impaired T-cell stimulation
CD137 deficiency	*TNFRSF9*	Impaired T-cell stimulation
CARMIL2 deficiency	*CARMIL2*	Impaired T-cell stimulation and proliferation
LRBA deficiency	*LRBA*	Defective T-cell signaling
B-cell expansion with NF-κB and T-cell anergy (BENTA) disease	*CARD11*	Defective B-cell and T-cell signaling
Defective T-Cell and NK-Cell Development		
SCID	*RAG1* and *RAG2*	Defective V(D)J recombination and impaired T- and B-cell development
SCID	*DCLRE1C*	Defective V(D)J recombination and DNA DSB repair impair T- and B-cell development
SCID	*IL2RG*	Defective T/NK-cell development
SCID	*JAK3*	Defective T/NK-cell development
SCID	*IL7RA*	Defective T/NK-cell development
Combined immunodeficiency syndrome	*ZAP70*	Defective CD8$^+$ T-cell development
Wiskott-Aldrich syndrome	*WAS*	Defective T/NK-cell development and function
GATA2 deficiency	*GATA2*	Defective T/NK-cell development
MCM4 deficiency	*MCM4*	Defective T/NK-cell development and function
Defective DNA Repair		
Ataxia-telangiectasia	*ATM*	Defective DNA repair
Nijmegen breakage syndrome	*NBN*	Defective DNA repair
Ligase 4 syndrome	*LIG4*	Defective DNA repair, defective T/NK-cell development

ALPS, Autoimmune lymphoproliferative syndrome; *DSB*, double-strand break; *EBV*, Epstein-Barr virus; *HLH*, hemophagocytic lymphohistiocytosis; *IL*, Interleukin; *NK*, natural killer; *SCID*, severe combined immunodeficiency syndrome; *TCR*, T-cell receptor; *XLP1*, X-linked lymphoproliferative disease 1.

X-Linked Lymphoproliferative Diseases

X-Linked Lymphoproliferative Disease 1

Mutations or deletions in *SH2D1A* (Src homology 2 domain protein 1A) result in X-linked lymphoproliferative disease 1 (XLP1; Duncan disease), an immunodeficiency characterized by potentially fatal IM meeting the diagnostic criteria for HLH, agammaglobulinemia, or B-cell lymphoma. SH2D1A interacts with SLAM (signaling lymphocyte activation molecule), which plays a central role in the stimulation of B and T cells. SH2D1A controls several distinct key T-cell signaling pathways, and mutant SH2D1A does not bind SLAM, suggesting that it is a natural SLAM inhibitor. SAP association with SLAM receptors is crucial for development of normal natural killer (NK)/T cells, formation of normal GCs, and NK- and T-cell killing of EBV-infected B cells. T cells from patients with XLP1 are also resistant to apoptosis by radiation-induced cell death. Immune hyperactivation induced by primary EBV infection may be due to specific defects in NK and CD8$^+$ T-cell cytotoxicity rather than from decreased or absent cytotoxic proteins. Resistance to apoptosis may exacerbate the inflammatory response due to persistence of ineffective activated NK and T cells.

Following infection with EBV, patients with XLP1 mount a vigorous, uncontrolled polyclonal expansion of T and B cells. Infiltrating T cells cause extensive tissue destruction of the liver and bone marrow, resulting in death in 50% of XLP1 patients during primary EBV infection. Approximately 30% of patients have acquired hypogammaglobulinemia, and 25% of patients develop malignant B-cell lymphomas that are often extranodal, involving the intestinal ileocecal region. It is important to realize that some patients with *SH2D1A* mutations may present with only hypogammaglobulinemia, mimicking common variable immunodeficiency, and a diagnosis of XLP1 should be considered when more than one male patient with hypogammaglobulinemia is encountered in the same family. Patients with fulminant immunologic responses to primary EBV infection may be treated with HLH treatment strategies (glucocorticoids and etoposide) and/or rituximab. However, the only curative therapy for immune dysregulation associated with dysfunctional XLP1 is allogeneic HSCT.

X-Linked Lymphoproliferative Disease 2

A second X-linked immune deficiency characterized by recurrent HLH (with or without EBV infection) is XLP2, caused by *BIRC4* mutations and XIAP deficiency.[31] Unlike patients with XLP1, those with XLP2 have less pleotropic clinical manifestations. It rarely results in lymphoproliferation or lymphoma and may be more accurately characterized as "X-linked familial HLH." XIAP is a ubiquitously expressed member of a family of proteins defined by baculovirus IAP repeat (BIR) domains that inhibit apoptosis through inhibition of caspases. The mechanism of XIAP-induced HLH remains uncertain. Paradoxically, unlike in cases of XLP1, in which lymphocytes are resistant to apoptosis, XIAP deficiency in XLP2 confers increased sensitivity to radiation-induced cell death. The clinical manifestations of HLH in XLP2 patients with primary EBV infections appear less severe than in patients with XLP1. However, data remain insufficient to make specific therapy recommendations for XLP1 versus XLP2 or other forms of familial HLH.

Other Inherited Immunodeficiency Disorders Associated with Epstein-Barr Virus Disease

Most individuals recover from the acute phase of primary EBV infection with no long-term sequelae, including some patients with primary immunodeficiency disorders. However, a minority of patients with intrinsic defects in immune function may be vulnerable to severe complications from primary EBV infection (see Table 55.3). Impairment of T/NK-cell cytotoxicity primarily is associated with risk for potentially lethal uncontrolled pathologic inflammation driven by EBV infection, manifest by fever and multisystem organ failure, typically meeting diagnostic criteria for HLH. Others, with immune deficiencies derived from defective T/NK-cell development, proliferation, differentiation, and signaling pathways may develop CAEBV or even EBV-associated LPD or malignancies.[32,33] In addition to primary immunodeficiencies that result in failure to control EBV infection, there is an increasing list of gene defects associated with complex immune dysfunction that predispose to complications of EBV infection.[29,30,32,33]

Immune regulation of EBV in primary immune deficiency (PID) or regulation syndromes depends on the particular cellular defect. Table 55.3 categorizes immune deficiency syndromes associated with lymphoproliferative complications of EBV infection based on type of immune defect. For example, similar to XLP1 and XLP2, there are numerous other disorders characterized by impairment of T/NK-cell cytotoxicity are associated with EBV-driven HLH.[29,30,32,33] Primary T-cell deficiencies with defective T-, NK-, and/or B-cell development, such as severe combined immunodeficiency (SCID) lead to absence of T cells which render patients vulnerable to not only EBV, but a broad array of infectious diseases.[32] Immune disorders characterized by improper T-cell differentiation, antigen-induced expansion, and signaling also leave patients not only susceptible to EBV, but a broad range of herpesviral diseases.[29,30,32,33] Lastly, impaired T-cell immune regulation and poor B-cell control of EBV are associated with a risk of EBV-driven lymphoma in combined immunodeficiencies such as Wiskott-Aldrich syndrome, ataxia telangiectasia, as well as other DNA repair defects including Nijmegen breakage syndrome. Ultimately, although many of these immune deficiency syndromes are extremely rare, it is critical to evaluate patients with EBV-driven lymphoproliferation for potential underlying genetic alterations; identification of inherited predisposition not only sheds light on the disease etiology but has important implications in future therapeutic strategies. Such patients typically require restoration of immune function to provide curative intervention, be it through novel immunotherapeutic strategies or allogeneic HSCT.[33]

EPSTEIN-BARR VIRUS–ASSOCIATED NEOPLASIA

Over the past decades, EBV has been associated with a variety of different malignancies.[25] Each year it is estimated that 200,000 cases of EBV-associated malignancy are diagnosed worldwide. Nonlymphoid cancers—gastric carcinoma and NPC specifically—account for more than three quarters of these, while lymphoid neoplasms of B-, T-, and NK-cell origin plus the exceedingly rare EBV-associated leiomyosarcoma make up the remainder (Figs. 55.5 and 55.6).[25] The following sections focus on lymphoid neoplasms associated with EBV, categorized by the underlying cell of origin (i.e., B vs. T/NK cell, Table 55.4). Characteristics of EBV-associated lymphoid neoplasms occurring in patients with acquired immune deficiency will be discussed separately in an ensuing section.

The diverse spectrum of EBV-associated neoplasia is characterized by complex nuances. Although some neoplasms occur primarily in the context of immune deficiency, others typically occur in patients without underlying immune dysfunction, whereas others can occur in either scenario (Table 55.5). Although there is strong circumstantial evidence linking EBV to these malignancies, the potential causative relationship between EBV and these tumors remains to be firmly established. In addition, the frequency of EBV involvement in this spectrum of EBV-associated neoplasia ranges from virtually always to sporadic (Table 55.6). Nonetheless, all EBV-associated malignancies are associated with viral latency, and spontaneous viral replication occurs at a very low frequency. Because antiviral agents, like acyclovir, prevent only viral replication and do not affect latency, these agents are of limited therapeutic value for EBV-associated malignancies.

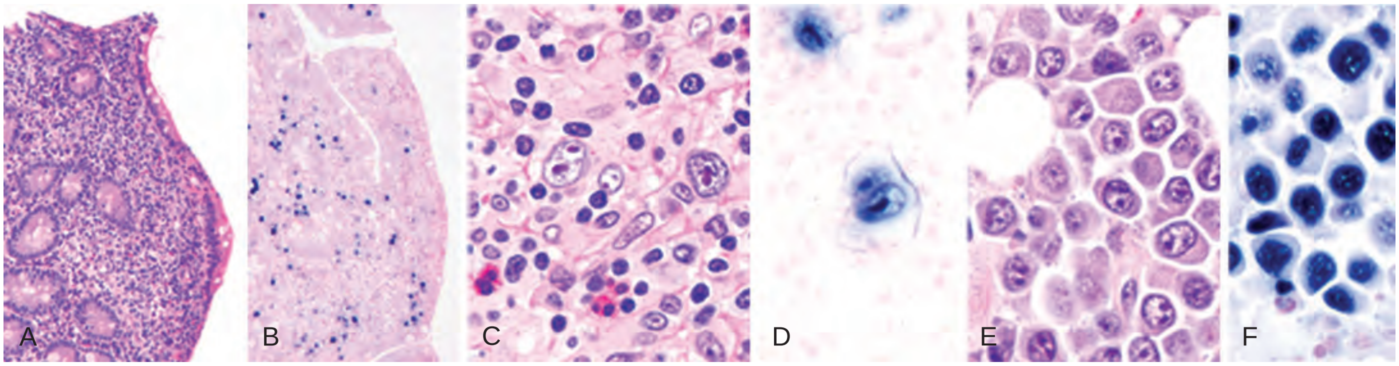

Figure 55.5 EXAMPLES OF EPSTEIN-BARR VIRUS–POSITIVE LYMPHOID MALIGNANCIES. Posttransplant lymphoproliferative disorder (PTLD), Hodgkin lymphoma, and large B-cell lymphoma. PTLD in the duodenum of a 15-month-old (A) with history of liver transplant. (B) The PTLD was classified as a polymorphic type and was Epstein-Barr virus (EBV)-positive. Hodgkin lymphoma (C) and EBV-positive Reed-Sternberg cells (D). Large B-cell lymphoma (plasmablastic type) in a human immunodeficiency virus–positive patient (E), diffusely EBV-positive (F). Note, all EBV studies are in situ hybridizations for EBV messenger RNA, EBER.

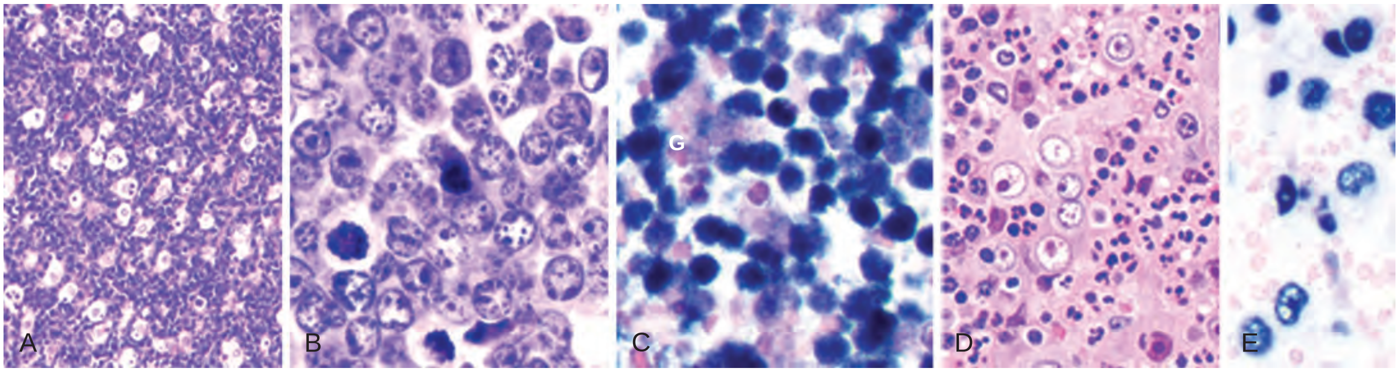

Figure 55.6 FURTHER EXAMPLES OF EPSTEIN-BARR VIRUS (EBV)-POSITIVE MALIGNANCIES. (A–E) Burkitt lymphoma and nasopharyngeal carcinoma. Low power of Burkitt lymphoma showing the classic "starry sky" appearance (A) and higher power illustrating the highly proliferative lymphoma cells (B), which are uniformly EBV-positive (C). Nasopharyngeal carcinoma (D) with EBV-positive cells (E) demonstrated by in situ hybridization for EBV messenger RNA.

TABLE 55.4 Epstein-Barr Virus–Associated Lymphoid Neoplasms Categorized by Cell of Origin

B Lymphocyte	T/NK Lymphocyte
Burkitt lymphoma	Systemic chronic active EBV
Diffuse large B-cell lymphoma	Hydroavacciniforme-like T-cell LPD
Classic Hodgkin lymphoma	Severe mosquito bite allergy
Plasmablastic lymphoma	Systemic EBV$^+$ TCL of childhood
Primary effusion lymphoma	Aggressive NK-cell leukemia
Primary CNS lymphoma	Extranodal NK/T-cell lymphoma, nasal type
Lymphomatoid granulomatosis	Primary EBV$^+$ nodal T/NK-cell lymphoma
Nondestructive and polymorphic PTLD	Angioimmunoblastic lymphoma
Monomorphic PTLD	Monomorphic PTLD (rare)
Other immunodeficiency-associated LPD	EBV-associated HLH
Systemic chronic active EBV (rare)	

CNS, Central nervous system; *EBV*, Epstein-Barr virus; *HLH*, hemophagocytic lymphohistiocytosis; *LPD*, lymphoproliferative disorder; *NK*, natural killer; *PTLD*, posttransplant lymphoproliferative disorder; *TCL*, T-cell lymphoma.

TABLE 55.5 Epstein-Barr Virus–Associated Lymphoid Neoplasms Categorized by Occurrence With or Without Identified Immunodeficiency

Primarily With Immune Deficiency	With or Without Immune Dysfunction	Primarily Without Immunodeficiency
PTLD	EBV-associated HLH	Burkitt lymphoma
Other immunodeficiency-associated LPD	EBV$^+$ DLBCL, NOS	Classic Hodgkin lymphoma
Primary effusion lymphoma	Lymphomatoid granulomatosis	Chronic active EBV (systemic and cutaneous)
Plasmablastic lymphoma		Systemic EBV$^+$ TCL of childhood
Primary CNS lymphoma		Aggressive NK-cell leukemia
		Extranodal NK/TCL, nasal type
		Primary EBV$^+$ nodal T/NK-cell lymphoma
		Angioimmunoblastic TCL

CNS, Central nervous system; *DLBCL*, diffuse large B-cell lymphoma; *EBV*, Epstein-Barr virus; *HLH*, hemophagocytic lymphohistiocytosis; *LPD*, lymphoproliferative disorder; *NOS*, not otherwise specified; *PTLD*, post-transplant lymphoproliferative disorder; *TCL*, T-cell lymphoma.

TABLE 55.6 **Neoplasms Categorized by Frequency of their Association With Epstein-Barr Virus**

Almost Always EBV$^+$ (>90%)	Usually EBV$^+$ (>50%)
Endemic Burkitt lymphoma	Plasmablastic lymphoma
Lymphomatoid granulomatosis	Primary effusion lymphoma
Nondestructive and polymorphic PTLD	Primary CNS lymphoma
Other immunodeficiency-associated LPD	Monomorphic PTLD
Chronic active EBV	Angioimmunoblastic lymphoma
Hydroavacciniforme-like T-cell LPD	Nasopharyngeal carcinoma
Severe mosquito bite allergy	**Sporadically EBV$^+$ (<50%)**
Systemic EBV$^+$ TCL of childhood	Sporadic Burkitt lymphoma
Aggressive NK-cell leukemia	Classic Hodgkin lymphoma
Extranodal NK/T-cell lymphoma, nasal type	Diffuse large B-cell lymphoma
Primary EBV$^+$ nodal T/NK-cell lymphoma	Gastric carcinoma

CNS, Central nervous system, *EBV*, Epstein-Barr virus; *LPD*, lymphoproliferative disorder, *PTLD*, posttransplant lymphoproliferative disorder; *TCL*, T-cell lymphoma.

Lymphoproliferative Disorders and Lymphomas of B-Cell Origin

EBV-driven B-cell LPDs and lymphomas can develop in patients with congenital or acquired immunodeficiencies, including HIV infection and iatrogenic immunosuppression in SOT or HSCT recipients (see Fig. 55.6).[34] The model of immunodeficiency-associated lymphoproliferative disorders (IA-LPDs) is based on the direct proliferative effects that EBV exerts on the B-cell compartment in patients who fail to amount an effective T-cell response to EBV infection. This model is exemplified by EBV-transformed LCL through in vitro models. EBV-driven B-cell LPD and LCL express the full spectrum of EBV latent proteins and are characterized as latency program III. Because the latency III profile of antigen expression is characteristically immunogenic, in immune-competent individuals, these EBV-transformed cells would be immediately eradicated. This highlights the necessary role that T-cell dysfunction plays in enabling the development of EBV-associated B-cell LPD.

The spectrum of proliferative effects caused by EBV on the B-cell compartment ranges from non-malignant B-cell hyperplasia, to polymorphic but monoclonal B-cell lymphoproliferation, to malignant transformation into monomorphic lymphomas of B-cell origin. These EBV-associated B-cell neoplasms are heterogeneous in many aspects—from the pathogenic role of EBV, to the clinical manifestations, all the way to the expected treatment response. Although non-malignant B-cell LPD is characteristically seen in patients with established T-cell dysfunction, overt EBV-associated B-cell lymphomas can occur in patients with or without known immune deficiency (see Table 55.5). Such lymphomas are characterized by the more restricted latency I and II profiles, and their pathophysiology is thought to be more complex in nature. These malignancies are not solely dependent on EBV-driven proliferation but rather on a multitude of factors including genetic and epigenetic alterations that seem to collaborate with EBV to drive the underlying oncogenesis.[25] The majority of immunocompetent patients with EBV-associated lymphomas are latency type II and express EBNA1, LMP1, and LMP2, except for BL, which is typically latency type I and only expresses EBNA1.

Immunodeficiency-Associated Lymphoproliferative Disorders

IA-LPDs are typically driven by an oncogenic virus in patients with underlying T-cell dysfunction. Although HHV-8 can also cause IA-LPDs, the majority of cases are associated with EBV infection and will be highlighted here. IA-LPD as a category includes the spectrum of neoplastic transformation ranging from non-malignant B-cell hyperplasia to polymorphic B-cell LPD to overt B-cell lymphomas.[35] This section will focus on the overarching characteristics of B-cell hyperplasia and polymorphic LPD, and subsequent sections will discuss various monomorphic lymphomas of B-cell origin as well as posttransplant lymphoproliferative disorders (PTLDs) in more detail.

EBV is a driver of B-cell hyperplasia and polymorphic LPD in patients with IA-LPDs of B-cell origin.[36] Whether the underlying immunodeficiency is inherited through genetic mutations in the immune system, acquired through infection with HIV, or iatrogenically imposed by immunosuppressive medications, the pathophysiology of EBV-associated IA-LPDs remains similar.[35] EBV-driven B-cell hyperplasia is characterized by nondestructive lymphocytic infiltrates with varying morphological patterns that virtually always stain positive for EBV on histologic evaluation. These lymphoproliferative changes may regress with restoration of T-cell function and carry low potential for transformation into lymphoma.

Polymorphic LPD is generally associated with EBV in patients with underlying immunodeficiency. Histologically, the disease pathology is characterized by EBV-infected lymphocytic infiltrates that are destructive to the tissue architecture of the affected lymphoid organ. Morphology of these lesions is characterized by infiltrates spanning the spectrum of B-cell development, thus rendering a “polymorphic” appearance. Despite this, the majority exhibits monoclonal *BCR* gene rearrangements and risk for transformation to a monomorphic lymphoma exists. While restoration of immune function can successfully induce remission in polymorphic LPD, some patients will require more aggressive therapeutic intervention with anti-CD20 humoral immunotherapy plus/minus chemotherapy.

EBV$^+$ mucocutaneous ulcer is a distinct form of EBV-driven IA-LPD that characteristically presents with ulcerating lesions confined to the oral mucosa or skin.[37] These ulcers are well-circumscribed and painful and, similar to polymorphic LPD, typically respond favorably to restoration of immune function through reduction of immune suppression. EBV$^+$ mucocutaneous ulcer can also occur in elderly patients who have undergone immune senescence. Differentiation from EBV$^+$ lymphomas is critical to avoid overaggressive treatment.[37]

These characteristics of EBV-associated B-cell hyperplasia and polymorphic LPD have historically been defined through experience in patients with PTLD. However, it has become apparent that similar features are shared by patients with EBV-associated LPD across a variety of immunodeficiency states.[35] Such patients are additionally at risk for developing monomorphic lymphomas as well. The following sections will discuss the most common lymphomas of B-cell origin associated with EBV; these occur in both patients with underlying immunodeficiency disorders and those that appear to be immune competent.

Burkitt Lymphoma

BL is a high-grade mature B-cell lymphoma. Typical histology reveals a “starry-sky” pattern resulting from numerous benign macrophages that have ingested apoptotic tumor cells (see Fig. 55.6A–C, Chapters 84 and 87). Although most cases of endemic BL in equatorial Africa are associated with EBV, the virus has been implicated less often in sporadic cases, and in the United States only 20% of BL are EBV-positive. In some low- and middle-income countries, an intermediate association with EBV has been described, which varies from 25% to 80%.[38] It is notable that EBV was first discovered in a patient sample from a Ugandan child with a jaw tumor through collaborative work between Denis Burkitt and Anthony Epstein.[39,40]

The EBV genome is clonal in BL as in other EBV-associated malignancies and is characterized by the latency I EBV antigen profile, although some subtle variants have been described.[25] BL is defined by its characteristic translocation of the *C-MYC* oncogene. The majority of cases carry a translocation between the long arm of chromosome 8, the site of *C-MYC* (8q24), and the Ig heavy chain region on chromosome 14, t(8;14). Although the t(8;14) translocation is seen in endemic as well as sporadic BL, the exact location of the chromosomal breakpoints on chromosome 8 and 14 can differ.[41] Other chromosomal translocations seen in BL are between *C-MYC* and the κ-light chain locus on chromosome 2, t(2;8), or the λ-light chain locus on chromosome 22, t(8;22).[42] Recent genomic studies comparing endemic and sporadic BL as well as EBV$^+$ and EBV-negative disease have shed light on some novel biological findings with distinctions and similarities shared between the epidemiological variants.[43–51] Compared with EBV-negative BL, EBV$^+$ BL has been associated with fewer driver mutations but higher mutation burden. The precise pathogenic role of EBV in BL and its contribution to the distinct epidemiological pattern observed in equatorial Africa remain elusive.

Current treatment strategies rely on intensive chemotherapy, and event-free survival in high-income countries in the contemporary era after treatment with rituximab plus combination chemotherapy now exceeds 90%, even for patients with advanced-stage disease.[52,53] The prospect for the development of an EBV-specific immunotherapy for BL is problematic because lymphoma cells evade the immune system by downregulating the expression of EBV latency antigens, cell adhesion molecules, and MHC class I molecules. EBNA1, the only EBV protein expressed in BL, autoregulates its own translation and inhibits its HLA class I presentation because of an internal glycine-alanine repeat region. The relatively dismal outcomes for African children with BL remain dismal and expose the injustice of global health disparities rooted in unequal access to healthcare resources,[54] highlighting the critical importance in improving healthcare infrastructure across the globe, establishing equal access to healthcare resources to all of humankind, and capacity building for healthcare professionals throughout low- and middle-income countries.

Hodgkin Lymphoma

HL is a malignant neoplasm of lymphoreticular cell origin, and 20% to 40% of cases in immunocompetent individuals are associated with expression of EBV-derived antigens in malignant Hodgkin and Reed-Sternberg (HRS) cells and their variants (see Fig. 55.5C and D).[55,56] The frequency of EBV association with HL differs by histologic subtype and is highest with the mixed-cellularity subtype. Evidence linking EBV to the pathogenesis of HL includes the findings that (1) every HRS cell in an EBV-positive tumor mass carries the virus, and (2) the EBV genome is clonal, indicating that the malignant HRS cells originated from a single EBV-infected cell. In addition, LMP1, one of the EBV proteins expressed in HRS cells, activates the transcription factor nuclear factor κB (NF-κB), which is thought to play an important role in HL pathogenesis. EBV-positive HL patients also differ in their antibody response to the major EBV-associated antigens in comparison with healthy controls. Ultimately, while the precise etiological role of EBV remains unknown, alterations in the NF-κB and Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathways and disruptions in apoptotic mechanisms have been implicated.[56]

The overall outcome of EBV-positive and EBV-negative HL is similar; with combination chemotherapy and radiation, the prognosis is excellent for low-stage disease, and overall survival rate for advanced-stage disease exceeds 85% (see Chapters 77–79). Depending on age and histologic subtype, the presence of EBV might be associated with better survival. As with BL, mechanistic role for EBV in pathogenesis of HL remains uncertain. Studies evaluating the role of EBV viral load and its utility as a prognostic biomarker have produced interesting preliminary results. Adult data from a large cooperative group trial in North America demonstrated inferior failure-free survival for patients with plasma EBV viremia at baseline and those with persistent EBV viremia at the 6-month time point as well.[57] However, there was no correlation with survival and histologic evidence of EBV on tumor biopsy. The pediatric HL experience was evaluated similarly and demonstrated inferior event-free survival if EBV viremia was detected on day 8 of induction in cell-free blood samples. However, baseline EBV viremia was not prognostic.[58] These studies highlight the potential utility of leveraging EBV viral load as a prognostic biomarker for lymphoma, both at baseline and as gauge for treatment response, similar to the precedent established for NPC.[59]

Interesting patterns of association between EBV and HL have been long been observed but without precise explanation. Nearly 50 years ago, descriptions of increased risk for HL in individuals with a previous diagnosis of IM were published. More recently, onset of EBV-associated HL occurring after episodes of IM was confirmed in children as well.[55] The association between HL and EBV is more commonly seen in children and in low- and middle-income countries.[60] However, connecting the dots between such epidemiologic observations is complex because IM occurs much less frequently in low- and middle-income countries, despite HL having a much higher frequency of association with EBV.[55]

Other B-Cell Neoplasms Associated With Epstein-Barr Virus

A variety of other B-cell neoplasms is associated with EBV across a spectrum of clinical contexts including diffuse large B-cell lymphoma (DLBCL), lymphomatoid granulomatosis, plasmablastic lymphoma, primary effusion lymphoma (PEL), and primary central nervous system (CNS) lymphoma (PCNSL). The association of these lymphomas with EBV varies, ranging from 10% to 95%, and all of them occur in both immune competent individuals and those living with underlying immunodeficiency.

EBV$^+$ DLBCL, not otherwise specified (NOS) was previously known as EBV$^+$ DLBCL of the elderly prior to the 2016 version of the World Health Organization (WHO) classification of lymphoid neoplasms.[61] While it had previously been described as occurring in elderly patients who presumably had undergone immune senescence, it is now accepted that this disease entity can occur in individuals of any age and in patients with or without defined immunodeficiency.[62] Younger patients with EBV$^+$ DLBCL, NOS typically present with nodal involvement. The neoplastic cells express both latency II (in younger patients) and III (in elderly patients) EBV antigen profiles and most often are categorized as the activated B-cell–like subtype of DLBCL. The diagnosis represents a heterogeneous group, and the histology can display a variety of patterns including the T-cell/histiocyte-rich large B-cell lymphoma, B-cell lymphoma unclassifiable with features intermediate between DLBCL and classic HL (also known as gray zone lymphoma), and DLBCL, NOS.[62,63] In addition, variants with very specific clinical phenotypes have been described such as EBV$^+$ DLBCL associated with chronic inflammation (e.g., chronic pyothorax) and fibrin-associated DLBCL (in patients with localized chronic fibrin deposition).[25] Younger patients tend respond favorably to rituximab plus combination chemotherapy, and long-term remission has been reported as high 80%.[63]

Lymphomatoid granulomatosis is an EBV-driven B-cell LPD associated with impaired cytotoxic function, clinically characterized by a unique predilection for the lungs.[64,65] The most common extrapulmonary sites of involvement are the CNS, skin, and kidneys.[66] Lymphomatoid granulomatosis shares significant overlap in the clinical and histological characteristics between EBV$^+$ DLBCL, NOS, which also can present with lung involvement. The typical histological pattern of lymphomatoid granulomatosis is described as angioinvasive and angiodestructive lymphoproliferative lesions with numerous EBV$^+$ B cells amid a polymorphous background including T-cell infiltrates.[67] Lesions contain EBV$^+$ large atypical B cells, and the density of these determine a histologic grade ranging from 1 to 3; grade 3 lesions share significant morphologic overlap with EBV$^+$ DLBCL, NOS. Unlike the majority of other EBV-driven lymphoid neoplasms (including EBV$^+$ DLBCL, NOS), peripheral blood EBV viral load is often undetectable or displays low-level viremia in patients with lymphomatoid granulomatosis.[64] Patients with grade 3 disease are treated similarly as patients with EBV$^+$ DLBCL, NOS; however, the response to therapy is rarely sustained, and relapse is common.[64,65] Allogeneic HSCT is often a consideration in patients with lymphomatoid granulomatosis based on patient status, treatment response, and available donor options.

Plasmablastic lymphoma and PEL are relatively rare B-cell lymphomas with an overlapping malignant cell immunophenotype demonstrating plasmablastic cell differentiation; they are associated with EBV, HIV, and, in the case of PEL, HHV-8 as well.[68] PCNSL is another acquired immunodeficiency syndrome (AIDS)-defining lymphoma that is etiologically linked with EBV; the underlying histology in HIV-infected patients is typically a GC-derived DLBCL.[68] Although the incidence of these three lymphomas is dramatically increased in HIV-infected patients, they can occur rarely in HIV-negative, immune-competent individuals; in such scenarios, they are not necessarily EBV associated.

Plasmablastic lymphoma typically presents with masses in the oral cavity or other extranodal sites, is EBV associated in approximately 75% of HIV$^+$ and 50% of HIV-negative cases, expresses either a latency I or III EBV antigen profile, and often carries *C-MYC* gene rearrangements.[69] PEL is distinguished from plasmablastic lymphoma by a unique clinical presentation and its characteristic association with HHV-8. Large effusions in the pleural, pericardial, or peritoneal cavities, in the absence of a solid mass, characterize the typical presentation of PEL, although an extracavitary variant has also been described. Approximately 80% of PEL cases are EBV-associated, and latency profile I is most commonly displayed.[70,71] PCNSL is a heterogenous diagnostic entity; as noted earlier, in the context of HIV infection, it is frequently EBV$^+$ and with a DLBCL morphology. However, it is important to note that PCNSL also refers to other NHLs that present primarily with CNS tumors, and the clinical characteristics and treatment strategies are typically derived based on the underlying histopathology, which can include anaplastic large cell lymphoma, BL, and lymphoblastic lymphoma, among others. In these scenarios, PCNSL is often EBV negative.[72] All three of these rare lymphomas have generally poor prognoses; however, successful treatment with intensive multiagent chemoimmunotherapeutic regimens has been reported.[68]

Lymphoproliferative Disorders and Lymphomas of T/Natural Killer–Cell Origin

Seeming to defy convention, EBV-associated T- and NK-cell lymphoid neoplasms also occur despite B cells serving as the typical host target for EBV infection. The mechanism by which EBV extends its tropism to the T- or NK-cell compartment remains unknown and has been the subject of investigation. Theories postulating a virological synapse to transfer from B to T/NK cells have yet to be validated, and recent evidence supports EBV infection of precursor lymphoid cells that extend to all three lymphocyte lineages.[73] Regardless of infectious entry point in lymphocyte differentiation, EBV-associated LPD and lymphomas of T/NK-cell origin are a rare but critical group of diseases that are often characterized by poor survival.

The most recent WHO classification of lymphoid neoplasms stratifies diagnostic entities based on systemic versus localized clinical presentation. It has been proposed that chronic active T/NK-cell EBV infection (T/NK CAEBV) as well as EBV-associated HLH (EBV-HLH) be included in this classification (see Table 55.4).[67,74–76] Localized disease specifically refers to two forms of CAEBV that present with primarily cutaneous manifestations—hydroavacciniforme-like lymphoproliferative disease (HV-LPD) and severe mosquito bite allergy (SMBA). Systemic EBV$^+$ T/NK cell lymphoid neoplasms include the systemic form of T/NK CAEBV, EBV-HLH, and four overt lymphomas—systemic EBV$^+$ T-cell lymphoma of childhood (sEBV$^+$ T-NHL), primary EBV$^+$ nodal T/NK-cell lymphoma (EBV$^+$ PTCL), aggressive NK-cell leukemia (ANKL), and extranodal NK/T-cell lymphoma, nasal type (ENKTL). This heterogeneous spectrum of EBV-associated diseases of T/NK-cell origin shares some common characteristics. There is a unique susceptibility in individuals of East Asian or indigenous ancestry of Central and South America, the EBV latency profile pattern varies between type I and II, and although there has yet to be an identified immunodeficiency associated with them, the patterns of genetic predisposition in distinct populations are evident.[25]

EBV-associated lymphoproliferation in T/NK cells does not appear to mimic the model established by the spectrum of disease entities observed in the B-cell compartment. Although a gradation of EBV-driven lymphoproliferation is well described in B cells, ranging from premalignant B-cell hyperplasia, to lymphoproliferative states of varied malignant potential and ultimately to overt B-cell lymphomas, the occurrence of EBV-associated T/NK-cell LPD and lymphomas is seemingly idiosyncratic. It typically arises in patients without obvious immune dysfunction, and reasons for ethnic predisposition in Asians and indigenous populations of the Americas are not known. EBV$^+$ T/NK-cell diseases range from indolent (e.g., CAEBV) to acutely fulminant (e.g., all the systemic disorders). There does not appear to exist an initial state of polymorphic T-cell lymphoproliferation that is observed in B-cell PTLD.[77,78] Nonetheless, there has been significant progress achieved over the past two decades, shedding light on the biologic and clinical characteristics of this enigmatic spectrum of disease. Recently discovered primary immunodeficiency disorders have been associated with EBV-HLH and a clinical phenotype of T/NK CAEBV. Meanwhile, preliminary data demonstrating efficacy of immune checkpoint blockade in a case series of patients with relapsed/refractory EBV-HLH suggest that some form of immune restoration may indeed have a role to play in the therapeutic approach for EBV$^+$ T/NK-cell LPD.[79]

Epstein-Barr Virus–Associated Hemophagocytic Lymphohistiocytosis

HLH is a syndrome characterized by uncontrolled inflammation (see Chapter 53). Diagnostic criteria defined by the Histiocyte Society reflect the clinical features of pathologic immune activation, including persistent fever, splenomegaly, cytopenias, hyperferritinemia, decreased fibrinogen or increased triglycerides, hemophagocytosis (in bone marrow, spleen, or lymph nodes), increased soluble IL-2 receptor α, and decreased or absent NK-cell function. The diagnosis of HLH can also be established by a pattern of familial inheritance or proven gene defects. HLH may be associated with EBV in a variety of clinical scenarios including: (1) primary EBV infection as an inciting factor in a patient with inherited predisposition to familial/primary HLH, (2) primary EBV infection provoking a secondary HLH syndrome in a patient without genetic predisposition to HLH, and (3) HLH occurring secondary to an EBV-associated T/NK LPD/lymphoma (including CAEBV).

Gene defects resulting in impaired cytotoxic NK- and T-cell function have been associated with autosomal recessive inheritance of HLH, including *PRF1* (familial [f]HLH-2), *UNC13D* (fHLH-3), *STX11* (fHLH-4), *STXPB2* (fHLH-5), *Munc18-2, RAB27A* (Griscelli syndrome, type 2), *LYST* (Chédiak-Higashi syndrome), *AP3B1* (Hermansky-Pudlak syndrome, type II), *ITK*, *CD27*, and *MAGT1* (X-MEN syndrome). The X-linked lymphoproliferative diseases (XLP1 *(SH2D1A)* and XLP2 *(BIRC4)* are also associated with HLH.[80] EBV infection may trigger HLH in patients with any form of familial disease. Gene defects are identified in only 50% of patients with family history consistent with inherited HLH. Therefore, although a diagnosis "primary" or "familial" HLH may be proven, it is impossible to exclude. Familial HLH commonly presents in young children, but there are reports of new onset of HLH in adults as old as 62 years with hypomorphic mutations in HLH-associated genes. Patients with familial HLH typically require prompt treatment with chemotherapy and immune suppression (etoposide/dexamethasone) followed by HSCT.[81] Recently, a phase 2 to 3 study of interferon(IFN)-γ inhibition led to US Food and Drug Administration (FDA) approval of emapalumab for recurrent or refractory primary.[82] Without therapy, survival of patients with active familial HLH is approximately 2 months. The first international treatment protocol for HLH organized by the Histiocyte Society in 1994 reported long-term survival of greater than 50%. For those who are able to undergo allogeneic HSCT, reduced-intensity condition has contributed to improved survival but with suboptimal engraftment.[83,84]

The term "secondary" HLH generally refers to older children (or adults) who present without a family history or known genetic cause for their HLH. EBV is a common trigger for "secondary HLH," ranging from inflammation that resolves spontaneously to unrelenting disease requiring allogeneic HSCT. Differentiating IM from EBV-HLH can be challenging in patients who are systemically ill. Clinical criteria for HLH should be evaluated in patients with persistently high cell-free EBV genome copy numbers in plasma or whole blood, persistent symptoms of inflammation, or severe symptoms. Patients who initially meet clinical criteria for HLH may occasionally improve spontaneously. Patients with less severe presentations may also respond to corticosteroids, intravenous Igs, or cyclosporine. However, in patients with progressive or severe disease, early initiation (within 4 weeks of onset of symptoms) of etoposide is associated with significant improvement in survival.[85] Because it can eliminate EBV-infected B cells, rituximab may be a beneficial addition to other therapies in patients with HLH secondary to EBV infection.[86] However, one must take caution, recognizing that an underlying lymphoproliferative process within the T- or NK-cell compartment characterizes the vast majority of patients with EBV-HLH.[87,88] In such cases, rituximab will counteract only EBV-infected B cells, while the aberrant T/NK-cell population will proliferate unmitigated.

Ultimately, it is extremely challenging to differentiate non-malignant EBV-HLH from HLH secondary to an underlying EBV$^+$ T/NK-cell LPD/lymphoma. This umbrella of EBV$^+$ T/NK-cell LPD/lymphoma includes the following diagnoses that are discussed in further detail later: systemic T/NK CAEBV, sEBV$^+$ T-NHL, EBV$^+$ PTCL, ANKL, and ENKTL.[67,74,75] Attempts to establish clinical criteria to differentiate EBV$^+$ T/NK-cell LPD/lymphoma from non-malignant EBV-HLH have failed to definitively identify patients with EBV$^+$ malignancy in prospective fashion. The inability to effectively do so prevents appropriate risk-stratification and intensification to multiagent chemotherapy and allogeneic HSCT, which would be needed to avoid the otherwise fatal clinical course for patients with EBV$^+$ T/NK-cell LPD/lymphoma. A few clinical factors, including hyperbilirubinemia, hyperferritinemia, younger age, higher levels of EBV viremia, and presence of cytogenetic abnormalities, have been identified that increase diagnostic suspicion for EBV$^+$ T/NK-cell LPD/lymphoma.[87,89,90] It is important to recognize that histopathology features of non-malignant EBV-HLH and EBV$^+$ T/NK-cell LPD/lymphoma share considerable overlap, and pathologists often struggle to definitively determine the diagnosis as well.[67,75,76] For some patients, an underlying EBV$^+$ T/NK-cell LPD/lymphoma declares itself only after an initial clinical improvement with HLH-directed therapy, to only later develop recurrent HLH requiring immunochemotherapy and HSCT. Therefore it remains important to follow patients beyond resolution of initial symptoms until they successfully establish viral suppression of EBV, a process which can take up to 12 months.[91] Patients with persistent or recurrent symptoms and or persistent high-level EBV viremia may in fact have EBV$^+$ T/NK-cell LPD/lymphoma and intensification of therapy would be indicated.[91]

Chronic Active Epstein-Barr Virus

CAEBV represents a range of clinical manifestations resulting from persistent, uncontrolled infection of T or NK cells by EBV.[91–93] Inability to control infection is likely due to defects in cytotoxic immune function. The systemic form of CAEBV has considerable pathologic and clinical overlap with HLH, and immune dysfunction is likely due to a variety of causes. Early descriptions of CAEBV primarily reported disease in Asian patients, and almost all cases were due to proliferation of EBV-infected T or NK cells.[94] A review of several centers in the United States found a predominance of B cell–associated CAEBV in the Western hemisphere; however, B-cell CAEBV is considered extremely rare.[93] Therefore the focus of this section will be on the predominant phenotype, T/NK CAEBV. CAEBV is further categorized as systemic versus cutaneous (localized) disease.

To establish the diagnosis of CAEBV, patients must have (1) sustained or recurrent IM-like signs and symptoms for 3 to 6 months, (2) elevated EBV viral load in the peripheral blood or diagnostic tissue biopsy, (3) EBV infection of T or NK cells in the blood or affected tissues, and (4) exclusion of other possible diagnoses.[95] The systemic and life-threatening form of T/NK CAEBV is characterized by high fevers, hepatosplenomegaly, and extensive lymphadenopathy, followed by hepatic, cardiac, or pulmonary dysfunction.[91] These patients have very high EBV DNA levels (viral loads) in their whole blood or peripheral blood mononuclear cells and can also demonstrate elevated EBV VCA titers. Although B cells are the typical host target for EBV, in severe CAEBV, either T or NK cells are infected, predisposing the patient to transformation to lethal T-cell or NK-cell lymphomas. Severe, often fatal CAEBV is more common in East Asia but has recently been described throughout the world.[91] Case series from the United States have included a predominance of patients with ancestry originating from Central and South America; however, cases have also been reported in children of European or African ancestry.[96–98]

Milder, more indolent forms of CAEBV primarily demonstrate cutaneous lesions. The two clinical phenotypes of cutaneous CAEBV are HV-LPD and SMBA, which have similarly been described predominantly in East Asia and Central/South America. HV-LPD skin lesions typically occur in sun-exposed areas of skin and most often involve CD8$^+$ T cells, whereas lesions in SMBA, as the name suggests, are characterized by exaggerated hypersensitivity reactions to mosquito bites and most often involve CD56$^+$ NK cells. These cutaneous forms of T/NK CAEBV tend to run indolent courses of remitting and relapsing disease; however, the severe form of HV-LPD includes systemic symptoms and carries a risk of progression to overt lymphoma.[76]

Patients with CAEBV do not have XLP-associated *SH2D1A* or *BIRC4* mutations, and although the etiology of CAEBV remains poorly understood, a recent study demonstrated that GATA2 deficiency can be associated with CAEBV and HV-LPD.[74] While the initial diagnostic criteria for CAEBV described seemingly immune competent patients, increased access to comprehensive genetic diagnostic tools has discovered some underlying mutations in patients with CAEBV.[30,91] Whether an underlying immune deficiency is identified, it remains clear that patients with CAEBV exhibit impaired T- and NK-cell cytotoxic activity.[94]

Although sporadic clinical improvements of mild/moderate CAEBV have been reported after infusion of IL-2, high-dose Ig, antiviral drugs, tumor necrosis factor (TNF)-α antibodies, or steroids, the only curative option for severe CAEBV is HSCT. Survival rates vary between 50% and 95%, with better outcomes for patients who (A) are transplanted early after diagnosis, (B) have fewer complications before transplant, and (C) have received reduced intensity conditioning regimens.[99–101] The largest clinical experience with CAEBV comes from Japan, where many of the contemporary therapeutic strategies originated. Expert opinion from Osaka advocates for pretransplant cytoreductive chemotherapy using CHOP-like regimens (CHOP = cyclophosphamide, doxorubicin hydrochloride, vincristine (oncovorin), prednisone) to decrease the lymphoproliferative burden of T/NK CAEBV infection. They argue that this approach provides a safe bridge as patients are prepared for allogeneic HSCT, improves engraftment of donor cells, and decreases the risk for post-HSCT relapse. However, this approach has not yet been validated in a randomized clinical trial.[100,101] Besides HSCT, the adoptive transfer of autologous EBV-specific T cells has been explored in five patients with mild or moderate CAEBV. Infusion of EBV-specific T cells resulted in resolution of fatigue, malaise, fever, lymphadenopathy, and splenomegaly lasting for 6 to 36 months. For severe CAEBV in which EBV resides in the T- or NK-cell compartment, the use of EBV-specific T cells has been investigated anecdotally. For example, the Center for Cell and Gene Therapy (CAGT) at Baylor College of Medicine in Houston, Texas, has infused donor-derived LMP2-specific T cells with a good partial response as judged by decreasing EBV-DNA load.[4,102]

Epstein-Barr Virus–Associated T/Natural Killer–Cell Lymphomas

NK/T-cell lymphomas that are always associated with EBV include sEBV$^+$ T-NHL, EBV$^+$ nodal PTCL, ANKL, and ENKTL.[74,75] This group of malignancies is distinct in its predilection to occur more commonly in persons of Asian and indigenous Central and South American ancestry. They tend to occur with overlapping yet distinct clinical patterns differentiated by the phenotype of the clinical presentation and its predilection to occur in either children or adults. Angioimmunoblastic lymphoma is a nodal peripheral T-cell lymphoma that is also often EBV-associated but does not share the epidemiological pattern as the other EBV-associated NK/T-cell lymphomas. The overall outcome of EBV-associated T/NK-cell NHL depends on histologic subtype and risk factors present at diagnosis, but most are high-grade malignancies with an unfavorable prognosis.

One of the most deadly diagnoses encountered in pediatric oncology, sEBV$^+$ T-NHL of childhood, is a rare but aggressive malignancy characterized by a fulminant clinical course and high case fatality rates.[96] Patients virtually always present with systemic features consistent with HLH in the setting of extreme EBV viremia. High fevers, pancytopenia, hepatosplenomegaly, and multiorgan failure are commonly seen. Both non-malignant EBV-HLH and sEBV$^+$ T-NHL are characterized by proliferation of EBV$^+$ CD8$^+$ cytotoxic T cells, most often identified by bone marrow aspirate/biopsy. However, because sEBV$^+$ T-NHL cells may lack overt atypia on histopathology, these two diagnoses are extremely difficult to differentiate on initial evaluation. This presents a major clinical dilemma because patients with non-malignant EBV-HLH may be cured with well-tolerated HLH-directed therapy (etoposide plus dexamethasone), whereas patients with sEBV$^+$ T-NHL require intensive multiagent chemotherapy followed by allogeneic HSCT. Ultimately, the overlap between non-malignant EBV-HLH and sEBV$^+$ T-NHL presents one of the most acute challenges in contemporary pediatric oncology.[75,98]

ANKL is the analogous NK-cell version of sEBV$^+$ T-NHL. Characterized by a virtually identical clinical presentation, it differs in that the lymphoproliferative population is an aberrant EBV$^+$ NK cell. It shares the same clinical challenges as sEBV$^+$ T-NHL because, although less common, non-malignant EBV-HLH can also be characterized by an EBV$^+$ NK-cell lymphoproliferation. Thus differentiation between non-malignant EBV-HLH and ANKL can be extremely challenging as well. ANKL shares immunophenotypic overlap with ENKTL; however, the clinical phenotypes differ because ANKL typically presents with severe systemic and/or leukemic disease and ENKTL often presents with extranodal masses.[74,75]

ENKTL and EBV$^+$ nodal PTCL essentially represent the extranodal and primary nodal clinical presentations of lymphoma and occur most commonly in adults. Nasal-type ENKTL represents 70% to 80% of ENKTL cases, with patients presenting with a mass in the upper aerodigestive tract. However, extranasal presentations may also occur in other extranodal sites, most commonly in the skin, gastrointestinal (GI) tract, soft tissue, and testis. Although the majority of cases are characterized by an NK-cell immunophenotype, T-cell variants also occur.[103,104] In contrast, primary EBV$^+$ nodal PTCL is represented by a mature T-cell immunophenotype in the majority of cases, although a subset of patients can have NK-cell disease. Although the clinical presentation is primarily limited to lymph node involvement, extranodal disease may also occur.[105] These two diagnoses are not as fulminant as sEBV$^+$ T-NHL or ANKL; however, they both still carry guarded prognoses with high rates of relapse.[75]

ACQUIRED IMMUNODEFICIENCY AND EPSTEIN-BARR VIRUS–ASSOCIATED NEOPLASMS

Posttransplant Lymphoproliferative Disorders

PTLDs constitute a heterogeneous group of diagnostic entities that mirror the spectrum described in the earlier section on IA-LPD. This umbrella of lymphoproliferative disorders ranges from early lesion/nondestructive PTLD (reactive EBV-associated B-cell hyperplasia) to polymorphic, destructive PTLD (polymorphic but invasive and often clonal lymphocytic infiltrates) all the way to monomorphic, destructive PTLD (overt lymphoma). PTLD is the specific category of IA-LPD that occurs in patients who are iatrogenically immunosuppressed post-allogeneic HSCT (to prevent graft-versus-host disease [GVHD]) or post SOT (to prevent graft rejection). In the setting of SOT, the reported incidence of EBV$^+$ PTLD ranges from 1% to 25%, with the highest risk in seronegative recipients, patients receiving intensive immunosuppressive therapy, and patients receiving grafts with a high lymphoid content. Host factors such as younger age (and higher chance of being EBV-naïve at time of transplant) and recipients of heart, lung, and intestinal transplants carry a higher risk of PTLD.

After allogeneic HSCT, the incidence of EBV-PTLD varies with the transplant regimen and may be as high as 25%. Risk factors for the development of EBV-PTLD post HSCT include the use of stem cells from an HLA-mismatched family member (including haploidentical donors) or HLA-matched unrelated donor, T-cell depletion of the donor cells, intensive immunosuppression, and an underlying diagnosis of primary immunodeficiency. The incidence is much lower when methods that also deplete B cells are used in the conditioning regimen (i.e., receiving alemtuzumab instead of antithymocyte globulin).

The clinical presentation of PTLD is variable. Patients can manifest with systemic symptoms (fevers, night sweats, weight loss), involvement of lymphoid (lymphadenopathy, hepatosplenomegaly, tonsillar/adenoidal hypertrophy) or extranodal tissue (GI symptoms such as malabsorption, nausea/vomiting, or bloody stool), or with dysfunction of the allograft. Fulminant PTLD is a relatively rare phenomenon but is severe and characterized by rapid progression of multiorgan failure with severe cytopenias. Careful history taking and physical exam are critical tools in evaluating patients post transplant, particularly in the setting of EBV viremia.

The onset of EBV-PTLD seems to be preceded by a large increase in viral load as well as the proliferation of EBV-infected B cells. Frequent monitoring of the EBV DNA load in peripheral blood is a valuable screening test for early detection of EBV-PTLD after HSCT or SOT. However, it remains a subject of debate which is the optimal sample (whole blood, isolated peripheral blood mononuclear cells, plasma) for EBV DNA quantitation. Lastly, the threshold level of EBV-DNA suggestive of impending EBV-PTLD varies according to the polymerase chain reaction (PCR) method of quantifying viral DNA. However, it should be emphasized that not all patients with high EBV-DNA levels, especially those with an SOT, develop EBV-PTLD. Several distinct patterns of EBV latent gene expression have been identified in the memory B cells of high-load EBV carriers, with type III latency conferring the highest risk for EBV-LPD development. Besides EBV-DNA levels, determining the frequency of EBV-specific T cells or the functionality of T cells in patients with high EBV-DNA load might also assist in identifying patients who are at increased risk for developing EBV-PTLD. In addition, host factors such as polymorphisms in the promoter regions of cytokines have been implicated in increasing the risk for developing EBV-PTLD. Thus an elevated EBV-DNA load can lead to early diagnosis of EBV-PTLD, with consequent reductions in mortality and treatment-related morbidity, although additional results such as clinical signs and symptoms, as well as radiographic findings, must be taken into account before therapy is initiated.[106,107] Besides EBV and a dysfunctional cellular immune system, genetic alterations in B cells have also been implicated in the pathogenesis of PTLD, especially in SOT recipients. These alterations can be characterized by microsatellite instability, DNA hypermethylation, aberrant somatic hypermutation, and mutations in specific genes such as *MYCC, BCL-6, N-ras*, and *p53*.

Treatment of Posttransplant Lymphoproliferative Disorders

The treatment of PTLD will depend on the specific diagnostic histology and the involvement of EBV, with a variety of therapeutic considerations available (Fig. 55.7). Treatment also differs for recipients of SOT versus HSCT.

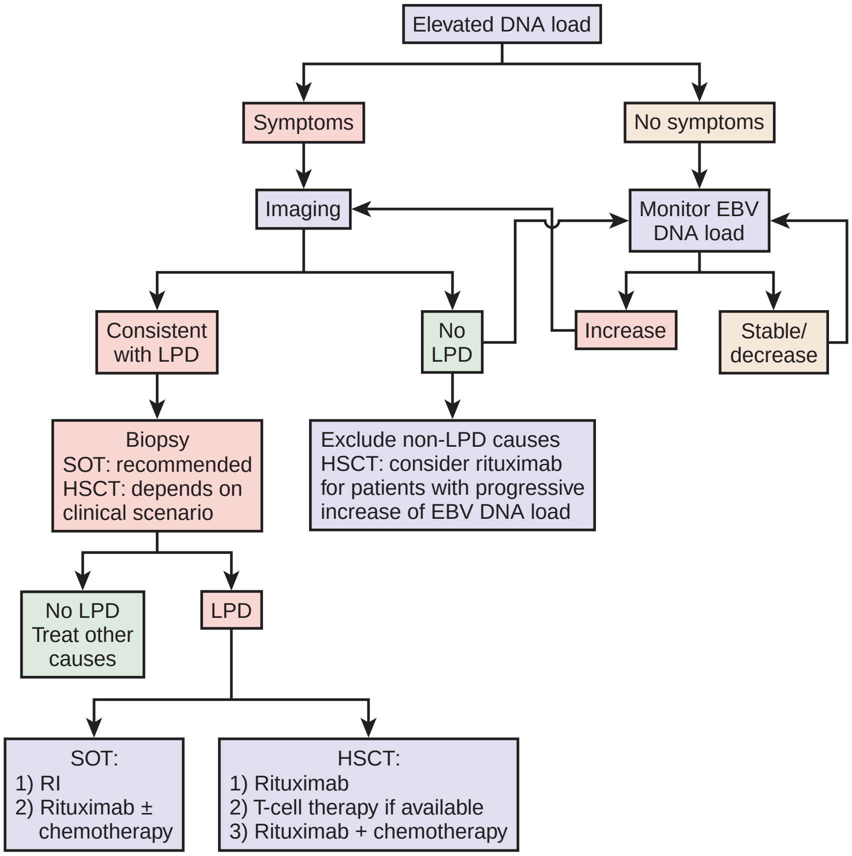

Figure 55.7 ALGORITHM FOR FOLLOWING PATIENTS WITH INCREASED EPSTEIN-BARR VIRUS (EBV)-DNA LOAD. With the caveat that many individualized factors contribute to clinical decisions, a general diagnostic and clinical approach is outlined. *HSCT*, Hematopoietic stem cell transplant; *LPD*, lymphoproliferative diseases; *RI*, reduction of immunosuppression; *SOT*, solid organ transplant.

For patients who are post allogeneic HSCT, strict monitoring of EBV viral loads is performed in the posttransplant period to monitor for viral reactivation manifest by persistent EBV viremia. For asymptomatic patients with a reassuring radiographic work-up, PTLD can essentially be ruled out and patients would be categorized as posttransplant EBV viremia. It is commonly accepted to preemptively treat HSCT recipients with rituximab, not only to prevent potential development of PTLD, but just as importantly to avoid graft failure caused by EBV reactivation.[108,109] For those patients who do develop PTLD, treatment would be similar to the approach outlined later for SOT recipients with PTLD.

Preemptive rituximab for patients post SOT with persistent EBV viremia is not a universally standard practice. Weaning of immunosuppression, when feasible, is typically the first intervention upon recognition of post-SOT EBV viremia. If it persists, there are some institutions that prefer to give preemptive rituximab with the goal of suppressing the EBV viral load. Although definitive evidence that this practice is effective in preventing PTLD is lacking, it is a widely accepted practice. For those clinicians who opt to use preemptive rituximab, it is typically based on the rationale that it is well tolerated, and any potential mitigation of risk for PTLD may have benefit, particularly if it helps to avoid future exposure to multiagent chemotherapy. Conversely, it is also evident that many patients post SOT have persistent EBV viremia and never develop PTLD. Therefore the counterargument to preemptive therapy is that patients may unnecessarily be exposed to the adverse effects of rituximab without definitive clinical benefit.

For SOT or HSCT recipients who develop PTLD, the therapeutic approach depends heavily on the underlying histology. Patients with early lesion/nondestructive PTLD are almost always EBV associated and typically improve after reduction of immunosuppression. This diagnostic entity has three morphologic variants, including IM-like, plasmacytic, and florid follicular hyperplasia. These reactive B-cell hyperplasias stain positive for EBV on histology, with only rare exceptional cases of florid follicular hyperplasia having been described as EBV negative. Typically, weaning of immune suppression, when feasible without compromising the allograft, is sufficient to restore cellular immune function enough to suppress this EBV-driven benign lymphoproliferation. However, this approach is limited by the risk for graft rejection, and it is not useful after HSCT because of the profound immunosuppression and the risk for inducing GVHD. In such cases, treatment with rituximab monotherapy is indicated and often successful in treating early lesion/nondestructive PTLD.

Polymorphic PTLD is more aggressive than early lesion PTLD; however, it is similarly responsive to reductions of immunosuppression and/or treatment with rituximab. Unlike early lesion PTLD, polymorphic disease is a destructive lymphoproliferative lesion that effaces the affected lymphoid organ tissue. It is usually EBV$^+$ and often responsive to weaning of immunosuppression. Especially in SOT patients for whom consequences of allograft rejection can be dire, it is important to balance risk of weaning immune suppression versus relative risks of rituximab monotherapy, which is generally well tolerated and effective. This is of particular importance in recipients of allografts for whom the regenerative potential is less robust and the risk of graft rejection is severe. Patients with polymorphic PTLD tend to have excellent responses to rituximab monotherapy, and their overall prognosis is favorable. In both EBV$^+$ polymorphic and early lesion PTLD, EBV viral load monitoring can be useful as a biomarker to monitor treatment response and potential for future relapse.

For patients with monomorphic PTLD, the therapeutic approach hinges on the specific underlying histology. The majority of cases of monomorphic PTLD are DLBCL histology. Occasionally, these get more generically classified as an aggressive, mature B-cell lymphoma, NOS. DLBCL PTLD is often EBV-associated but is more likely to be EBV-negative than polymorphic PTLD. The treatment approach to DLBCL PTLD is similar to that of polymorphic PTLD; however, the chance of improvement simply by weaning immunosuppression is low. Treatment approaches combining rituximab with low-dose cyclophosphamide and prednisone, or even rituximab monotherapy, have resulted in approximately 70% event-free survival.[110–114] Treatment for those patients with DLBCL PTLD who relapse or do not achieve complete remission is a bigger challenge. In such scenarios, conventional multiagent chemotherapy, radiation for localized disease, and adoptive transfer of T cells or EBV-specific T cells are all considerations. Recently, traction has gained on adoptive cellular therapies for EBV^+ PTLD, and this will be discussed in depth in the following section on immunotherapy.[113]

Finally, for those patients with non-DLBCL monomorphic disease, the treatment approach must be tailored to the specific histological diagnosis. For patients with BL PTLD (sometimes EBV^+) or HL PTLD (usually EBV^+), disease-specific multiagent chemotherapy is indicated. On rare occasion, peripheral T-cell lymphomas or plasma cell neoplasms present as monomorphic PTLD. These histologies are less frequently EBV^+ and also require disease-specific treatment plans. The aforementioned strategy of rituximab monotherapy or rituximab with low-dose chemotherapy will not be successful for these non-DLBCL monomorphic PTLD diagnoses.[112–114]

Epstein-Barr Virus–Associated Non-Hodgkin Lymphoma in Human Immunodeficiency Virus Patients

Patients infected with HIV are at high risk to develop NHL. The incidence increases with age, and the male-to-female ratio is approximately 2:1. Depending on specific histologies, the EBV association ranges from 30% in systemic HIV-related BL, to 70% to 80% in HIV-related DLBCL, and virtually all cases of HIV-related PCNSL are EBV-positive.[115] In biopsies of EBV-associated HIV-NHL, there is considerable variation in the number of EBV-positive cells, and the pattern of EBV latent gene expression varies among tumor types as in immunocompetent individuals (see Fig. 55.5E and F). As discussed in the section on EBV-associated B-cell lymphomas, other specific diagnoses that are more prominent in HIV-infected patients include PEL and plasmablastic lymphoma. In addition, HL is EBV-positive in upwards of 80% of HIV-related cases.[115]

In HIV-infected patients, the development of EBV-associated HIV-NHL is preceded by a loss of functional EBV-specific T cells, suggesting that strategies to boost the endogenous EBV-specific T-cell response might prevent lymphomas. Additional factors known to predispose HIV-infected patients to EBV-associated lymphomas include underlying cytokine dysregulation and proinflammatory state.[115] Restoring $CD4^+$ T-cell counts in patients with HIV with highly active antiretroviral therapy (ART) has decreased the incidence of PCNSL and HIV-related DLBCL.[116] The incidence of HIV-related BL, which tends to occur in patients with higher CD4 counts and with less HIV viremia, has remained stable over time despite improved access to ART.[116]

Oral hairy leukoplakia (OHL) develops frequently, although not exclusively, in patients who are HIV-positive. It is a non-malignant hyperplasia of epithelial cells, and most patients present with white, corrugated lesions on the tongue. Besides IM, OHL is the only EBV-associated disease in which active viral replication is apparent, and multiple strains are often present within the same lesion. Inhibiting EBV replication in vivo with antivirals such as valacyclovir results in resolution of OHL. However, after valacyclovir treatment, EBV replication recurs in normal tongue epithelial cells, indicating that productive EBV replication is necessary but not sufficient to induce OHL.[25,117]

IMMUNOTHERAPY FOR EPSTEIN-BARR VIRUS–ASSOCIATED NEOPLASMS

Monoclonal Antibody Therapy for Lymphoproliferative Disease

The CD20 monoclonal antibody rituximab is currently widely used as prophylaxis and as therapy for EBV-LPD. A comprehensive review of the literature that included articles and abstracts published between 1999 and 2008 reported that the use of rituximab as preemptive therapy prevented the development of EBV-LPD in 90% of 341 HSCT recipients, whereas therapy was associated with a response rate of 63% in 126 HSCT patients.[108,109] However, response rates varied widely, likely reflecting heterogeneity in patient populations and the fact that early diagnosis and treatment lead to better outcomes. For EBV-LPD after SOT, a recent multicenter analysis of 80 patients reported that rituximab-based therapy had a 3-year progression-free survival of 70% compared with 21% for patients treated without rituximab.[3] Half of the patients treated with rituximab also received chemotherapy, most of them having bulky disease and a high International Prognostic Index. A recent prospective multicenter study suggests that sequential therapy of rituximab followed by chemotherapy results in excellent disease control and overall survival. However, at present it remains unclear for which group of patients rituximab monotherapy is sufficient. Retrospective studies have identified risk factors including extra-lymphatic disease, high LDH, low albumin, and poor performance status, but these risk factors need to be validated in prospective studies.[118] Rituximab has led to a dramatic improvement in outcome of EBV-LPD but does not restore the cellular immune response to EBV, which may be crucial for the long-term control of EBV-mediated B-cell proliferation. EBV-infected B cells may therefore increase with B-cell recovery, and EBV-LPD may recur. Although rare, the recurrence of CD20-negative lymphomas with the use of rituximab has been reported. Patients who fail to respond to chemoimmunotherapy strategies may respond to high-dose chemotherapy followed by autologous HSCT or adoptive T-cell therapies.

Epstein-Barr Virus–Directed T-Cell Therapies

Donor lymphocyte infusions were first used to treat post-HSCT EBV-LPD over 30 years ago.[119,120] Although clinical responses were observed in the vast majority of patients treated, the risk of acute GVHD posed by these nonspecific T cells made this an untenable option.[121,122] Ex vivo–manufactured polyclonal EBV-specific T cells (EBVSTs) have emerged as a cellular therapeutic strategy able to treat EBV lymphoproliferation while reducing the risk of GVHD.[123] Initially, HSCT donor–derived EBVSTs were generated ex vivo by repeated stimulation with autologous LCLs. Clinical studies in HSCT recipients have shown that these EBVSTs are safe, do not cause significant GVHD, reconstitute EBV-specific cellular immunity, and are effective as prophylaxis *and* therapy for EBV-LPD.[4,5,124] In SOT recipients who develop EBV-LPD, donor-derived T cells are of limited value because the tumor almost always arises in recipient B cells, and donor T cells are unlikely to survive in the recipient's hematopoietic system.

Although donor-derived EBVSTs have potent clinical activity in EBV-LPD, their generation using LCLs as antigen-presenting cells (APCs) is a lengthy process, requiring a minimum of 6 to 8 weeks to first establish autologous LCLs, then at least 4 weeks for T-cell expansion, followed by 2 weeks for quality testing. Thus several groups have developed strategies to rapidly select or generate EBVSTs.[125–128] Rapid selection strategies rely on the use of HLA-peptide multimers or streptamers, or mechanisms such as IFN-α capture, in which T cells that secrete IFN-α in response to antigen stimulation are selected.[127,129] Although these selection procedures require limited (<48 hours) ex vivo culture, they require substantial amounts of donor blood to generate a clinical product; thus leukopheresis is sometimes required. In addition, HLA-peptide multimer or streptamer selection requires knowledge of a particular epitope and is restricted to the selection of CD8$^+$ T cells. Our group has therefore focused on rapid expansion protocols in which we have replaced LCLs with APCs stimulated with overlapping peptide libraries (pepmixes) spanning the protein sequence of selected viral antigens to stimulate and expand EBVSTs in the presence of cytokines. Resulting cell lines are polyclonal and contain CD4$^+$ and CD8$^+$ T cells recognizing MHC class I as well as class II restricted viral antigens. This “rapid pepmix” method has shortened EBVST manufacture to as few as 10 days and is now widely used in clinical trials, with promising results. More recently, generation of EBVSTs as part of multivirus-specific T-cell products using the rapid pepmix method has been effective in treating patients with EBV-LPD or EBV viremia in the post-HSCT setting.[130]

Adoptive Immunotherapy for Epstein-Barr Virus$^+$ Lymphomas in Immunocompetent Individuals

In contrast to EBV-LPD, only a limited number of EBV-derived antigens (EBNA1, LMP1, and LMP2) are present in EBV-positive HL and NHL. Initial studies with patient-derived, LCL-generated EBVSTs demonstrated their safety, but infused T cells had limited antitumor activity against HL and NHL in comparison with EBV-LPD.[131] This lack of efficacy was postulated to be due in part to immunosuppressive factors secreted by lymphoma cells (leading to T-cell anergy) or dominance of clones reactive to viral proteins not expressed in latency type II lymphoma. In an effort to improve T-cell efficacy, we generated patient-derived T cells specific for EBV proteins LMP1 and LMP2 expressed in latency type II lymphoma using LCLs as APCs and recombinant adenovirus vectors encoding LMP1 and LMP2. Although these EBVSTs homed to tumor sites and some patients experienced transient clinical benefit, only a small percentage of these T cells were specific for the type II latency antigens.[132]

Clinical studies with LMP1/2 (LMP)-specific T cells demonstrate efficacy in patients with EBV-positive HL and NHL.[133,134] One trial targeted LMP2 alone and the subsequent LMP1 and LMP2. Combined with a follow-up study, 50 patients received LMP-specific T cells. Of 29 patients who received these cells as adjuvant therapy, 28 remained in remission for a median of 3.1 years. Thirteen out of 21 patients infused with active disease had objective clinical responses, with 11 patients being complete. Although LMP-specific T cells had clinical activity, generation required not only LCLs but also recombinant adenovirus vectors encoding LMP1 and LMP2, which was lengthy and added regulatory complexity. This strategy has been extended to donor-derived EBVSTs with promising results.[102] More recent clinical trials have used the rapid pepmix method to specifically target type II latency proteins using overlapping peptide libraries and cytokine stimulation (NCT01555892; NCT02287311).

Immediately Available “Off-the-Shelf” Epstein-Barr Virus–Specific T-Cell Options

Despite the clinical responses observed with use of stem cell donor-derived EBVSTs as treatment for EBV LPD, there are several limitations to this approach. For one, this treatment is restricted to patients in the post-HSCT setting with available and willing EBV-seropositive donors. In addition, even when using rapid methods, the shortened manufacture time frame is still too long for patients with fulminant, aggressive disease. In an effort to create an immediately available EBVST product that can be used in patients with post-HSCT or post-SOT EBV LPD as well as in pretransplant immunocompetent patients, several groups, including ours, have created healthy donor-derived third-party EBVST banks.[135] These cryopreserved “off-the-shelf” banks of EBVSTs are generated from the peripheral blood of blood-bank eligible healthy EBV-seropositive donors and can be manufactured using a variety of techniques. Importantly, third-party banks allow selection of donors with highest in vitro EBV antigen-specific activity (thus predicted to have greatest clinical activity) as well as selection of the EBVST product with highest degree of HLA match with confirmed HLA-restricted cytotoxicity through shared HLA alleles with the recipient, which corresponds with clinical response. To date, banks with as few as 25 EBVST lines have been able to cover the majority (>90%) of referred patients.[136–139]

To date, third-party or “off-the-shelf” EBVSTs have been administered to patients with EBV LPD in the post-HSCT, post-SOT, and pretransplant settings. Importantly, no reports of de novo acute or chronic GVHD or flares of preexisting GVHD have occurred (likely related to the manufacturing processes which reduce alloreactive T cells and the limited persistence of these partially HLA-matched allogeneic EBVSTs). Banked EBVSTs have also shown remarkable clinical responses and possess the potential for use as a preemptive strategy in patients with EBV viremia prior to development of overt LPD or PTLD. Larger trials of third-party EBVSTs continue, and ongoing research is aimed at enhancing persistence of these allogeneic cells as well as incorporating them earlier into therapy.[140] Lastly, combination strategies combining adoptive transfer of EBVSTs with immune checkpoint blockade such as PD-1/PD-L1 (programmed death 1/programmed death ligand 1) inhibition are currently being explored.[141]

OTHER EPSTEIN-BARR VIRUS–ASSOCIATED DISEASES

Nasopharyngeal Carcinoma

NPC arises from the epithelial cells of the nasopharynx. The WHO classifies NPC into keratinizing squamous cell carcinoma (type 1), nonkeratinizing carcinoma (type 2), and undifferentiated carcinoma (type 3, most common). Type 2 and 3 carcinomas are associated with EBV (see Fig. 55.6D and E); however, environmental and genetic factors play an important role in oncogenesis, because the incidence of NPC varies 50- to 100-fold from Southern China to Western countries. EBV was initially linked to NPC by the observation that patients had elevated levels of VCA-IgG, VCA-IgA, and EA-IgG antibodies. Further studies showed that EBV-DNA is present in every tumor cell of type 2 and 3 carcinomas with remarkable consistency. As in HL, the EBV episome in an individual tumor is clonal.

EBV antibody responses have been used to follow tumor burden in patients with NPC; in addition, VCA-IgA antibodies and antibodies against EBV DNase are predictive for NPC in high-risk populations. More recently, detection of EBV-DNA in serum by different PCR methods has shown to be useful for the diagnosis, prognosis, and monitoring of patients with NPC. Most patients with NPC are treated with radiation with or without chemotherapy. Other modalities such as surgery and combined approaches may be appropriate in selected circumstances, but a detailed discussion is beyond the scope of this chapter. In NPC, as for EBV-positive lymphomas, only a limited number of EBV latent antigens are expressed. Therapeutic vaccine studies targeting LMP2, LMP1, and LMP2, or EBNA1 and LMP2 have been conducted, and the results of these trials were discussed in the earlier section EBV Vaccine Development.

The adoptive transfer of autologous EBV-specific T cells has shown promise for NPC, using manufacture strategies similar to those mentioned in previous section. Several groups have reported that the infusion of T cells is safe and has resulted in clinical responses, especially in patients with loco-regional disease. In addition, EBV-specific T cells, given as adjuvant after chemotherapy, resulted in a significant increase in 3-year overall survival in comparison with historical controls, who only received chemotherapy.[142] A pivotal, randomized clinical study to validate these findings is in progress.

Multiple Sclerosis

Multiple sclerosis (MS) is a rare inflammatory demyelinating disease of the CNS. MS is triggered by a combination of genetic as well as environmental factors. The role of EBV in the pathogenesis of MS has been studied for the past 30 years.[143] Although the vast majority of

EBV-seropositive individuals do not develop MS, thereby questioning an association with EBV, the incidence of EBV seropositivity is higher in MS patients than healthy controls. In addition, individuals who have IM as their clinical presentation of primary EBV infection have a higher incidence of MS. Lastly, increased or decreased cellular immune responses to EBV antigens have been reported in MS patients. If this dysregulation of EBV-specific cellular immune responses contributes to the pathogenesis of MS is the subject of active investigation. Based on findings from these studies, EBV-targeted approaches might be explored in the future.

FUTURE DIRECTIONS

Since its discovery in 1964, EBV has been linked to a heterogeneous group of diseases. EBV was the first human virus implicated in oncogenesis, and the biology of the virus has been studied extensively on a cellular and molecular level. Over the past two decades immunotherapeutic approaches targeting EBV have been developed for EBV-associated malignancies, and later-phase clinical studies are currently in progress. Although adoptive transfer of T cells so far has been more successful than vaccines, novel, more potent vaccines have been developed that await testing in humans. Combinatorial therapies, for example combining EBV-targeted immunotherapy with antibodies that block immune checkpoints, are currently being evaluated in clinical studies and hold the promise to improve outcomes. Lastly, whole-exome sequencing will continue to identify genes that are associated with life-threatening complications of EBV infections, providing clues into their pathogenesis and novel therapeutic interventions. There is much potential to leverage EBV as a diagnostic, prognostic, and therapeutic biomarker in EBV-associated lymphoproliferative disorders and lymphomas, and current translational and clinical research appear poised to improve outcomes for patients.

PART VII HEMATOLOGIC MALIGNANCIES

CHAPTER 56

PROGRESS IN THE CLASSIFICATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS: CLINICAL IMPLICATIONS

Mohamed E. Salama and Ronald Hoffman

Defining and classifying tumors of the hematopoietic and lymphoid tissue accurately is critical for providing optimal treatment to patients with hematologic malignancies. Explicit definitions and terminologies are prerequisites for the precise classification of hematologic malignancies. A reproducible classification that is based on consensus definitions and terminologies is fundamentally essential for proper medical practice and the advancement of medical knowledge. Generally, such classifications should be based upon clinically distinct disease entities that can be grouped together based on shared distinguishable clinical features, as well as phenotypic and molecular markers which allow for reproducible laboratory testing, clinical outcomes, and responses to therapeutic agents. Traditionally, preliminary attempts at disease classification were initiated by the personal experience of experts, and then evolved after many years or even decades of controversy and exhaustive debate. Subsequently, classification schemes change when new scientific discoveries are validated.

Following many years of controversy, a collaborative project of members of the European Association for Haematopathology and the Society for Hematopathology, along with advice from clinical hematologists and oncologists, resulted in the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues.[1,2] This WHO classification, which is the first true worldwide consensus classification of hematologic malignancies, is based on the principles initially defined in the "Revised European-American Classification of Lymphoid Neoplasms" (REAL) from the International Lymphoma Study Group (ILSG).[3] The most recent WHO classification (4th edition) was formulated in a series of meetings by two clinically advisory committees: one for myeloid neoplasms, and another for acute leukemias and lymphoid neoplasms.[4] The current WHO classification, which addresses new developments related to disease definitions, nomenclature, grading, and clinical relevance, provides the basis for an approach to hematopoietic and lymphoid neoplasm classification that employs clinical features, morphology, immune phenotype, and genetic features to define diseases.[4] The relative importance of each of these components varies among diseases and is dependent on the current state of knowledge. This process of classification is an ever changing process which evolves upon new scientific and clinical advances. These classifications should be used as ever changing tools, not as groupings of disease entities that are fixed in academic concrete. Morphologic assessment remains a key element of the diagnostic evaluation and classification of hematologic malignancies, as many diseases have characteristic diagnostic features. Morphologic evaluation also remains a decisive step for prioritization of ancillary testing choices that may include phenotyping, as well as molecular or genetic testing. Immunophenotypic studies such as flow cytometry and immunohistochemistry (IHC) are used routinely to identify the lineage of the benign or malignant process, and often are necessary to reach a definitive diagnosis. In several lymphoid and myeloid neoplasms, a specific diagnosis can be facilitated by using genetic or molecular abnormalities (e.g., *CCND1* in suspected mantle cell lymphoma [MCL] or *BCR/ABL* for chronic myeloid leukemia [CML]). In addition, some abnormalities can serve as prognostic markers in several diseases (e.g., *TP53 deletion or mutation*). However, many entities still lack defining genetic or molecular abnormalities.

In some conditions, rendering an accurate diagnosis requires knowledge of the patient's clinical features, such as age and prior therapy, as well as the anatomic site and/or extent of disease. Although most of the disease entities described in the WHO classification represent distinct entities, some categories are not as clearly defined and are regarded as provisional entities. In addition, borderline categories have been created for cases that do not clearly fit into one category; thus well-defined categories can remain homogeneous while borderline cases require further study and characterization. Furthermore, the WHO classification stratifies hematologic neoplasms according to lineage into three main groups: myeloid, lymphoid, and histiocytic/dendritic cells. In this chapter we provide a summary of neoplasms in these three groups, emphasizing changes that have had an effect on practice guidelines along with highlights to significant findings that have been identified in these entities since the publication of the most recent WHO classification in 2016.

PROGRESS IN THE DIAGNOSIS AND CLASSIFICATION OF MYELOID NEOPLASMS

Clinical Implications

The myeloid neoplasms are a heterogeneous group of diseases. In general terms, they are clonal hematopoietic malignancies that can arise in or affect a single myeloid lineage (e.g., monocytic). Alternatively, they can be derived from a pluripotent stem cell and can affect multiple or even all myeloid cell types (erythroid, megakaryocytic, monocytic, neutrophilic, basophilic, eosinophilic, and mast cells). The myeloid neoplasms include chronic and acute diseases, along with diseases that evolve from an indolent process to a more aggressive state. As such, they can manifest as proliferative disorders, mostly involving primary mature hematopoietic elements; they can predominately affect immature or blastic cells; or sometimes they can be a combination of these two cell types. The diseases can result in excess production of blood cells, or they can proliferate in the bone marrow (BM) and exhibit ineffective hematopoiesis, resulting in peripheral cytopenias. Because the diseases range from indolent to acute, they exhibit a wide variation in prognosis. Some disorders are fairly indolent and require only supportive care and transfusional support; others slowly progress but have no successful treatment option. Acute and life-threatening disorders are often curable, even within days or weeks after presentation, if appropriately managed. Accurate, timely diagnosis and correct classification has a tremendous impact on patient outcomes. Treatment of a particular hematological malignancy should only proceed once the nature of the blood cancer is known, which allows for the selection of rational choices of treatment options.

The diagnosis of the myeloid neoplasms typically requires a multifaceted team approach that relies on cooperation among the clinician, laboratory personnel, and a skilled pathologist. The precise diagnosis requires compiling accurate historical data, clinical information, general laboratory findings, and carefully interpreted observations from the peripheral blood smear, bone core biopsy, and aspirate, merged with information gained from immunophenotyping, cytogenetic analysis, and molecular analyses (Table 56.1). Although in some cases a diagnosis can be made with a quick examination of the blood smear, with a single molecular test, or with a simple immunophenotype, in general, careful assessment of the total clinical picture provides the most accurate and clinically relevant diagnosis. Future routine diagnostic modalities may include next-generation sequencing, single-nucleotide polymorphism array karyotyping, gene expression arrays, and genome-wide epigenetic studies.

The myeloid neoplasms are grouped as different categories of diseases. These categories seem to be changing constantly, both in name and in the components of the disorders. However, refinements have led to an increased understanding of the clinical, pathologic, and genetic basis of the diseases and ultimately serve, or at least strive to, improve diagnosis, treatment, and outcome. The current classification of myeloid neoplasms includes the categories of myeloproliferative neoplasms (MPNs), acute myeloid leukemias (AMLs), myelodysplastic syndromes (MDS), and MDS/MPNs, which is a category with features that are intermediate between MDS and MPN (Table 56.2). This generally accepted classification system was derived from a number of earlier classification systems[5] and represents the working system of the WHO as of 2008.[4,6] The recent 2016 update of the WHO classification is based on the additional information gained from molecular testing modalities that further impact the classification and categorization of these neoplasms.[7,8]

TABLE 56.1 Components in the Routine Clinical Evaluation of Myeloid Malignancies

Current

- Accurate clinical history, including family history and physical examination findings
- General laboratory findings, including CBC, and other specific tests (e.g., EPO) when appropriate
- Evaluation of well-prepared and stained peripheral blood smear with 200 cell differential count
- Review of BM aspirate, including iron stain, and 500 cell differential count
- Evaluation of H&E sections of BM biopsy of sufficient length and reticulin stain
- Phenotyping studies, including cytochemical reactions (nonspecific and specific esterase reactions and myeloperoxidase) and flow cytometric analysis of peripheral blood or BM for phenotype of blasts or other cells when appropriate
- Cytogenetic analysis, including karyotype, and FISH for specific abnormalities when appropriate
- Single-nucleotide polymorphism array karyotyping
- Genetic analysis for particular genetic rearrangements or mutations, including gene sequencing when appropriate
- Next-generation sequencing

Potential Future Clinical Studies

- Gene expression arrays,
- RNA, sequencing
- Genome-wide epigenetic studies

BM, Bone marrow; *CBC*, complete blood count; *EPO*, erythropoietin; *FISH*, fluorescence in situ hybridization; *H&E*, hematoxylin and eosin.

TABLE 56.2 World Health Organization Classification of Myeloid Neoplasms

The myeloproliferative neoplasms (MPNs), including the myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, and *FGFRA*

Acute myeloid leukemia (AML)

The myelodysplastic syndromes (MDS)

The MDS/MPN ("overlap") syndromes

AML, Acute myelogenous leukemia; *MDS*, myelodysplastic syndromes; *MPN*, myeloproliferative neoplasm.

The Myeloproliferative Neoplasms

The MPNs, formerly referred to as *myeloproliferative disorders* (see Chapters 69–74), are a group of clonal multipotential hematopoietic stem cell disorders that have a proliferative nature, presenting frequently with hypercellular BMs, and an elevation of one or more myeloid cell types in the blood. The MPNs are insidious in onset and chronic in course but have a variable tendency to terminate in BM failure or acute leukemia.[9] The MPNs include CML (Table 56.3), which illustrates how the elucidation of pathways involved in the molecular pathogenesis (i.e., dysregulation of *ABL1* tyrosine kinase [TK] signaling) can successfully lead to the rational targeted therapy (i.e., imatinib and other TK inhibitors).[10]

The MPNs also include *BCR-ABL1*–negative entities, essential thrombocythemia (ET), polycythemia vera (PV), and primary myelofibrosis (MF) (see Chapters 70–72). These MPNs share common features, including multipotential hematopoietic stem cell origin, clonal proliferation, and chronic nature. Although these disorders seem to be distinctive, they can present a diagnostic challenge, and they can have subtle and overlapping presentations. Recent discoveries in the underlying molecular pathology of these entities have demonstrated that, similar to CML and eosinophilic disorders, they too share TK

TABLE 56.3 Tyrosine Kinase Involvement in Myeloproliferative Neoplasms

Disease	Tyrosine Kinase Involvement
Chronic myeloid leukemia, *BCR-ABL1+*	*ABL1* (100%)
Myeloid and lymphoid neoplasms with eosinophilia TK abnormalities	*PDGFRA, PDGFRB*, or *FGFRA*
Polycythemia vera	*JAK2* V617F (≈95%), *JAK* exon 12 (≈4%)
Primary myelofibrosis	*JAK2* V6174 (≈50%), *MPL* W515 K/L (5%–9%), *CALR* (35%)
Essential thrombocythemia	*JAK2* V617F (≈50%), *MPL* W515 K/L (≈1%), *CALR* (35%)
Chronic neutrophilic leukemia	*CSF3R* (83%–90%)
Chronic eosinophilic leukemia, not otherwise specified	—
Mastocytosis	*KIT* D816V (≈95%)
MPN, unclassified	—

MPN, Myeloproliferative neoplasm; *TK*, tyrosine kinase.

signaling dysregulation, at least to some degree. This is attributable to an associated mutation in the TK, *JAK2* (*JAK2* V617F), which is present in about 50% to 95% of cases of Ph-negative MPNs. Variants of *JAK2* mutations involving exon 12 are also observed in 2% to 3% of PV patients. This association has led to significant revisions in the 2008 WHO criteria for diagnosis, but it also has raised questions as to how a single mutation can be associated with such heterogeneous phenotypic characteristics. Proposed revisions in 2016 WHO classifications for the diagnosis of the Ph-negative MPNs include suggested modifications of lower hemoglobin thresholds for PV. BM biopsy results and the presence of *JAK2* mutations now represents a major criterion. A subnormal erythropoietin level became a minor criterion, and the endogenous erythroid colony assay is no longer included in the current WHO diagnostic criteria for MPNs.[11] These changes are intended to capture patients with subtle presentations, such as those with masked PV. Experts also have recommended inclusion of mutations in calreticulin (*CLAR*) and the thrombopoietin receptor, MPL, which is identified in 20% to 30% of ET and MF cases, as well as the colony-stimulating factor 3 receptor mutations in the next revision.[11–13]

All three (*JAK2*, *CLAR*, and *MPL*) driver mutations are negative in approximately 10% of cases (so-called "triple negative" [TN] cases). In these TN cases, the non-clonal differential diagnostic considerations pose significant diagnostic challenges. As such large-scale next generation sequencing is increasingly being used to establish not only the clonal nature of the disease, but also to guide molecular risk stratification and management decisions, including clinical trial selection for these patients when evaluated for MF.

JAK2 V617F inhibitors are among several agents in use to treat patients with MPNs. In 2011 the US Food and Drug Administration (FDA) approved ruxolitinib for the treatment of patients with intermediate or high-risk MF. Subsequently, the FDA also designated ruxolitinib as an orphan product, as it demonstrated potentially significant improvement in safety and efficacy over other available therapies for PV. A number of ruxolitinib-based combination therapies, as well as novel agents that target various pathways, are currently being investigated and will be further discussed in detail later (see Chapters 70–72).

Chronic neutrophilic leukemia (CNL) (see Chapter 72) and mast cell disease (see Chapter 75) are currently included in the category of MPNs. CNL is now better defined with the integration of *CSF3R* mutation as a diagnostic tool, and is distinct from atypical CML.[14]

Mast cell disease is yet another disease related to abnormal TK signaling—in this case, the *KIT* gene.[15] Its classification system generally considers systemic mastocytosis and cutaneous mastocytosis as main entities but also includes a mast cell proliferation associated with clonal non-mast cell hematopoietic malignancies; this can be another myeloid malignancy or, less commonly, a lymphoid malignancy. With the advances of comprehensive mutational profiling, it is proposed that additional mutations in *SRSF2*, *ASXL1*, and/or *RUNX1* identify a high-risk group of patients with *KIT* D816V^{+} advanced systemic mastocytosis.[16] A more recently improved understanding of the cellular and molecular basis of eosinophilic disorders has translated into more biologically oriented classification schemes that carry therapeutic implications. Thus, in 2008, the WHO established a semi-molecular classification scheme of separately listed disease subgroups including "myeloid and lymphoid neoplasms with eosinophilia and abnormalities of platelet-derived growth factor receptors (PDGFRA, PDGFRB), or fibroblast growth factor receptor 1(FGFR1)," chronic eosinophilic leukemia (CEL), not otherwise specified (NOS), lymphocyte-variant hypereosinophilia, and idiopathic hypereosinophilic syndrome (see Chapter 74). Although quite uncommon, these are noteworthy because, similar to CML, they have also been found to be caused by dysregulation of TK signaling (caused by mutations in *PDGFRA*, *PDGFRB*, or *FGFRA*) and at least partially successfully treated with TK inhibitors.[17]

It is important to emphasize that the modern diagnosis of the MPNs does not rest solely with the routine microscopic examination. The diagnostic work-up is more far-reaching and must include reviewing the clinical history and pertinent physical findings, as well as obtaining and assessing laboratory values, including recent complete blood cell counts. Examination of a well-prepared peripheral blood smear and both BM aspirate and biopsy specimens are still crucial. However, ancillary studies, such as cytogenetic and molecular analysis, as well as other more specific laboratory evaluations, are just as important in formulating the correct diagnosis, and in particular, in distinguishing MPNs from reactive myeloid proliferations. This is particularly true, for example, regarding the MPN driver mutations, and the impact not only on deciding the diagnosis but also on the prognosis and treatment of MPN patients.

Acute Myeloid Leukemia

The historical and emerging classifications systems for AML dramatically illustrate the marked heterogeneity of these diseases (see Chapters 59 and 60). Despite this heterogeneity, however, to date a major breakthrough has not been made in the development of specific initial treatment for AML as an entity apart from acute promyelocytic leukemia. However, to a large extent this concept is changing as newer agents targeting molecularly or genetically defined forms of AML have become available (e.g., FMS-like tyrosine kinase-3 [FLT3] inhibitors for FLT3-mutated cases).[18,19] It is anticipated that the gap between the growing number of unique or genetically defined acute leukemia types and the somewhat limited treatment options may begin to close.

The French–American–British (FAB) classification of AML, introduced in 1976 with its subsequent revision in 1985, provided the first real framework for classifying the AMLs. It also provided fairly reproducible definitions of diseases. The classification was mainly based on morphologic and cytochemical features of the leukemic blasts in the BM. In general, the FAB scheme required that 30% of the BM-nucleated elements be blasts; then, it further defined AML subtypes based on the presence of maturation in the granulocytic series, the presence of a monocytic component, and the presence of an erythroid component. Later, as immunophenotyping allowed for improved identification of myeloid precursors, acute megakaryoblastic leukemia and AML with minimal differentiation were added. The types of AML noted in the revised FAB scheme included one with minimal differentiation (M0), AML without maturation (M1), AML with maturation (M2), and acute promyelocytic leukemia (M3). Also included was a type with combined monocytic and myeloid (neutrophilic) components (M4), a pure monocytic or monoblastic type (M5A, M5B), a type with a prominent erythroid component (M6), and a megakaryoblastic type (M7) (Table 56.4).

The FAB classification provided a framework and defined criteria for different types of acute leukemia. However, leukemia-associated genetic changes, first recognized in the 1980s, seemed to provide more important prognostic information and did not always correlate well with the FAB-defined entities. As the cytogenetic abnormalities became more widely appreciated and their prognostic implications better understood, classification schemes based solely on the "favorable," "intermediate," and "adverse" prognostic cytogenetic findings were introduced and used along with, or as an alternative to, the FAB scheme (see Table 56.4).

The AML WHO classification published in 2001 provided a different strategy from that used by the FAB in two important ways: it redefined AML as requiring only 20% blasts in the BM or blood, and it emphasized the importance of the associated cytogenetic abnormalities. The change in blast percentage came from the recognition that patients with 20% to 30% blasts, who previously were classified as having MDS (refractory anemia [RA] with excess of blasts in transformation [RAEB-T] in the FAB MDS classification), often had outcomes similar to those with AML and frequently required treatment as if they had been diagnosed with AML. Furthermore, the inclusion of karyotypic abnormalities recognized the important prognostic information associated with these abnormalities, as well as the fact that a karyotypic abnormality could point to the underlying molecular pathogenesis. As we learned from our experience with CML, this was critical in developing new drugs and treatment strategies.

TABLE 56.4 **Classification Schemes for the Acute Myeloid Leukemias**

French–American–British (FAB, 1985)	Cytogenetic	WHO (2001)	WHO (2008)	WHO (2016)
M0: AML with minimal differentiation	**Favorable**	**Genetic**	**With recurrent genetic abnormalities**	**With recurrent genetic abnormalities**
M1: AML without maturation	t(8;21)	t(8;21)	With t(8;21)(q22;q22)	AML with t (8;21)(q22;q22.1);RUNX1-RUNX1T1
M2: AML with maturation	inv(16)/t(16;16)	t(inv(16)/t(16;16)	With inv(16)/t(16;16)(p13.1;q22)	AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22);CBFB-MYH11
M3: APL	t(15;17)	t(15;17)	With t(15;17)(q22;q12)	APL with PML-RARA
M3v: microgranular variant	**Intermediate**	t(v;11q23)	With t(9;11)(p22;q23)	AML with t(9;11)(p21.3;q23.3);MLLT3-KMT2A
M4: AMML	Normal	**AML with dysplasia therapy–related AML**	With t(6;9)(p23;q34)	AML with t(6;9)(p23;q34.1);DEK-NUP214
M4eo: AMML with abnormal eosinophils	+8	Etoposide	With inv(3)/t(3;3)(q21;q26.2)	AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); GATA2, MECOM
	t(v;11q23)	Cytotoxic or radiation	With t(1;22)(p13;q13)	AML (megakaryoblastic) with t(1;22)(p13.3;q13.3);RBM15-MKL1
M5A: acute monoblastic leukemia	del(7q)	**Not otherwise specified**	With mutated NPM1 (provisional)	Provisional entity: AML with BCR-ABL1
M5B: acute monocytic Leukemia	+21	With minimal differentiation	With mutated CEBPA (provisional)	AML with mutated NPM1
M6: erythroleukemia	+22	Without maturation	**With myelodysplasia related changes**	AML with biallelic mutations of CEBPA
M7: acute megakaryoblastic leukemia	Other	With maturation	Previous history of MDS	Provisional entity: AML with mutated RUNX1
	Adverse	Myelomonocytic leukemia	Multilineage dysplasia	**AML with myelodysplasia-related changes**
	del(5q)	Monoblastic leukemia	MDS-related cytogenetic abnormalities	**Therapy-related myeloid neoplasms**
	−5	Monocytic leukemia	**Therapy-related myeloid neoplasms**	**AML, NOS**
	−7	Erythroleukemia	t-AML/t-MDS (t-MN)	AML with minimal differentiation
	Complex	Erythroid myeloid type	**Not otherwise specified**	AML without maturation
	abn (3q)	Pure erythroid	With minimal differentiation	AML with maturation
		Megakaryoblastic	Without maturation	Acute myelomonocytic leukemia
			With maturation	Acute monoblastic/monocytic leukemia
			Myelomonocytic leukemia	Pure erythroid leukemia
			Monoblastic leukemia	Acute megakaryoblastic leukemia
			Monocytic leukemia	Acute basophilic leukemia
			Erythroleukemia	Acute panmyelosis with myelofibrosis
			Erythroid myeloid type	**Myeloid sarcoma**
			Pure erythroid	**Myeloid proliferations related to Down syndrome**
			Acute megakaryoblastic leukemia	Transient abnormal myelopoiesis (TAM)
			Acute basophilic leukemia	Myeloid leukemia associated with Down syndrome
			Acute panmyelosis with myelofibrosis	
			Myeloid sarcoma	
			Myeloid leukemia associated with Down syndrome	
			Blastic plasmacytoid dendritic cell tumor	

AML, Acute myeloid leukemia; *AMML*, acute myelomonocytic leukemia; *APL*, acute promyelocytic leukemia; *WHO*, World Health Organization.

However, the WHO classification recognized that not all acute leukemias could be defined by cytogenetic abnormalities and that some needed to be defined either clinically or still based on morphologic findings. In this regard, the 2001 classification recognized four major subclasses of AML: AML with recurring cytogenetic abnormalities; therapy-related AML (subclassified further as those following etoposide treatment and those with a history of cytotoxic drug therapy or radiation); AML with multilineage dysplasia; and cases that did not fit into the other subclasses were referred to as AML not otherwise categorized (see Table 56.4).

A 2008 revision of the 2001 classification scheme emphasized risk-based stratification and made a number of changes (see Table 56.4).[4] In particular, it expanded the cytogenetic abnormality-associated cases to those with some less common translocations. It added provisional entities defined by mutations often occurring in cytogenetically normal cases, namely those with *NPM1* and *CEBPA* mutations. It combined the different types of therapy-related MDS/AML and renamed this category *therapy-related myeloid neoplasm* (t-MN). It also redefined the dysplasia-associated cases by allowing the cases to be identified by history (of previous MDS), morphology (with multilineage dysplasia), or by cytogenetics (with defined chromosomal changes associated with dysplasia). Additional categories were also added, including AML associated with Down syndrome, acute panmyelosis with MF, granulocytic sarcoma, and blastic plasmacytoid dendritic cell tumor (see Chapter 64). The 2008 classification eventually defined more than 25 different types of AML. The advent of newer technologies, such as single-nucleotide polymorphism array karyotyping and next-generation sequencing, facilitated the recognition of several relevant driver mutations.[20] Molecular analysis for leukemic driver mutations, particularly in the cytogenetically normal AML subgroup (40% to 50% of AML patients), has been incorporated into routine clinical practice to assess disease progression and prognosis. Important mutations involve *FLT3*, *NPM1*, *KIT*, *CEBPα*, *TET2*, *DNMT3A*, and *IDH1*. Although the relevance of many of these mutations to prognosis is defined, some are still debated and their coexisting consequences are yet to be determined.

With the development of more sensitive analysis, the subclassification of AML patients has become more detailed. The revisions to AML classification in 2016 remain largely unchanged for the entities of AML and NOS, with the exception of including the erythroid/myeloid subtype of acute erythroid leukemia with MDS. The 2016 revisions include recognition of new cytogenetic subgroups, such as a provisional entity of AML with BCR-ABL and accompanied cryptic deletions of antigen receptors, particularly immunoglobulin heavy chain (IGH) gene rearrangement; this was recently shown to be specific for de novo disease.[21,22] This update also included new and revised subgroups based on the presence of myeloid gene mutations. For example, AML with *RUNX1* mutations include only de novo cases. AML with *CEBPα* now are heterozygous/double mutations (Fig. 56.1). In addition, *NPM1* and double mutations in *CEBPα* trump multilineage dysplasia in de novo disease without MDS-related cytogenetic abnormalities other than del(9q). There is also a greater emphasis on the recognition of familial myeloid neoplasms, with an added classifications section.20 Overall, the 2016 WHO classification of AML has limited changes but recognizes the importance of myeloid gene mutation studies without making the classification overly complex. Cytogenetic studies, screening for gene rearrangements, and assessment of gene panels, including *NPM1, CEBPA, RUNX1*, are currently required to assign AML to the recurrent genetic abnormalities category.

The Myelodysplastic Syndromes

The earliest recognition of myelodysplastic disorders as a clinical entity came with the identification of long-standing and treatment-refractory anemia as occasionally representing a preleukemic disorder (see Chapters 61 and 65). MDS patients classically present with peripheral cytopenias, a hypercellular BM with ineffective hematopoiesis and uni- or multi-lineage dysplasia, with or without an increase in blast cell numbers. Although this is fairly typical, it belies the wide pathologic spectrum of MDS, which includes cases that are diagnostically challenging, and which can be difficult to distinguish on one hand from benign causes of cytopenias in older adult patients, and on the other hand from AML and other more aggressive clonal myeloid neoplasms.

The FAB group proposed the first formal classification of MDS in 1982.[5] In this classification scheme, the myelodysplastic disorders

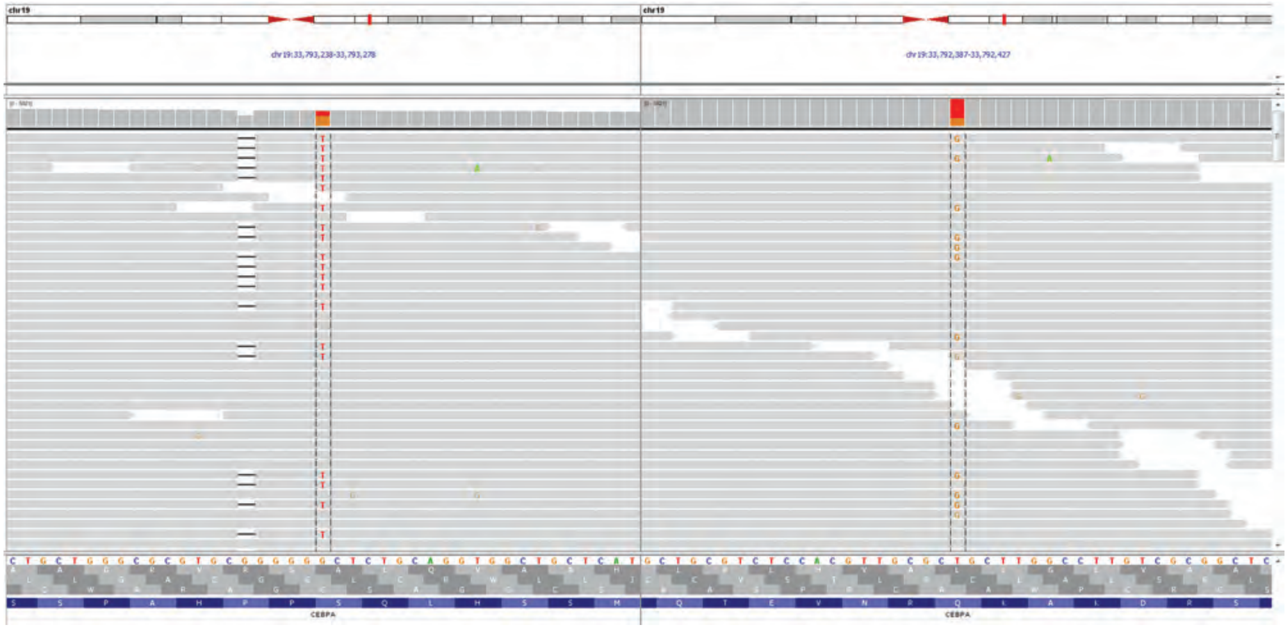

Figure 56.1 ALIGNMENT DATA OF INTEGRATIVE GENOMICS VIEWER FOR DOUBLE CEBPA MUTATIONS IDENTIFIED IN AN AML PATIENT. The *left* side shows c.63_64delinsA, p.Ser21fs, the *right* side shows c.914 A>C, p.Gln305Pro. The *CEBPα* N-terminal frame-shift mutation (p.Ser21fs) is predicted to disrupt the normal function of *CEBPα*. The other *CEBPA* mutation (c.914 A>C, p.Gln305Pro) is a C-terminal missense mutation that has been reported in acute myeloid leukemia (AML) patients. Double-*CEBPα* mutations (as seen in this patient) are found in 5% of patients with AML and are associated with a favorable outcome.[23] *CEBPα*-double mutant AML patients also had a significantly better overall survival at 8 years.

were divided into four subtypes based on increasing blast cell numbers or as chronic myelomonocytic leukemia (CMML). The four entities included RA, refractory anemia with ring sideroblasts (RARS), refractory anemia with excess of blasts (RAEB), and refractory anemia with excess of blasts in transformation (RAEB-T). These entities were differentiated mainly by the percentage of blasts seen in the BM (Table 56.5). As noted earlier, in the FAB scheme AML was defined by the presence of 30% or more blasts in the blood or BM.

The FAB included CMML in the MDS category, although it was recognized that CMML differed in that it had a proliferative component with increased numbers of circulating monocytes. At times, leukocytosis was a predominant feature of the so-called *myeloproliferative type* of CMML, but this was considered to be a dysplastic form and was classified as a type of MDS when the white blood cell count was less than 13,000/μL.

The 2001 WHO classification of MDS included significant changes to the classification of both MDS (see Table 56.5) and AML (as discussed earlier). As mentioned previously, the most notable change was the reduction in the blast percentage required for a diagnosis of AML from 30% to 20%, leading to the elimination of the RAEB-T category. The 2001 classification also included a new subtype of MDS that, despite the lack of increased blasts (less than 5%), had a more aggressive course, probably owing to the presence of more pronounced multilineage dysplasia. This category was called *refractory cytopenia with multilineage dysplasia* (RCMD), and it included a substantial proportion of cases previously grouped in the low-grade RA and RARS categories. Although the recognition of RCMD served to deemphasize the importance of the blast percentage when determining prognosis, these classifications subdivided the RAEB category into two types, with 5% to 9% blasts (RAEB-1) and 10% to 19% blasts (RAEB-2), paradoxically emphasizing the prognostic significance of blast percentage in this category.

TABLE 56.5 Evolving Classifications of the Myelodysplastic Syndromes

FAB 1982	WHO 2001	WHO 2008	WHO 2016
RA	RA	RCUD RA RN RT	MDS with single lineage dysplasia (MDS-SLD)
RARS	RARS	RARS	MDS-RS with single lineage dysplasia (MDS-RS-SLD)
	RCMD RCMD-RS	RCMD (-RS)	MDS with multilineage dysplasia (MDS-MLD)
			MDS-RS with multilineage dysplasia (MDS-RS-MLD)
RAEB	RAEB-1	RAEB-1	MDS with excess blasts (MDS-EB-1)
	RAEB-2	RAEB-2	MDS with excess blasts (MDS-EB2)
		MDS-U	MDS, unclassifiable (MDS-U)
		MDS with 5q-	MDS with isolated del(5q)
		RCC (provisional)	Refractory cytopenia of childhood
RAEB-T			
CMML			

CMML, chronic myelomonocytic leukemia; *FAB*, French–American–British classification; *MDS-U*, myelodysplastic syndrome, unclassified; *RA*, refractory anemia; *RARS*, refractory anemia with ring sideroblasts; *RAEB*, refractory anemia with excess blasts; *RAEB-T*, refractory anemia with excess blasts in transformation; *RCC*, refractory cytopenia of childhood; *RCMD*, refractory cytopenia with multilineage dysplasia; *RCUD*, refractory cytopenia with unilineage dysplasia; *RN*, refractory neutropenia; *RS* ring sideroblasts (% indicates percent RS of total nucleated erythroid precursors); *RT*, refractory thrombocytopenia; *WHO*, World Health Organization classification.

An additional significant change in the WHO 2001 MDS classification scheme included the exclusion of CMML from the MDS category, and the development of a separate nosologic group for CMML and other diseases in which there were features of both myelodysplasia and myeloproliferation at the time of diagnosis. These "overlap" disorders are mentioned briefly later.

Further refinements in the WHO classification scheme for MDS were made subsequently in 2008 (see Table 56.5). These included expanding low-grade MDS from RA to refractory cytopenia with unilineage dysplasia (RCUD), thereby recognizing that the megakaryocyte or granulocyte lineage could be equally affected. The 2008 WHO classification scheme also emphasized the key role of cytogenetic analysis in the diagnosis of MDS, particularly in cases with otherwise insufficient morphologic evidence to substantiate a diagnosis of MDS. This is reflected in the inclusion of the subtype MDS unclassified (MDS-U), defined by the presence of cytopenias, less than 1% peripheral blasts, less than 10% dysplastic cells in any lineage, and less than 5% BM blasts with the presence of specific cytogenetic abnormalities commonly associated with MDS. In addition, the WHO 2008 classification now includes "MDS with an isolated del(5q)" including the "5q minus syndrome." This syndrome had been recognized for some time and is characterized typically by its presentation in middle-aged women with macrocytic anemia, splenomegaly, normal-to-elevated platelet counts, hypolobated megakaryocytes in the BM, and an isolated del(5q). The specific types of MDS have been increased and there are more than 10 different entities.

The 2016 WHO revision introduced nomenclature changes including replacement of the terminology "refractory anemia" and "refractory cytopenia" with "myelodysplastic syndrome with single lineage dysplasia." Other changes in the 2016 revision include the considerations of the prognostic significance of myeloid gene mutations in MDS, revising the diagnostic criteria for MDS entities with ring sideroblasts based on the detection of *SF3B1* mutations, slightly modifying the cytogenetic criteria for MDS with isolated del(5q), reclassifying most cases of the erythroid/myeloid type of acute erythroleukemia, and recognizing the familial link in some cases of MDS.[24] Flow cytometric immunophenotyping is recognized as a useful ancillary technique in the evaluation of MDS.[24]

The Overlap Myelodysplastic/Myeloproliferative Neoplasms

In 2001 WHO introduced the overlap syndromes—that is, the MDS/MPNs (Table 56.6)—because at the time there was disagreement among committee members as to whether CMML was an MDS, as the FAB suggested, or an MPN, as a number of investigators suggested. This group of diseases was defined to include disorders that share features of the MPNs and of MDS at the time of initial presentation but do not fit well into either group. Some of the entities in the MPD/MPN category still are not well understood and

TABLE 56.6 The Myelodysplastic/Myeloproliferative Neoplasms

- CMML
- "aCML," *BCR-ABL1*-negative
- JMML
- RARS-T (provisional)

aCML, "Atypical" chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *JMML*, juvenile myelomonocytic leukemia; *RARS-T*, refractory anemia with ring sideroblasts and thrombocytosis.

may represent a disease in transition from MDS or MPN, although a patient should not be placed in this category if initially diagnosed as MDS or MPN. However, without complete knowledge of the historical pathology of each individual patient, it is useful to have this category in order to construct a more reasonable classification. The overlap syndromes include CMML, including the juvenile type and juvenile myelomonocytic leukemia (JMML; see Chapter 65), in addition to "atypical" CML (atypical CML, *BCR-ABL1* negative), and an "unclassifiable" category that includes refractory anemia with ring sideroblasts and thrombocytosis (RARS-T) (see Chapter 73). The MDS/MPNs share proliferative features in some cell lineages but also have dysplastic features, including ineffective hematopoiesis, in others. Similar to the MPNs, the overlap syndromes require a full evaluation of clinical and morphologic findings and evaluation of ancillary studies before a firm diagnosis can be rendered.

In the 2008 WHO classification, RARS-T was proposed as a provisional entity; however, the strong association with *SF3B1* mutation and MPN-driver mutations (JAK2, MPL and CALR) supported its inclusion as a full entity in the 2016 revision.

The most common mutations reported with CMML include *TET2, SRSF2, ASXL1*, and genes of the *RAS* pathway. In fact, the coexistence of *SRSF2* and *TET2* mutations is particularly helpful in the appropriate clinical setting and can provide support to the diagnosis of CMML. Despite the progress in the molecular characterization of MPN/MDS neoplasm, significant molecular overlap with abnormalities have been noted in the spectrum of other myeloid neoplasms. As such, no disease-defining molecular abnormalities have been identified in this group, with the notable exception of JMML, which is caused by either somatic or germline mutations in one of the *RAS* pathway genes (*PTPN11, NF-1, NRAS, KRAS, CBL*). The diagnosis of MPN/MDS neoplasms requires an integrated approach to incorporate clinicopathologic findings along with cytogenetic and molecular findings.[25]

EVOLVING CONCEPTS IN CLASSIFICATION OF LYMPHOID NEOPLASMS

Hodgkin lymphoma was first described by Thomas Hodgkin in 1932 and is a distinct entity (Table 56.7) that can be distinguished from the majority of lymphomas that are designated non-Hodgkin lymphomas (NHL) (see Chapters 78 and 79).[4] Historically, different classification systems have been proposed for NHL (Table 56.8). Henry Rappaport utilized the histologic features and the architectural arrangement of the neoplastic cells and their cytology when developing a classification system in 1956, which became widely accepted. This system was created prior to the advent of modern immunology; as such, the Lukes–Collins classification in 1975 attempted to relate cell morphology to immunologic function. Subsequently in 1982, the Working Formulation for classifying NHL replaced the Rappaport and Lukes–Collins classification. This system had three groups based on patient prognosis: low, intermediate, and high grade. In 1994, the REAL classification implemented a new approach for classifying NHL, taking into account immunologic, genetic, and clinical features, and not solely relying on histopathologic characteristics of the tumor cells.[3] In 2001, the WHO classification successfully provided a common language and was adopted as the standard for clinicians and investigators worldwide.[1] The modifications made in the 2008 classification are the result of a successful coordination between pathologists, clinicians, and biologists.[4]

REAL, Revised European-American Classification of Lymphoid Neoplasms; *WHO*, World Health Organization.

B-cell, T-cell, and natural killer (NK)-cell neoplasms often represent clonal expansion of these cells at certain developmental stages. Although B-cell neoplasms tend to mimic stages of normal B-cell development, some common B-cell neoplasms, such as hairy cell leukemia, do not conform to a normal B-cell differentiation stage. Additionally, some lymphomas show overt heterogeneity or lineage plasticity; consequently, the normal counterpart of neoplastic cells cannot be used as the sole basis for developing a classification system. The 2008 WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues schema routinely employs a multiple-parameter approach that is based on clinical, morphologic, and biologic features, keeping in mind that a precise separation between entities is not possible in certain cases. Thus, the WHO recognized "gray zones" in which tumor cells may cross boundaries between currently used categories, such as the boundaries between classic Hodgkin lymphoma (CHL) and primary mediastinal large B-cell lymphoma.[4]

In 2008 WHO expanded the classification of lymphoid neoplasms, with more consideration being given to disease definitions, nomenclature, grading, and clinical relevance. Since then, disease definitions have continued to evolve and expand, with new entities and variants being recognized.[26,27] The most recent 2016 WHO revisions developed a focus on early or in situ lesions, as well as definition of the earlier steps of neoplastic transformation, age as a disease-defining feature (e.g., diffuse large-cell lymphoma of the older adult; Table 56.9), and site-specific impact on disease definition. In addition, there was an emphasis on overlapping or borderline entities, with fuzzy demarcation of morphologic, molecular, and genetic characteristics as areas of diagnostic challenge.[8,26]

Early Events in Lymphoid Neoplasms

Recent studies have identified additional clonal lymphoid lesions that share genetic and/or phenotypic properties with well-defined neoplasms such as chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL),[28,29] multiple myeloma (MM), follicular lymphoma (FL), and MCL (see Chapter 81). However, these entities do not fulfill the diagnostic criteria for these well-defined neoplasms, and many appear to have a limited potential for progression. Monoclonal gammopathy of undetermined significance (MGUS), monoclonal B-cell lymphocytosis (MBL), FL in situ, and MCL in situ (see Chapter 86) are examples of such entities.

MGUS is considered an early form of its malignant counterpart MM, with an age-related increased incidence and a small but definitive risk of progression to MM at an annual rate of 1% (see Chapter 90). Recent reports have emphasized the significance of genetic profiling in MGUS for risk stratification, and support the view that progression from MGUS to MM results from the selection and expansion of multiple aberrant clones rather than a linear step-wise acquisition of specific genetic abnormalities.[30,31] The International Myeloma Working Group (IMWG) 2010 guidelines recommend a MGUS risk stratification system, with periodic follow-up with serum electrophoresis for low-risk MGUS patients. However, patients with intermediate-risk and high-risk MGUS are suggested to undergo a baseline BM examination including cytogenetics and skeletal survey, and to be followed with serum electrophoresis studies twice in the first year following diagnosis and annually thereafter.[32]

TABLE 56.9 **World Health Organization Classification of Mature B-Cell Neoplasms**

- Chronic lymphocytic leukemia/small lymphocytic lymphoma
- B-cell prolymphocytic leukemia
- Splenic marginal zone lymphoma
- Hairy cell leukemia
- Splenic lymphoma/leukemia, unclassifiable
- Splenic diffuse red pulp small B-cell lymphoma
- Hairy cell leukemia variant
- Lymphoplasmacytic lymphoma
- Waldenström macroglobulinemia
- Heavy chain diseases
  - μHeavy chain disease
  - γHeavy chain disease
  - αHeavy chain disease
- Plasma cell myeloma
- Solitary plasmacytoma of bone
- Extraosseous plasmacytoma
- Extranodal marginal zone lymphoma of MALT lymphoma
- Nodal marginal zone lymphoma
- Pediatric nodal marginal zone lymphoma
- Follicular lymphoma
- Pediatric follicular lymphoma
- Primary cutaneous follicle center lymphoma
- Mantle cell lymphoma
- DLBCL, NOS
- T-cell/histiocyte–rich large B-cell lymphoma
- Primary DLBCL of the CNS
- Primary cutaneous DLBCL, leg type
- EBV-positive DLBCL of the elderly
- DLBCL associated with chronic inflammation
- Lymphomatoid granulomatosis
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- ALK-positive large B-cell lymphoma
- Plasmablastic lymphoma
- Large B-cell lymphoma arising in HHV8-associated multicentric Castleman disease
- Primary effusion lymphoma
- Burkitt lymphoma
- B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma
- B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classic Hodgkin lymphoma

ALK, Anaplastic lymphoma kinase; *CNS*, central nervous system; *DLBCL*, diffuse large B-cell lymphoma; *NOS*, not otherwise specified; *EBV*, Epstein-Barr virus; *HHV8*, human herpesvirus-8; *MALT*, mucosa-associated lymphoid tissue.

MBL has been diagnosed more frequently than previously reported; this is thought to be related to high sensitivity of flow cytometric analyses (see Chapter 76). MBL is defined as the presence of a circulating monoclonal B-cell population below 5×10^9/L, persisting for at least 3 months, in otherwise asymptomatic individuals. Based on clonal B-cell counts and clinical significance, MBL is now subdivided into high-count MBL ($0.5–5.0 \times 10^9$/L) and low-count MBL (less than 0.5×10^9/L).[33] High-count MBL progresses to CLL at an annual rate of 1% to 2%, with the clonal B-cell count at presentation being the greatest risk factor. The presence of palpable lymphadenopathy, organomegaly, and/or infiltration of lymphocytes within the BM (greater than 30% of nucleated cells) fulfills the International Workshop on Chronic Lymphocytic Leukemia (IWCLL) criteria for CLL, even in the absence of clonal lymphocytosis, while the WHO diagnosis of CLL/SLL is based upon the presence of extramedullary involvement. Current recommendations for management of CLL-like MBL include yearly monitoring with therapeutic intervention if clinically indicated. Low-count MBL, based on current data, is unlikely to progress to CLL and does not warrant clinical monitoring. MBL with the understanding that an atypical CLL-like phenotype ($CD5^+$, bright CD20, $CD23^-$) could represent an early leukemic manifestation of MCL, and a thorough staging workup, including fluorescence in situ hybridization (FISH) testing for t(11;14) translocation, is warranted.

FL in situ (see Chapter 82) was initially described[34] as the localization of atypical B cells that have t(14;18) (IgH-B-cell lymphoma [BCL2]) translocation in the germinal centers of reactive-appearing lymph nodes with strong expression of CD10 and BCL-2. The lymph node architecture is generally intact. The majority of cases of FL in situ do not progress to overt lymphoma, thus the alternate term “follicular lymphoma-like B cells of undetermined significance” was recently proposed. In the 2016 WHO classification revision, an alternative term for in situ FL neoplasia is used in order to reflect the uncertain clinical significance of this entity. In situ FL neoplasia must be differentiated from partial involvement by low-grade FL, which usually shows partially effaced nodal architecture with enlarged, crowded follicles, and attenuated mantle zones. This distinction is clinically relevant, as partial involvement by low-grade FL is more likely to be associated with or progress towards overt FL.

Analogous to in situ FL neoplasia, incidental diagnosis of colonization of the mantle cuffs of reactive follicles by cyclin D1-positive B cells has been termed in situ mantle cell neoplasia (MCLIS) (see Chapter 86). In these cases,[35] cyclinD1 highlighted a small subset of B cells within the mantle zone, indicating low-level involvement by lymphoma. This peculiar pattern of cyclinD1 positivity encircling follicles is characteristic of an early or in situ MCL. The in situ variant of MCL is rare and exhibits cyclinD1 positivity within the innermost mantle zone B lymphocytes, and often is reserved for only partial encircling of follicles by MCL cells. In contrast, it has been proposed that full encircling of follicles by cyclin D1-positive cells should be interpreted as an early sign of involvement by MCL. This distinction is important as partial MCL is more likely than MCLIS to progress or coexist with advanced disease. Current management recommendations for MCLIS include whole-body imaging and unilateral BM biopsy (if indicated) to rule out a concomitant overt lymphoma. In the absence of overt disease, no treatment is required and careful follow-up is advised.

Age as a Disease-Defining Feature

The 2008 WHO classification introduced the concept of age as a defining feature in several disease categories.[4] The entities of FL and nodal marginal zone lymphomas (MZLs) that present in the pediatric age group differ from their adult counterparts clinically and biologically (see Chapter 88). The pediatric variant of FL usually presents with localized disease and is of high histologic grade. These lymphomas lack translocations t(14;18) and do not express BCL2 and have good prognosis, although the optimal management remains to be determined. Nodal MZLs in children also appear to have a low risk of progression. Pediatric nodal MZLs are clonal diseases characterized by marginal zone expansion with fragmentation of germinal centers and progressive transformation of germinal center-like changes. Presentation with isolated cervical lymphadenopathy is common in pediatric nodal MZL. The WHO classification also recognizes two rare Epstein-Barr virus (EBV)–associated T-cell diseases: systemic EBV$^{\text{-positive}}$ T-cell lymphoproliferative disease of childhood and hydroa vacciniforme-like lymphoma (see Chapters 87–89). These diseases occur almost entirely in children, primarily in those of Asian origin.

On the opposite spectrum of age-related lymphoproliferative disorders (LPDs) is EBV-positive diffuse large B-cell lymphoma (EBV-positive DLBCL) of the older adult, which is among the newly included provisional entities in the 2008 WHO classification (see Chapter 85). The underlying immunologic deficit in this setting is believed to be immunosenescence, which is defined as the natural decay of the immune system as a consequence of aging. This entity also is defined histologically as malignant B-cell lymphoproliferation in people older than 50 years of age, without any known immunodeficiency or prior lymphoma diagnosis, and is associated with an aggressive clinical behavior pattern. Initial studies reported some overlap with classic Hodgkin lymphoma encountered in the older adult.[26] At present, there is a broader understanding than previously appreciated of the wide clinicopathologic spectrum of age-related EBV-positive LPD. This spectrum includes reactive lymphoid hyperplasia, polymorphic extranodal LPD (76% have EBV mucocutaneous ulcer), polymorphic nodal LPD and EBV-positive DLBCL. Both polymorphic nodal lesions and EBV-positive DLBCL are characterized by poor survival. In this clinicopathologic spectrum, histologic types are highly predictive of outcome, and small-volume disease, particularly in mucosal sites and skin (EBV mucocutaneous ulcer), which are associated with a good prognosis. It is important to keep in mind that although these lymphomas tend to cluster in the very young or the older adult age groups, they are not age restricted. Similarly, EBV-positive DLBCL of the older adult can occur in a younger population.[36]

Aggressive B-Cell Lymphoma, Borderline Entities, and Site-Specific Categories

The 2008 WHO classification identified several subtypes of DLBCLs (see Table 56.9). However, many DLBCLs lack pathologic, clinical, or other defining features that can be used to stratify them. Thus, these are designated DLBCL, NOS in the WHO classification. Stratification according to gene expression profiling as germinal center B-cell (GCB) versus activated B-cell (ABC) types has proven to have prognostic value. The GCB and ABC subtypes are now formally recognized in the 2016 WHO classification, despite the absence of a reproducible routine diagnostic test and the imperfect correlation of immunohistochemical surrogate markers with genomic studies.[37] Digital multiplexed gene expression utilizing formalin-fixed paraffin-embedded–derived RNA at a reasonable cost and turnaround time to classify B-cell lymphomas according to cell of origin is currently being validated as a routine clinical assay.[38,39] The clinical need and utility of this designation is rising, with more studies suggesting that ABC versus GCB lymphomas exhibit differential sensitivity to certain drugs and therapeutic modalities.[37]

In addition to the designation of DLBCL to ABC or GCB subtypes, next-generation sequencing technologies have unveiled the remarkable complexity of DLBCL (see Chapters 81 and 84). More importantly, it has become increasingly clear that these complexities represent lymphoma subtypes which are driven by very different intracellular oncologic signaling pathways, and which can be differentially exploited for therapeutic benefit.[40] Recent studies have demonstrated the high frequency of abnormalities (i.e., noted in greater than 50% of DLBCLs) affecting histone/chromatin-modification enzymes, such as *CREBBP*, *EP300*, *MLL2*, and *EZH2*.[41] The role of therapeutic agents that target the epigenome has been suggested in DLBCL subgroups due to the variability in DNA methylation and its association with outcome.[42,43]

Currently, the role of MYC and BCL2 proteins in DLBCL is an area of active investigation. It has been proposed that individuals with DLBCL be evaluated for concurrent MYC and BCL2 dysregulation at diagnosis, in order to determine the presence of translocation/protein overexpression. Patients with dual overexpression of MYC and BCL2 have a significantly poorer outcome compared with patients who express only one or neither protein. In addition, concurrent MYC and BCL2 translocation, known as *double-hit lymphoma*, indicates a subgroup of patients who are refractory to treatment and have a median survival of approximately 8 months.

The 2008 WHO classification system emphasizes the importance of integrating morphologic, immunophenotypic, and molecular data to make a final diagnosis. This integration has refined our ability to diagnose several entities such as DLBCL and Burkitt lymphoma (BL). The 2008 WHO classification eliminated the variant category of atypical BL, which had been included in the 2001 WHO classification. Thus, a case with the typical BL phenotype (CD20$^+$, CD10$^+$, BCL2$^-$) and genotype (so-called *MYC-simple* or *MYC/IG* in the absence of other major cytogenetic anomalies) may be classified as BL even if there is some variability in the morphology of the neoplastic cells. In addition, the 2008 WHO classification recognizes a group of high-grade B-cell lymphomas that are not readily classified as either BL or DLBCL. This provisional category is termed *B-cell lymphoma, unclassifiable*, with features that are intermediate between DLBCL and BL, including double-hit lymphomas.[4] In the 2016 WHO classification, DLBCL with MYC and BCL2 and/or BCL6 rearrangements are designated high-grade B cell lymphoma (HGBL), with MYC and BCL2 and/or BCL6 rearrangements (see Chapter 85). The category of BCLU was eliminated. Cases that appear blastoid or cases intermediate between DLBCL and BL, but lacking an MYC and BCL2 and/or BCL6 rearrangement, are placed in the category of HGBL, NOS. The 2008 WHO classification recognized another provisional category of B-cell neoplasms with features that are intermediate between DLBCL and CHL. These tumors occur predominantly in young men and appear to be more aggressive than either primary mediastinal large B-cell lymphoma or nodular sclerosis CHL. There are other settings in which the distinction between DLBCL and CHL is challenging. For example, some EBV-associated B-cell lymphomas may exhibit features that closely resemble or mimic CHL. The borderline category should be used sparingly but is appropriate when a distinction between CHL and DLBCL is not possible.[4]

Several aggressive B-cell lymphomas have a distinct immunoprofile or resemble a cell-specific stage of differentiation. These include plasmablastic lymphoma, ALK$^+$ large B-cell lymphoma, human herpesvirus 8-associated malignancies, primary effusion lymphoma, and large B-cell lymphoma associated with multicentric Castleman disease. All of these entities resemble a stage of plasma cell differentiation. Other site-specific categories are primary DLBCL of the central nervous system and primary cutaneous DLBCL, leg type (see Chapters 81 and 84). Both primary central nervous system DLBCL and other DLBCLs arising in privileged sites, such as the testis, may exhibit distinctive biologic feature (see Chapter 84). However, clinical features remain important in clinical management. Interestingly, primary central nervous system DLBCL has a distinctive gene expression signature that may continue to justify it as a separate entity.

Follicular Lymphoma Grading

Revisions to the 2008 WHO classification incorporated changes related to the grading of FL (see Chapter 82). Both grade 1 and grade 2 were combined in one category and designated "low-grade FL." This revision was the result of questioning the clinical significance of separating grade 1 from grade 2 despite minimal differences in long-term outcome.[4] In addition, several studies identified biologic differences between grades 3A and 3B, with the latter being more closely related to DLBCL. The separation of FL grade 3A from 3B is based on the absence of centrocytes in 3B; however, in routine practice this distinction is difficult. Further studies in this area are needed, as they may be helpful in increasing reproducibility of this distinction. According to the 2008 WHO classification, diffuse areas in grade 3 FL should be designated DLBCL, along with FL, as the bottom-line diagnosis.[4]

Mature T-Cell Neoplasms

In the 2016 WHO classification, over 30 defined or provisional entities were named under mature and T-cell neoplasms. However, since then, there have been significant findings impacting diagnosis, prognostication and management of T-cell NHL (see Chapter 89). The genetic basis of ALK-positive, ALK-negative, and breast implant-associated forms of anaplastic large cell lymphoma are further elucidated. In addition, molecular alterations of gastrointestinal and peripheral T-cell (PTC) lymphoma have been characterized in depth. For instance, the proposed molecular GATA3 and TXB21 subtypes of PTCL, NOS demonstrated distinct genetic aberrations.

Peripheral T-cell lymphomas (PTCLs) comprise 10% to 15% of all NHLs and encompass numerous entities (Table 56.10) that are characterized by a poor prognosis, with the exception of histologic subtype "ALK-positive anaplastic large-cell lymphoma." Most PTCLs lack distinct genetic or biologic features, and the mechanisms underlying the pathogenesis of these lymphomas are not yet fully understood (see Chapter 89). However, development of genomic high-throughput profiling techniques now allows us to extensively identify the molecular abnormalities present in these entities.

Anaplastic Large Cell Lymphoma

ALCLs share a common pathologic feature that include expression of CD30 and the presence of characteristic cells, designated "hallmark cells" (see Chapter 89). ALCL classifications depend on clinical presentation (systemic or localized) and the expression of anaplastic lymphoma kinase (ALK). Systemic ALCLs include ALK-positive ALCL and ALK-negative ALCL, while the localized form includes primary cutaneous ALCL. Although ALK-positive ALCL are associated with a better outcome compared to ALK-negative ALCL, recent reports highlighted genetic heterogeneity where cases with *RNF213-ALK, ATIC-ALK*, and *TPM3-ALK* fusions have been shown to have copy number gains of the rearranged ALK gene, whereas only one copy of NPM1-ALK was present. It was also shown that pediatric ALK-positive ALCLs with NPM1-ALK fusions could be distinguished into two groups based on the expression levels of the NPM1-ALK fusion transcript (see Chapter 89).[44]

TABLE 56.10 **World Health Organization Classification of Mature T-Cell and Natural Killer Cell Neoplasms**

- T-cell prolymphocytic leukemia
- T-cell large granular lymphocytic leukemia
- Chronic lymphoproliferative disorder of NK cells
- Aggressive NK-cell leukemia
- Systemic EBV-positive T-cell lymphoproliferative disease of childhood
- Hydroa vacciniforme-like lymphoma

- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-associated T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Mycosis fungoides
- Sézary syndrome
- Primary cutaneous $CD30^-$ T-cell lymphoproliferative disorders
- Lymphomatoid papulosis
- Primary cutaneous anaplastic large-cell lymphoma
- Primary cutaneous T-cell lymphoma
- Primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T-cell lymphoma
- Primary cutaneous small/medium $CD4^+$ T-cell lymphoma
- Peripheral T-cell lymphoma, NOS
- Angioimmunoblastic T-cell lymphoma
- Anaplastic large-cell lymphoma, ALK-positive
- Anaplastic large-cell lymphoma, ALK-negative

ALK, Anaplastic lymphoma kinase; *EBV*, Epstein-Barr virus; *NK*, natural killer; *NOS*, not otherwise specified.

ALK-negative ALCL is recognized as definite entities in the 2016 WHO revisions. Although noted in only 5% of the cases, recurrent *FRK* rearrangements were recently reported exclusively in ALK-negative ALCL. Chromosomal rearrangements of the DUSP22/IRF4 locus on chromosome 6p25.3 are noted in 30% of ALK-negative ALCL and are associated with favorable outcome similar to that of ALK-positive ALCL. DUSP22-rearrangement is not specific to ALK-negative ALCL cases and can be seen in a subset of primary cutaneous ALCLs and occasional cases of lymphomatoid papulosis.[44] An additional group of ALK-negative ALCL shows rearrangement of *P63* gene; a finding consistently associated with aggressive clinical course. IHC for P63 is a sensitive method to screen for *P63* fusion; however, it is worth mentioning that it is not specific as ALK IHC, and a positive P63 IHC result needs to be confirmed by another method, such as FISH.

T-Cell Lymphomas of T-Follicular Helper Cell Origin

WHO introduced nodal lymphomas of T-follicular helper (TFH) as a new category in the 2017 classification based on common phenotype of the postulated TFH cell of origin, and, in some cases, underlying genetic features among a subset of tumors (see Chapter 89). This category encompasses angioimmunoblastic T-cell lymphoma (AITL) as the classic form and the new provisional entities, including nodal PTCL with TFH phenotype and follicular T-cell lymphoma. AITL and approximately 20% of PTCL-NOS[4] that show TFH phenotyping share a spectrum of genetic abnormalities, such as *TET2* and *DNMT3A*, as well as mutations in the motility and adhesion gene *RHOA*.[45]

Peripheral T-Cell Lymphoma, Not Otherwise Specified

The diagnosis of many T-cell lymphoma cases is challenging even for expert hematopathologists, and about one-third of the cases cannot be further classified and consequently are relegated to a "waste basket" category PTCL-NOS (see Chapter 88). Despite its intentional heterogeneity, gene expression profiling identified two subgroups based on differential expression of the transcription factor gene *TBX21* and GATA3 along with their Target genes. The GATA3 subgroup of PTCL-NOS has an inferior prognosis.

Cutaneous T-Cell Lymphoma

Mycosis fungoides and Sézary syndrome are the most common cutaneous T-cell lymphomas, and the diagnostic criteria for both entities did not change significantly in the 2016 WHO classification; however, their association with a variety of genetic abnormalities, including mutations and loss of tumor suppressor genes, including *TP53, RB1, PTEN, CDKN2A*, and *CDKN1B*, have been reported (see Chapter 89). Three variants of primary cutaneous PTCL were introduced in the 2008 WHO classification: primary cutaneous gamma-delta T-cell lymphoma, primary cutaneous $CD4^+$ small/medium T-cell lymphoma as a provisional entity, and primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T-cell lymphoma. Cutaneous gamma-delta T-cell lymphomas have a diverse histologic and clinical spectrum and may display a panniculitis-like pattern. However, this disease has a much poorer prognosis than subcutaneous panniculitis-like T-cell lymphoma, which is defined as a lymphoma exclusively of alpha-beta phenotype in the 2008 WHO classification. Primary cutaneous small/medium CD4^{+} T-cell lymphoma is another lymphoma with T-cell origin that presents commonly as an isolated lesion in the head and neck region.[46] In the 2016 WHO classification, a change in the terminology of this entity is proposed—to primary cutaneous small/medium CD4^{+} T-cell lymphoproliferative disease instead of lymphoma.

T-Cell Lymphoma of the Gastrointestinal Tract

The WHO classification required more stringent criteria to establish a diagnosis of enteropathy-associated T-cell lymphoma (EATL), previously designated type I EATL—a highly aggressive disease that is associated with celiac disease with most cases showing TCRαβ phenotype (see Chapter 89). Specifically, in order to make the diagnosis of EATL, evidence of celiac disease was required either at the genetic level, with the appropriate HLA-DQ2 or DQ8 phenotype, or intraepithelial T cells characterized by varying degrees of cellular pleomorphism histologically. The monomorphic epitheliotropic intestinal T-cell lymphoma, formerly known as *type II EATL*, is not associated with celiac disease and exhibits some distinctive immunophenotypic and genotypic features. Most cases show a T-cell receptor γδ (TCRγδ) phenotype with CD8^{+} and CD56^{+} expression.[4]

Epstein-Barr Virus–Associated Neoplasms of T and Natural Killer Cells

Extranodal NK/T-cell lymphoma, nasal type is the most common of these types of disorders with a usual upper aerodigestive tract presentation and high prevalence in Asia and some areas of Central and South America (see Chapter 86). In the pediatric population, EBV-positive T-cell and NK-cell LPDs can be categorized into two major groups in the 2016 WHO classification: systemic EBV-positive T-cell lymphoma of childhood and chronic active EBV infection. Systemic EBV-positive T-cell lymphoma of childhood is a clonal proliferation of EBV-infected cytotoxic T cells with a characteristic fulminant and aggressive clinical course usually associated with hemophagocytic syndrome, multiorgan failure, and sepsis. The disease most often occurs in the context of chronic active EBV infection, though it can occur shortly after primary acute EBV infection (see Chapter 88). Chronic active EBV infection is a systemic EBV-positive polyclonal, oligoclonal, or monoclonal LPD that is characterized by persistent infectious mononucleosis-like symptoms. Patients may show a predisposition to T-/NK-cell lymphoma or aggressive NK-cell leukemia.

Precursor Lymphoid Neoplasms

The lymphoblastic neoplasms are derived from precursor cells or blasts, most of which are precursor B- and T-cell neoplasms that present as leukemia. However, the designation of lymphoblastic lymphoma is used when the neoplasm is confined to a mass lesion with or without minimal blood or BM involvement. The WHO classification retains the convention that precursor neoplasms are designated *leukemia/lymphoma*. When distinction between leukemia and lymphoma is required for clinical protocol eligibility at presentation with a patient mass lesion and increased blasts in the BM, a threshold of 25% blasts is used as the defining feature of leukemia.[4]

The 2008 classification recognizes genetic features in the definition of some forms of B-lymphoblastic leukemia (B-ALL) (see Chapters 66–68). One such example is Philadelphia chromosome-positive (Ph^{+}) B-ALL, associated with *BCR-ABL1*, which is more common in adults than in children and is considered very high risk, regardless of other factors. Deletions and other alterations in the *IKZF1* (Ikaros) gene are adverse prognostic indicators in both Ph= and Ph^{-} patients with B-ALL. Another variant with distinctive clinical features at presentation is B-ALL/lymphoma with t(5;15)(q31;q32) (*IL3-IGH*). These patients present with a marked increase in eosinophils, which may mask a relatively small number of blasts in the BM—a diagnostic pitfall worthy of note. The ongoing and increasing complexity highlights the importance of clinicopathologic correlation and the value of ancillary studies in the classification and workup of patients with B-ALL.[47]

T-lymphoblastic leukemia (T-ALL) is also associated with considerable genetic variability. Routine histopathology, flow cytometry immunophenotyping, conventional cytogenetic analysis, FISH, and/or clonality testing are usually adequate to establish the diagnosis. The most commonly involved genes include the HOX transcription factors. However, genotyping is recommended in the workup of the disease, although at this time it is not used as a criterion to define distinct entities.

Hodgkin Lymphoma

Hodgkin lymphomas are lymphoid neoplasms characterized histologically by large neoplastic cells that constitute only a small proportion of the tumor tissue in a background of nonneoplastic cells that account for the majority of the cellularity (see Chapters 79 and 80). Hodgkin lymphomas include two main types: nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) and CHL.

CHL is divided into four histological subtypes: lymphocyte rich, nodular sclerosis, mixed cellularity, and lymphocyte depleted. NF- κB is constitutively activated in the neoplastic cells of CHL (Hodgkin/Reed–Sternberg cells) and contributes to their proliferation and survival. In contrast, six distinct histologic patterns of NLPHL have been described: classic nodular B-cell rich (A), serpiginous nodular (B), nodular with prominent extranodular tumor cells (C), T-cell-rich nodular (D), diffuse T-cell-rich (E), and diffuse B-cell-rich (F). Pattern C through F are associated with advanced disease and higher relapse rate than patterns A and B.

NLPHL and T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL) share a number of features, and it has been suggested that NLPHL with a diffuse pattern overlaps with THRLBCL. In the 2016 WHO classification, NLPHL cases that progress to a diffuse T-cell-rich pattern are designated 'THRLBCL-like transformation of NLPHL.' Both NLPHL and THRLBCL have recently been shown to share recurrent mutations, including those involving JUNB, DUSP2, and SGK1, further supporting the close relationship between these entities.

DENDRITIC CELL AND HISTIOCYTIC NEOPLASMS

Dendritic and histiocytic neoplasms are hematologic malignancies that have distinct yet variable clinical presentations, and together they make up less than 1% of the neoplastic process involving the lymph nodes or soft tissues .[4] However, the true prevalence of these disorders remains uncertain because many have been recognized only recently. Several entities were recognized in the 2008 WHO classification of histiocytic and dendritic cell neoplasms (Table 56.11). Traditionally, these tumors are placed into two categories based on either BM precursors or mesenchymal cells being the cell of origin. Histiocytic sarcoma (HS), Langerhans cell histiocytosis (LCH), and interdigitating dendritic cell sarcoma (IDCS) are derived from BM precursors, while follicular dendritic cell sarcoma (FDCS), indeterminate dendritic cell sarcoma, fibroblastic reticular cell tumors, and disseminated juvenile xanthogranuloma (JXG) are derived from stromal-derived dendritic cells or are mesenchymal in origin. Erdheim-Chester disease (ECD) was added to the 2016 WHO classification to emphasize the need to distinguish it from other members of the juvenile JXG family based on clinical features. Irrespective of myeloid or mesenchymal origin, these tumors may occur subsequent to or concurrent with mature or precursor B- or T-cell neoplasms, with which they may share immunoglobulin or TCR gene rearrangements and chromosomal aberrations,

TABLE 56.11 World Health Organization Classification of Histiocytic and Dendritic Cell Neoplasms

- Histiocytic sarcoma
- Langerhans cell histiocytosis
- Langerhans cell sarcoma
- Interdigitating dendritic cell sarcoma
- Follicular dendritic cell sarcoma
- Fibroblastic reticular cell tumor
- Intermediate dendritic cell tumor
- Disseminated juvenile xanthogranuloma

a phenomenon known as trans-differentiation. Concomitant myeloid neoplasms was recently reported in ~10% of adults with non-Langerhans cell histiocytoses including ECD. Significant findings relating to HDC neoplasms since the 2016 WHO classification in this group includes the identification of recurrent mutations activating Ras-MAPK and PI3K pathways and frequent mutations of CDKN2A in HS, and the in-frame BRAF deletions in 25% of LCH without BRAF or MAP2K1 mutations.[44]

Excisional biopsies are often required to render the diagnosis of these disorders. Consultation with an experienced hematopathologist is often needed, as morphologic review and an adequate battery of immunohistochemical stains are the most important tools in making an accurate diagnosis of these entities and in differentiating them from other, often-mistaken categories, most commonly NHLs. The rarity of these disorders is the major factor that makes this group of diseases difficult to accurately diagnose and challenging to treat. Advances in IHC have contributed to an enhanced understanding of the biology of dendritic and histiocytic neoplasms and have improved our ability to classify and diagnose these disorders. For example, in contrast to LCH, IDCS are usually positive for S100 but negative for CD1a and langerin (CD207). Unlike FDCS, IDCS do not express follicular dendritic cell markers such as CD21 or CD35.[4]

These entities can involve various organs, although most occur in the lymph nodes and skin, with a unifocal or solitary presentation, and are associated with a good prognosis with surgical resection. On the other hand, patients with disseminated disease have shown a poor outcome, although data on treatment options are limited. Nonetheless, chemotherapy and referral to a tertiary-care center should be considered for patients with these diagnoses.

CHAPTER 57

CONVENTIONAL AND MOLECULAR CYTOGENOMIC BASIS OF HEMATOLOGIC MALIGNANCIES

Vesna Najfeld

Dedicated to the loving memory of Eta Najfeld, MD, a Holocaust survivor and an amazing mother.

Over the past 66 years the cytogenetic analysis of hematologic malignancies has been an area of prolific growth. Chromosome studies and karyotype analysis provide information of both biologic and clinical significance. Refinements in cell culture methods and the application of chromosome banding techniques have advanced our understanding of disease-specific abnormalities, and molecular cytogenetic and cytogenomic methods now have made possible the identification of genes involved at translocation breakpoints in specific chromosomal rearrangements. These advances in molecular cytogenetic methods permit mapping of structural rearrangements within a single gene and have fundamentally contributed to our knowledge of the biology of many hematologic malignancies. This evolution in our understanding of cancer genetics has resulted in a distinct terminology (Table 57.1). Application of conventional and molecular cytogenetic methods has identified over 100 fusion genes involving over 500 different genes and approximately 1000 recurrent balanced translocations in human cancers. Relevance of these methods has played a pivotal role in the diagnosis, treatment, and prognostications of the hematologic malignancies. This chapter discusses specific cytogenetic events and delineates molecular phenotypes that are important to understand the molecular pathogenesis of hematologic malignancies and provides several genetic testing algorithms. The remarkable hypothesis put forward by Boveri at the turn of the 20th century—namely, that an abnormal chromosome pattern is intimately associated with the malignant phenotype of a tumor cell—has proven correct. Knowledge of the molecular cytogenetic genotype of hematologic malignancies has led to innovative and targeted treatments. The first example of such gene-targeted therapy has already been successfully applied to chronic myeloid leukemia (CML) (Chapter 69).

METHODS

Fig. 57.1 shows the current cytogenomic methods and their resolution in detecting clonal chromosomal, gene, or other genomic rearrangements and abnormalities in hematologic malignancies.

Cytogenetic Analysis

Cells arrested in metaphase are obtained by exposing marrow cells sequentially to mitotic inhibitors, hypotonic potassium chloride, and fixative. Chromosomes obtained from leukemic marrow are then subjected to trypsin-Giemsa banding (Fig. 57.2). The criteria used to define clonal abnormalities are listed in Table 57.1 and described in the International System for Human Cytogenetic Nomenclature, 2021. Table 57.2 describes the optimal logarithm and evolving new testing strategies. These technologies are currently either stand alone or are used in combination.

Fluorescence In Situ Hybridization Methods

Fluorescence in situ hybridization (FISH) is a molecular method that allows detection of the number, size, and location of DNA and RNA segments within individual cells in a tissue sample. It is based on the ability of single-stranded DNA to anneal to complementary DNA. In hematologic disorders, the target DNA is the marrow or peripheral blood DNA present in interphase cells or the DNA of metaphase chromosomes that is fixed on a microscope slide.

Fig. 57.3 shows four types of FISH probes that are used alone or in combination to determine both numeric and structural rearrangements: (a) centromere enumeration probes, (b) whole chromosome painting probes, and (c) subtelomeric probes, while Fig. 57.4 shows the four FISH probe strategies used in probe design for detection of chromosomal translocations in hematologic malignancies. The first application of FISH technology for detection of chromosomal translocations in hematologic malignancies occurred when the *BCR-ABL1* hybrid gene was identified using two-color FISH in interphase cells as well as in metaphase marrow-derived CML cells. In the standard strategy for interphase evaluation of chromosomal translocation, a DNA probe comprising sequences mapped proximal to the breakpoint in one of the chromosomes involved in reciprocal translocations is combined with a differentially labeled DNA probe that includes sequences mapped distal to the breakpoint in the other chromosome. Nuclei positive for the translocation display one dual-color fusion signal, representing one of the derivative chromosomes generated by the translocation, and two single-color signals, one for each of the normal alleles. This standard FISH strategy has been used for detection of translocations in hematologic disorders at diagnosis.

One of the most significant advances in diagnostic leukemia cytogenetics has been the application of interphase FISH. Interphase cytogenetics is the term used to describe detection of chromosomal abnormalities in non-dividing, interphase nuclei (Fig. 57.5). Five aspects of interphase FISH are particularly useful: (1) Interphase cytogenetics allows screening of a large number of cells. This permits investigation of hematologic malignancies with a low mitotic yield, such as chronic lymphocytic leukemia (CLL) and multiple myeloma (MM). (2) Interphase FISH permits detection of chromosomal rearrangements in peripheral blood samples, thus obviating the need for marrow aspiration. For instance, in CML, which rarely yields a large number of dividing cells in peripheral blood, conventional cytogenetics usually is uninformative. However, detection of *BCR-ABL1*, the molecular equivalent of the Philadelphia chromosome (Ph), in peripheral blood using interphase FISH provides reliable, fast, quantitative results. (3) Interphase FISH offers a quantitative assay for monitoring disease progression or detection of minimal residual disease (MRD) following chemotherapy or hematopoietic stem cell transplantation (HSCT). (4) Use of specific probe sets allows detection of specific disease-associated abnormalities such as t(8;21), which denotes the M2 subtype of acute myeloid leukemia (AML), or t(15;17), which is associated with acute promyelocytic leukemia (APL), within 4 hours, allowing for timely and appropriate therapy. (5) FISH nomenclature is described in the International System for Human Cytogenetic Nomenclature.

Multicolor karyotyping permits examination of the entire genome in a single analysis (Figs. 57.1 and 57.6). In 1996 it became possible

TABLE 57.1 Glossary of Cytogenetic, Fluorescence in Situ Hybridization and Genomic Terminology

Aneuploidy	Abnormal chromosome number, either gain or loss.
Array CGH	A higher-level CGH technology that provides gene copy information.
Balanced translocation	Exchange of chromosomal material that creates no extra or missing DNA.
Banding	Set of dark and pale segments along the length of chromosomes, resulting from treatment with enzyme before staining. Each chromosome identified by its unique set of bands.
Breakpoint	Specific site on a chromosome containing a break in the DNA that is involved in chromosomal structural rearrangement, such as translocation or deletion.
Centromere	Constriction on the chromosome at the spindle site attachment. During cell mitosis two copies of the DNA in each chromosome are separated by shortening of the spindle fibers attached to opposite sides of the dividing cell.
Centromere enumeration probe (CEP)	Highly repetitive α (or β) satellite DNA, located in the heterochromatin of the centromeric area of chromosomes. CEP targets repetitive α (or β) sequences produces bright compact fluorescent signals.
Comparative genomic hybridization (CGH)	Molecular cytogenomic technique that provides a copy-number karyotype at the chromosome and band level.
Chromosomal rearrangement	Aberration in which chromosomes are broken and rejoined.
Clonal abnormality	In cytogenetic analysis, two cells showing the same additional or structural abnormality or three cells with loss of the same chromosome. In FISH analysis, any abnormality present after the probe has been validated and normal reference range established, above the normal reference range.
Chromothripsis	A catastrophic DNA damage occurring during a single mitotic division the application of molecular biology to determine genomic copy number.
Deletion	Segment of chromosome that is missing (terminal) or segment of chromosome missing between two breakpoints (interstitial).
DNA sequence	Order of nucleotides in a DNA segment, usually displayed from the 5′-triphosphate (5′ end) to the 3′-hydroxyl (3′ end) nucleotides.
Driver mutation	This mutation affects the biology of cell.
Enhancer	DNA sequence that increases the rate of transcription.
Exon	Portion of gene that encodes protein.
Fiber FISH	Application of FISH technology to extended DNA or free DNA fibers.
FISH	Fluorescence in situ hybridization, a method for detection of the number and location of DNA sequences (genes) in tissue section or cell population.
Fluorochrome	Fluorescence molecule that, when conjugated to a molecule, binds to a hapten to facilitate detection of the chromosomal probe. By definition, a fluorochrome is a molecule that will become excited by the light of one wavelength.
Gene construct	Recombinant DNA containing a gene of interest surrounded by sequences engineered to promote a measure of its expression.
Gene map	Order of genes within a chromosome or entire genome.
Genotype	Genetic constitution, usually with reference to particular alleles at a locus.
Haploid	Half of a normal complement (i.e., 23 chromosomes).
Haploinsufficiency	Deletion or inactivation of one allele producing disease caused by inadequate activity of the remaining allele.
Hybrid gene	Fusion of two different genes as a result of a structural chromosomal rearrangement that functions as one transcriptional unit.
Hybridization	Method for rejoining (reannealing) complementary DNA or RNA strands.
Hyperdiploid	Additional chromosomes (e.g., 47 or 48 chromosomes).
Hypermetaphase FISH	Application of FISH to accumulated large number of metaphase cells.
Hypodiploid	Loss of chromosomes (e.g., 45 or 44 chromosomes).
I-FISH	Interphase fluorescence in situ hybridization, application of FISH to nondividing (resting) cells.
Interphase	Stage of mitosis in which the cell is not dividing.
Inversion	Structural chromosomal rearrangement as a result of two breaks occurring in the same chromosome. Paracentric inversion refers to both breaks occurring on the same side of the centromere.Pericentric inversion refers to breaks occurring on the opposite side of the centromere.
Isochromosome	Structural chromosomal rearrangement that consists of doubling of one of the two chromosome arms (connected by the centromere) and loss of the other arm.
Karyotype	Arrangement of metaphase chromosomes from a particular cell according to size and banding so that the largest chromosome is placed first and the smallest one last (see Fig. 56.2).
kb (kilobase)	Unit of DNA/RNA length = 1000 base pairs of DNA.

TABLE 57.1 **Glossary of Cytogenetic, Fluorescence in Situ Hybridization and Genomic Terminology—cont'd**

Kataegis	Kataegis is a recently discovered phenomenon in which multiple mutations cluster in a few hotspots in a genome. This region is often colocalized with regions of somatic genome rearrangements.
Locus	Unique location of a gene on a chromosome.
Locus (sequence)-specific probe (LSI)	Probe targeted to unique sequence region of the chromosome. Useful for localization of genes on normal chromosomes (gene mapping) and for detection of gene amplification, deletion, inversion, or translocation.
Marker chromosome	Chromosome whose morphology cannot be identified using banding method. Marker chromosomes are frequent in hematologic neoplasms.
M-FISH	Multicolor FISH karyotyping, which allows identification of 24 different human chromosomes (22 autosomes, and the X and Y chromosomes) (see text for details).
NGS	Next generation sequencing.
Nonsilent mutations	Mutations that alter the protein sequences.
Oncogene	Locus that is activated in association with tumor growth. One abnormal allele is sufficient to cause tumor formation or cancer.
SNP	Single nucleotide polymorphism.
Passenger mutation	Is usually a subclone and does not affect the biology of cell.
PCR	Polymerase chain reaction, by which individual gene segments are amplified through sequential cycles of polymerization, heat denaturation, and reannealing.
Pseudodiploid	Diploid number of chromosomes (46) accompanied by structural rearrangement.
Recurrent abnormality	Structural or numerical abnormality observed in multiple patients with the same or similar disease. Recurrent chromosome abnormalities in hematologic neoplasms have prognostic significance.
Telomeric probe	Used in FISH to detect repeated DNA sequences present at the end of the chromosome, which is called the telomere. Telomeric DNA contains 10–15 kb of TTAGGG repeats.
Translocation	Structural chromosome abnormality resulting from a break in at least two chromosomes with an exchange of material. In reciprocal or balanced translocation, no loss of chromosomal material occurs. In unbalanced translocation, loss of chromosomal DNA occurs.
Tumor suppressor gene	Locus that prevents tumor growth when at least one allele is functional. Loss of both alleles, first through constitutional and then through somatic mutation, is associated with tumor formation or cancer.
Whole chromosome painting probe (WCP)	Spans the entire length of chromosomal DNA sequences and, as the name implies, targets the entire length of DNA sequences.
Nomenclature	
p	= Short arm
q	= Long arm
+	When placed before the chromosome, denotes a gain of a whole chromosome (e.g., +8)
−	When placed before the chromosome, indicates a loss of a whole chromosome (e.g., −7); in rare situations, when placed after the chromosome, as in 5q−, indicates loss of a part of the long arms of chromosome 5
t	translocation
del	deletion
der	derivative
inv	inversion
i	isochromosome
mar	marker chromosome
con	connected
nuc ish	nuclear in situ hybridization
nuc ish 21q22 (D21S65X2)	two copies of D21S65 DNA segment on chromosome 21
nuc ish 9q34 (*ABL1* x2), 22q11.2 (*BCRx2*) (*ABL1* con *BCRx1*)	two *ABL* and two *BCR* loci, but one of each locus is juxtaposed on one chromosome as a result of t(9;22)

Figure 57.1 COMPLEMENTARY METHODOLOGIES OF IDENTIFYING VARIOUS GENOMIC ALTERATIONS AND THEIR RESOLUTIONS. See text for detailed descriptions of how these methodologies are applied for detection of genomic abnormalities in hematologic malignancies. Conventional cytogenetic methods detect clonal numerical and structural chromosomal abnormalities on a single cell level, at the resolution of 5 to 7 Mb. Multicolor FISH method with 24 different colors is specifically useful to identify the origin of marker chromosomes, complex 3- or more-way translocations, origin of ring chromosomes and other chromosomal abnormalities present in a complex karyotype such as those in MDS, lymphoma, and multiple myeloma. As mentioned in the text, there are at least five different reasons to perform interphase FISH in non-dividing cells from specimens of patients with hematologic malignancies. Interphase FISH is specifically useful for initial screening of the most recurrent rearrangements associated with CML, AML, ALL, and multiple myeloma as well as for detection of minimal residual disease with a diagnostic abnormality originally determined by conventional cytogenetics. In the lab of the author interphase FISH for *PML-RARA* fusion for the diagnosis of APL is a stat test with results obtained within 4 hours. Array CGH+SNP is a molecular method for detection of small and cryptic DNA changes at the exon-level resolution to 1 Mb. SNP platform is particularly useful for detection of acquired copy-number neutral chromosomal regions as well as detection of chromothripsis (see text). Next-generation sequencing (NGS) is the most powerful method for detection of acquired somatic mutation at the single nucleotide level. Although not yet used routinely in clinical laboratories, the application of NGS to hematologic malignancies has revolutionized the current knowledge of many leukemic entities. *aCGH*, array comparative genomic hybridization; *ALL*, acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *APL*, acute promyelocytic leukemia; *CML*, chronic myeloid leukemia; *FISH*, fluorescence in situ hybridization; *MDS*, myelodysplastic syndrome; *SNP*, single-nucleotide polymorphism.

Figure 57.2 NORMAL ARRANGEMENT OF CHROMOSOMES IN A KARYOTYPE FROM A NORMAL BONE MARROW METAPHASE SHOWING A SLIGHTLY FUZZY MORPHOLOGY COMPARED WITH A NORMAL KARYOTYPE OBTAINED FROM PHYTOHEMAGGLUTININ-STIMULATED PERIPHERAL BLOOD CELLS.

to identify 24 different human chromosomes (22 autosomes and the X and Y sex chromosomes), each with a unique color, with the help of fluorochrome-specific optical filters. This method is called *multicolor FISH (M-FISH)*. When interferometer-based spectral imaging is used, the method is called *spectral karyotyping*. The starting point in both methodologies is the use of whole chromosome painting probes for each chromosome. Thus each chromosome is labeled with a different combination of fluorescent dyes and images are sequentially obtained using five different fluorochrome-specific optical filters. A computer program combines the data and displays each chromosome

TABLE 57.2 Recommended Testing for Different Hematologic Malignancies

Disease	Test	Requirement	Suggested Methodology
CML	Karyotype	Mandatory	Chromosome banding
	BCR-ABL1 gene fusion	Mandatory	FISH or molecular methods/NGS
	ABL1 mutation when resistance to therapy	Mandatory	Molecular methods
MPN	*JAK2, CALR, MPL* mutations depending on referral reason	Mandatory	Molecular methods
	Karyotype, if normal	Highly recommended	Chromosome banding/aCGH+SNP
Myeloid/lymphoid neoplasms with eosinophilia	Recurrent gene fusions involving *PDGFRA, PDGFRB, FGFR1, PCM1-JAK2*	Strongly recommended for most patients	FISH, molecular methods
	Karyotype	Recommended in absence of recurrent gene fusion	Chromosome banding
MDS	Karyotype	Mandatory	Chromosome banding
	Targeted chromosome abnormalities −5/del(5q),−7/del(7q), *MECOM* (extended panel +8,del 20q, de(*TP53*)	Recommended	FISH/aCGH+SNP
	High resolution chromosome analysis	Recommended	SNP array
	Mutation analysis of candidate genes	Recommended	Molecular methods, NGS
AML	Karyotype	Mandatory	Chromosome banding
	Gene mutations: *NMP1,CEBPA, RUNX1, FLT3,TP53, ASXL1*	Mandatory	Molecular methods
	Recurrent gene fusions: *PML-RARA, CBFB-MYH11, RUNX1- RUNXT1*. Gene rearrangements of *KMT2A, MECOM, TP53*	Mandatory	FISH or molecular methods
Treatment-related MDS/AML	Karyotype/FISH: −5/del(5q),−7/del(7q), *KMT2A, RUNX1*	Mandatory	Chromosome banding/FISH
ALL	Karyotype	Mandatory	Chromosome banding
	Recurrent gene fusions	Strongly Recommended	FISH
	Infants: K*MT2A;* Pediatric: *ETV1-RUNX1, BCR-ABL, TCF3* Adults: *KMT2A, ETV1-RUNX1, BCR-ABL1,*		
	Hyperdiploidy	Recommended in pediatric	aCGH+SNP
	Recurrent microdeletions/AMP/9p21, *RUNX1*	Mandatory	FISH/aCGH+SNP
CLL	Deletion 13q14, *ATM, TP53*, trisomy 12	Mandatory	FISH, aCGH+SNP or molecular methods
	TP53 mutation/IGHV mutational status	Mandatory	Molecular methods
	Karyotype	Recommended for clinical trials	Chromosome banding
Multiple myeloma	t(4;14), t(14;16), deletion *TP53* gain 1q/del(1p)	Recommended	FISH for gene rearrangements
	t(11;14), t(14;20), ploidy status (extended panel)		FISH or Array, MLPA for copy number gains and losses
Other mature B-cell neoplasms	Recurrent gene rearrangements depending on differential diagnosis		FISH
	MYC rearrangements for prognostic testing/IgH		FISH

aCGH, Array comparative genomic hybridization; *AML*, acute myeloid leukemia; *CML*, chronic myeloid leukemia; *FISH*, fluorescence in situ hybridization; *MDS*, myelodysplastic syndrome; *MLPA*, multiplex ligation-dependent probe amplification; *MPN*, myeloproliferative neoplasm; *NGS*, next generation sequencing; *SNP*, single-nucleotide polymorphism.

as if it were stained with a distinct color. Spectral karyotyping is based on the use of an interferometer (used by astronomers to measure the light spectra of distant stars) to determine the full spectrum of light emitted by each stained chromosome. A computer program then displays all the chromosomes simultaneously, each with its own unique color. These methods are applied with increasing frequency to resolve complex karyotypes and to resolve the origin of the marker chromosome.

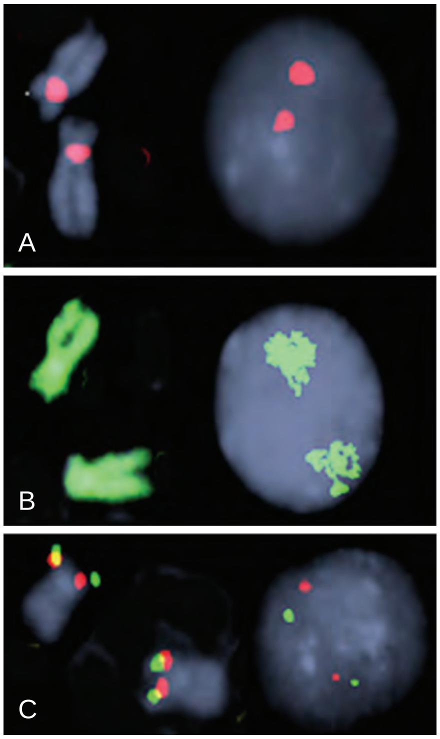

Figure 57.3 TYPES OF CHROMOSOMAL PROBES (SEE TEXT FOR DETAILS). (A) Pair of chromosome 12 *(left)* and interphase cell *(right)* after fluorescence in situ hybridization (FISH) study with centromere enumeration probe (CEP) showing two hybridization signals *(red)* in the centromeric area of chromosome and two tight signals in interphase cell consistent with disomy (normal copy number). CEP probes are most useful for detection of numerical abnormalities. (B) Hybridization with a whole chromosome 8 painting probe showing the hybridization signal *(green)* along the length of the entire chromosome 8 *(left)* and hybridization domains in interphase cell *(right)*. Whole chromosome painting probes are useful for identifying unknown chromosomes in metaphase cells. (C) Target of locus-specific indicators are specific gene sequences such as P53 seen after hybridization as two small signals *(red)* on chromosome 17, band p13. The main applications of locus-specific indicator (LSI) probes are gene mapping, numerical enumeration in interphase cells, and detection of translocations. Telomeric probe, shown in green for the short arms of chromosome 17, are repetitive probes and are useful for detection of cryptic translocations involving ends of chromosomes. Chromosomes and nuclei are counterstained with DAPI *(blue)*.

Comparative Genomic Hybridization and Next Generation Sequencing

Another powerful method used for identifying the location of chromosomal gains, losses, deletions, or amplifications, without prior knowledge of the chromosomal target that may be altered, is comparative genomic hybridization (CGH) (see Fig. 57.1). Briefly, isolated DNA from a patient's marrow or tumor tissue is labeled with a one-color fluorochrome (e.g., red), whereas DNA isolated from normal control tissue is labeled with a different color (e.g., green). These differently labeled DNAs are hybridized against each other in a competitive hybridization reaction onto normal metaphase spreads. Computer-assisted image analysis detects colors generated after hybridization, which indicate equal hybridization, relative excess, or deficiency of the target DNA (relative to control). The ratio of color intensity provides a "copy number" karyotype.

A particularly useful investigational approach is a "microchip array" in which labeled DNA or RNA from the sample of interest is hybridized with defined target sequences immobilized on a solid support system. This method can screen for genes that are gained/amplified or deleted from the genome on a large scale or, in the case of RNA, to learn whether such genes are expressed at a particular stage of disease. The first example of successful application of the RNA microchip array technique was the discrimination of AML from acute lymphoblastic leukemia (ALL) based solely on gene expression. As shown in Fig. 57.1, in the array CGH (aCGH) procedure, large-insert genomic clones, oligonucleotides, or single-nucleotide polymorphisms (SNPs) have replaced metaphase chromosomes used in routine CGH. Array CGH is a higher-resolution CGH technology of approximately 5 to 50 kb and provides diagnostic information for diseases associated with DNA dosage. It can also be used to discover previously unexpected sites of altered gene dosage associated with specific hematologic malignancies. The concept of obtaining gene copy number from multiple genome locations in a single measurement has been used to characterize numerous hematologic malignancies over the last 17 years, and its clinical utility is demonstrated throughout this chapter. Nowadays, SNP arrays are also used to genotype a few hundred to millions of SNPs in order to detect rare and common genomic rearrangements (see Fig. 57.1). These arrays require hybridization of only the test sample onto the array, unlike aCGH, which relies on co-hybridization of test and reference DNA. At this time aCGH+SNP arrays are used together in one study and they provide exon-level resolution of genomic changes.

The most advanced genomic technologies currently known is next generation sequencing (Chapter 3) or NGS (see Fig. 57.1). These approaches use a range of techniques that enable sequencing of hundreds of thousands of nucleic acids simultaneously. In order of complexity, these approaches include sequencing of gene panels, exome sequencing (protein-coding genes), transcriptome (expressed RNA), and sequencing the whole-genome sequencing (WGS). Implementation of these techniques requires several arrays of several hundred thousand sequencing templates in parallel generating up to several hundred million short reads of DNA sequence per lane. The basic principle of NGS involves a process of DNA fragmentation, adapter ligation, and immobilization of the fragments via the adapters to create libraries. The libraries then undergo a process of amplification, generating multiple copies of each DNA fragment which are then sequenced in parallel by a fluorescence- or chemiluminescence-based method, yielding billions of short sequence reads (Chapter 3). These reads are then aligned to the human reference genome and highly efficient algorithms are used to map these complex genomes. Because of its cost effectiveness and enormous sequencing capacity, NGS is revolutionizing hematologic malignancy research by facilitating the discovery of disease-initiating mutations, identifying novel drug targets, and allowing for the first time personalized treatment strategies for hematologic malignancies. Exome sequencing is a relatively inexpensive approach to identify protein-coding mutations, but is incapable of identifying structural genetic rearrangements, deletions, and insertions of DNA, a hallmark of many hematologic malignancies. Exome sequencing is performed at a depth of 100- to 200-fold coverage of the haploid genome, which enables detection of mutations present in leukemic subclones, which is important in the study of relapse. Transcriptome sequencing involves sequencing of genes actively expressed and can be adjusted to selectively study RNA transcripts that encode proteins (mRNA), transcripts regardless of coding potential (RNA), or a variety of small and noncoding RNA transcripts. RNA sequencing is a highly informative approach which enables identification of chromosomal rearrangements that result in the expression of chimeric fusion genes and sequence mutation detection. WGS usually involves sequencing leukemic and nonleukemic DNA from an individual. Although it is the most comprehensive modality, WGS may not identify all genetic alterations caused by variations in sequence coverage and difficulties in sequencing complex and GC-rich regions of the genome (including gene promoters). These modern cytogenomic methods have increased the resolution at which chromosomal and gene rearrangements can be identified. Conventional cytogenetics, FISH, and aCGH+SNP along with NGS are complementary. Each has its own pros and cons in investigating genomic rearrangements of malignant cells.

Although conventional cytogenetics is the comprehensive study of all chromosomes, it requires a large number of dividing cells, which, in some diseases, such as myelofibrosis, is difficult to obtain

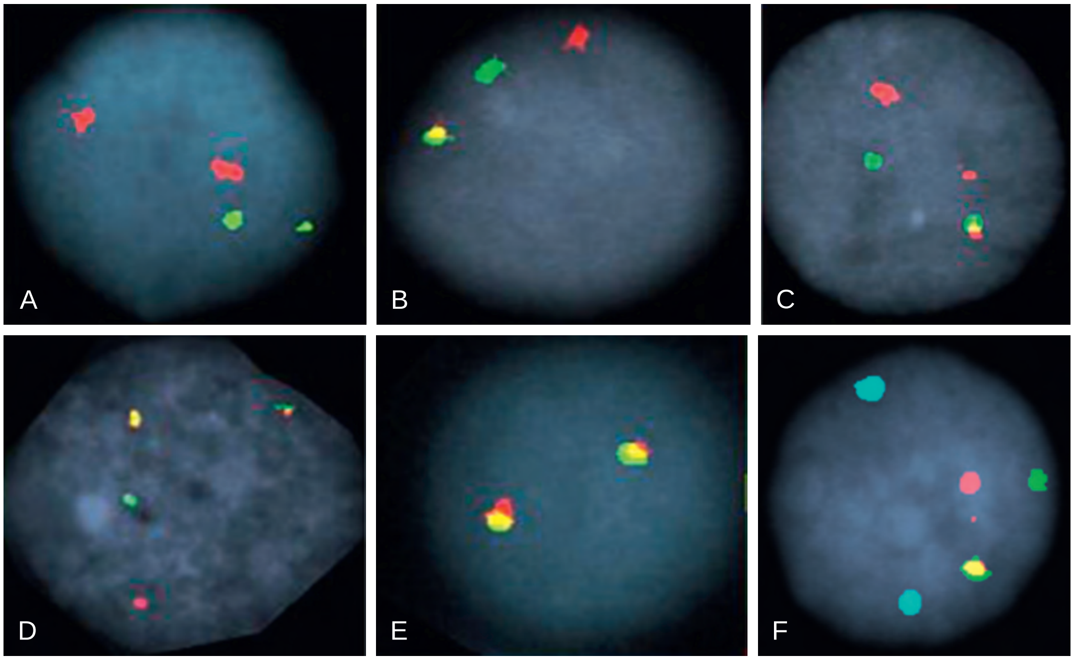

Figure 57.4 FOUR DIFFERENT PROBE STRATEGIES FOR DETECTION OF CHROMOSOMAL TRANSLOCATIONS (SEE TEXT FOR DETAILS). (A) Normal cell after in situ hybridization with breakpoint cluster region *(green)* and *ABL* (Abelson) *(red)* showing a normal distribution of two red and two green single signals. (B) Conventional fusion strategy after in situ hybridization shows one fusion *(yellow)* signal representing derivative chromosome generated by the translocation and one single-color signal, red and green, for normal homologues in positive nuclei. (C) An extra-sensitive fusion approach generates an extra small *(red)* signal, as well as a fusion signal *(yellow)* and one signal in single color *(green and red)* on normal homologues. (D) Dual-fusion strategy generates two fusion signals *(yellow)* on two derivative chromosomes and one single-color signal on each of two normal chromosomes. (E) Breakapart approach in a normal cell appears as two fusion signals *(yellow)*. In this strategy, the 3′ end and the 5′ part of the gene are labeled in two colors. (F) When the rearrangement occurs, the normal chromosomes show co-localization of red and green *(yellow)* as a result of the proximity of the sequences on the chromosome, whereas abnormal derivative chromosomes each have one single red and single green signal, indicating that the rearrangement occurred between the two ends of the gene separating the green and red signals on two different chromosomes. The third-color probe *(blue)* can be used as an internal control (usually centromere enumeration probe) to determine the disomic number of chromosomes.

(see Table 57.2). Furthermore, many small deletions or structural rearrangements are beyond the microscopic level of detection. FISH should be used in conjunction with conventional cytogenetics with both interphase and metaphase cells. It is a more sensitive method and detects rearrangements smaller than 1 kb. The main disadvantage of interphase FISH is that it cannot be used unless a known abnormality is suspected. When the abnormality is known, interphase FISH identifies the clonal aberration at the single-cell level. aCGH+SNP provides genome-wide higher resolution analysis and important information concerning genomic changes in patients with a normal karyotype as well as acquired loss of heterozygosity, and chromothripsis (chromosome shattering), which are important prognostic and predictive tools. With the introduction of high throughput genomic technologies such as NGS, FISH-based chromosome level detection has gradually changed focus to genome-wide detection of single nucleotide and copy number variants that are common in leukemia. It is evident that identification of chromosomal aberrations by molecular cytogenomic techniques is important in detecting novel chromosomal rearrangements and genes involved in leukemogenesis. Understanding the basis of these techniques and their application is critical in the accurate diagnosis of hematologic malignancies. Table 57.2 describes the optimal algorithm and evolving new testing strategies. New technologies, capable of simultaneously detecting copy number changes, structural variants, and mutations, are expected to be used in future in a diagnostic setting.

Genome sequencing has rapidly become routine practice. However, the intimate relationship between DNA sequencing, chromosome structure, and the position of chromosomes in the nucleus is not fully understood. The term “*chromosomics*” was recently proposed in order to integrate the original definition of cytogenetics (chromosomes and cytology) with genomics (gene content, structure and function) to ensure a closer integration of these fields. This term chromosomics is encompassing the integration of the latest advances in cytogenetics, genome sequencing, epigenomics, and cell biology. *Chromosomics* approaches in future will lead to additional success in answering fundamental biological questions in hematologic malignancies.

Next-Generation Karyotyping

In early 2021 three studies used novel *next-generation karyotyping* which employed WGS as a potential replacement for conventional cytogenetics (Chapter 3). These initial studies focused on patients with AML and myelodysplastic syndrome (MDS) and the genetic profiles and sequencing approaches were tested against the backbone of orthogonal results obtained at the same time using cytogenetics, FISH, and polymerase chain reaction (PCR) and/or NGS for detection of acquired somatic mutation. In a study reported by the Washington University group, in 235 patients who had undergone successful cytogenetic analysis, WGS provided rapid and accurate genomic profiling in patients with AML or MDS after modifications of sample preparation, sequencing, and analysis to detect mutations to be used for risk stratification using existing European Leukemia Network (ELN) guidelines.[1] The WGS detected all 40 recurrent translocations and 91 copy-number alterations that had been identified by cytogenetic analysis. In addition, next-generation karyotyping identified new previously unrecognized genomic events in 17% of patients. In 117 consecutive patients analyzed prospectively WGS provided results within a median of 5 days and additional genetic information was identified in almost 25%, which changed the ELN and Revised International Prognostic Scoring System (IPSS-R) genetic prognostic risk categories in 16% of patients. Standard AML risk groups, as defined by sequencing results instead of cytogenetic analysis, correlated with clinical outcomes. WGS was also used to stratify patients who had inconclusive results by cytogenetic analysis into risk groups in which clinical

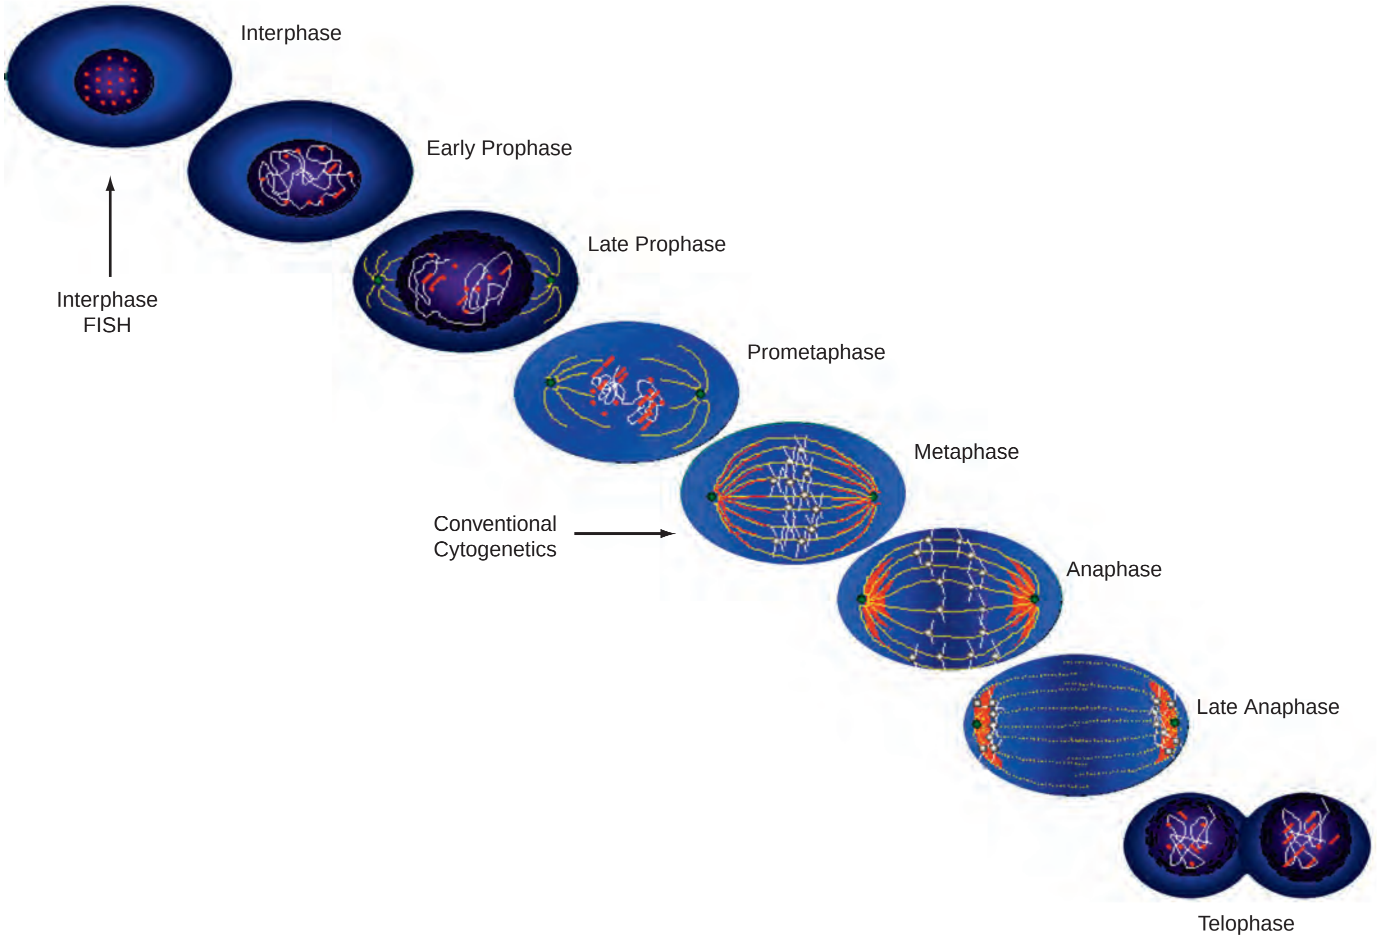

Figure 57.5 SCHEMATIC REPRESENTATION OF CELL DIVISION. Most clinical FISH studies are performed on non-dividing interphase cells, whereas conventional cytogenetics is performed at the metaphase stage of cell division. *FISH*, fluorescence in situ hybridization. *(Courtesy Dr. Ari Melnik, Cornell Medical Center, New York.)*

outcomes were measurably different.[1] These initial data are highly promising because they provided a greater diagnostic yield than conventional cytogenetic analysis and allowed for more efficient risk stratification on the basis of standard risk categories. Moreover, the speed by which the clinically relevant genomic profiles were obtained allowed reports to be generated in as little as 3 days.

Clonal Origin of Leukemia

The question of whether cell proliferation is monoclonal or polyclonal is fundamental to understanding the underlying origins of hematologic malignancies. Markers of clonality are used to determine the origin of disease; to differentiate malignant from nonmalignant populations; to establish hematopoietic hierarchy, clonal evolution, and clonal remission; and to delineate steps involved in the multistep pathogenesis of hematologic malignancies.

The clonal origin of leukemias and lymphomas can be assessed by either intrinsic or extrinsic cellular markers. Intrinsic cellular markers are specific for a cell population, arising either during normal differentiation or as a part of disease process. For instance, cell surface-associated immunoglobulin (Ig) markers such as the λ or κ light chain or idiotypes and T-cell receptors (TCRs) can be useful for evaluating lymphoid malignancies. Application of *IgH* markers demonstrated for the first time that MM was of clonal origin. Somatic cytogenetic alterations are useful intrinsic markers for identifying abnormal clones and following disease progression. Thus the observation of identical chromosome anomalies in different cells of the same tumor is evidence of clonality. Since the discovery of the Ph in 1960 it has been well established that nonrandom, recurrent chromosomal abnormalities characterize many hematologic malignancies. The finding of the Ph in different CML-derived hematopoietic cell lineages led to the hypothesis that CML originates in a single precursor cell that has a clonal development pattern. Moreover, the presence of additional recurrent chromosomal abnormalities in the Ph-positive clone (such as trisomy 8, duplication of the Ph, or trisomy 19) not only indicates the progression of the disease to accelerated phase or blast crisis, but also demonstrates the subclonal evolution of the Ph-positive clone. Currently, disease-associated somatic genomic mutations, such as rearrangements of *KMT2A (MLL)*, runt-related transcription factor gene *(RUNX1), ETV6, PML-RARA*, and many others, can be identified by PCR-based assays, FISH assay, and novel aCGH and NGS, and may serve, with or without conventional cytogenetics, as intrinsic markers of disease processes.

On the other hand, extrinsic marker systems use cellular mosaicism that is completely independent of the disease being studied and is not restricted to the cell lineages. Individuals with Turner or Klinefelter syndrome are mosaic for XX or XY and monosomy X cells or XXY and XY cells, respectively. The mosaicism created by X-chromosome inactivation in females is much more widely applicable, and initially provided fundamental insights into the pathogenesis of hematologic malignancies. Original studies with X-linked glucose-6-phosphate dehydrogenase (*G6PD*) as a marker of clonality were based on the Lyon hypothesis, which asserts that early in embryogenesis, one X chromosome in females is inactivated in somatic cells and the activation status is stably transmitted to daughter cells during mitosis (Fig. 57.7). The choice of maternal versus paternal X-chromosome inactivation is random; however, once it occurs, it is maintained in all daughter cells. Random X inactivation occurs by embryonic day 6.5

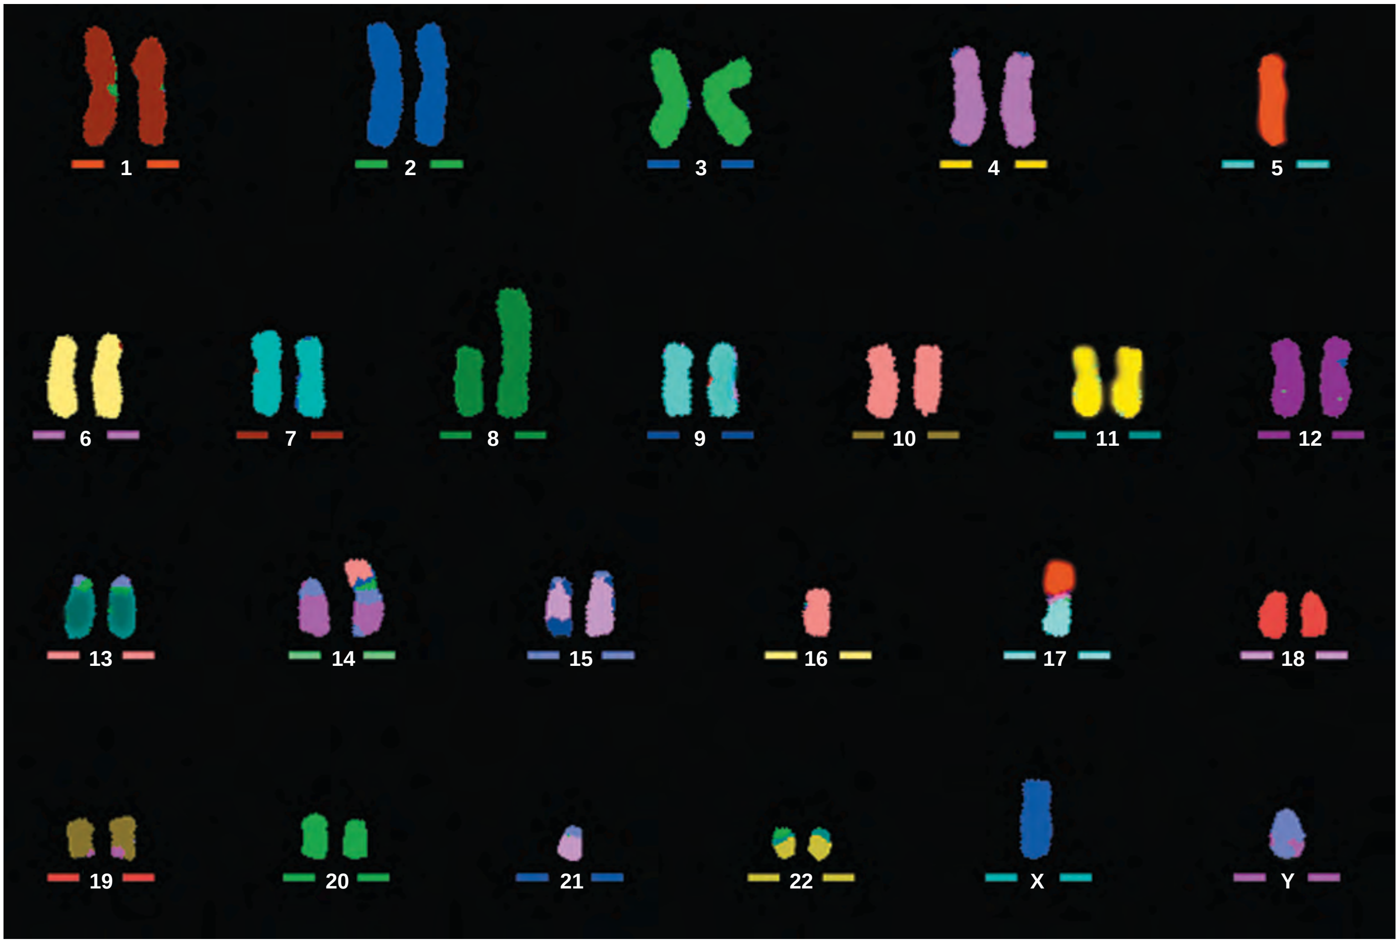

Figure 57.6 Multicolor metaphase FISH of a bone marrow cell from a patient with myelodysplastic syndrome documenting 43,XY, −5, der(8)t(8;8)(p23; q11.2), der(14;16)(p12;p11.1), inv(15)(q21;q24), der(17)t(5;17)(p13;p13), −21 karyotype. The origin of t(8;8) and der(14;16) could not have been determined by conventional cytogenetic study alone. *FISH*, fluorescence in situ hybridization.

around the start of gastrulation and results in a mosaic pattern that characterizes adult females. Therefore an adult female is a mosaic for two-cell populations, one expressing genes from an active X chromosome and the other expressing genes from the inactive X chromosome. Incidentally, mammalian X-chromosome inactivation is a mechanism that equalizes the dosage of X-linked genes between sexes. Although the exact mechanism of X-chromosome inactivation remains to be elucidated, the process of X inactivation starts with methylation of CpG islands. The inactivation process is believed to occur before differentiation of the embryonic stem cell into various cell lineages. Hematopoietic cells do not originate from a single embryonic stem cell but from several hematopoietic stem cells, thereby allowing for mosaic expression from both X chromosomes.

The observation that human females were heterozygous for the G6PD variant A and A^{-} and that two mosaic cell populations may be distinguishable by electrophoretic mobility was reported in the 1960s. The X-inactivation *G6PD* mosaic system was then applied to the study of clonality in human tumors (uterine leiomyomas) in 1964 by Gartler and Linden. In females who were heterozygous for the *G6PD* polymorphism and had malignant hematologic disorders such as CML, the finding of a single *G6PD* type in marrow or blood cells and both the A and B type *G6PD* in tissues not involved by the malignant process first demonstrated that CML was of clonal origin and provided evidence that the malignant transformation occurred at the level of a stem cell common to most hematopoietic cell lineages. Additional studies with heterozygous *G6PD* females who had CML demonstrated that some CML-derived B lymphocytes had a single G6PD type, but these clonal cells were Ph-negative; thus leukemic transformation might predate development of the chromosomal abnormality. This observation provided evidence that CML has a multistep pathogenesis. Application of this approach to hematologic malignancies demonstrated the clonal and stem cell origin for AML, ALL, Ph-negative myeloproliferative neoplasm (MPN), MDS, and CLL.[2] Studies using *G6PD* were particularly useful in the investigation of red blood cells and platelets in hematologic malignancies because the absence of nuclei in these cells did not allow them to be studied with cytogenetics or DNA analysis. Although it is now considered common knowledge that hematologic malignancies are characterized by clonal development, this concept was largely developed by Dr Phillip Fialkow.

Despite the importance of the *G6PD* approach, it is limited by the rarity of females who are heterozygous for the G6PD isoenzymes. An alternative and more extensive DNA-based X-chromosome clonal assay used common polymorphic markers that are caused by changes in DNA methylation patterns that accompany inactivation of the X chromosome. These X-linked loci such as phosphoglycerine kinase, hypoxanthine phosphoribosyltransferase, DXS25 (M27β), and human androgen receptor (HUMARA), have been extensively used in assessment of clonality, and can be used to identify clonal cell populations in virtually all females. DNA-based marker systems rely on a sequence polymorphism that has adjacent differences in methylation on the active and inactive X chromosomes. The inactive X chromosome is more highly methylated than its active homologue, but this is only true for certain regions of genes as 10% to 20% of X-linked genes escape inactivation and can be found both in clusters and in isolation. The most widely used HUMARA assay appears to maintain stringent methylation differences. The number of CAG tandem repeats differentiates the maternal from the paternal X chromosome.

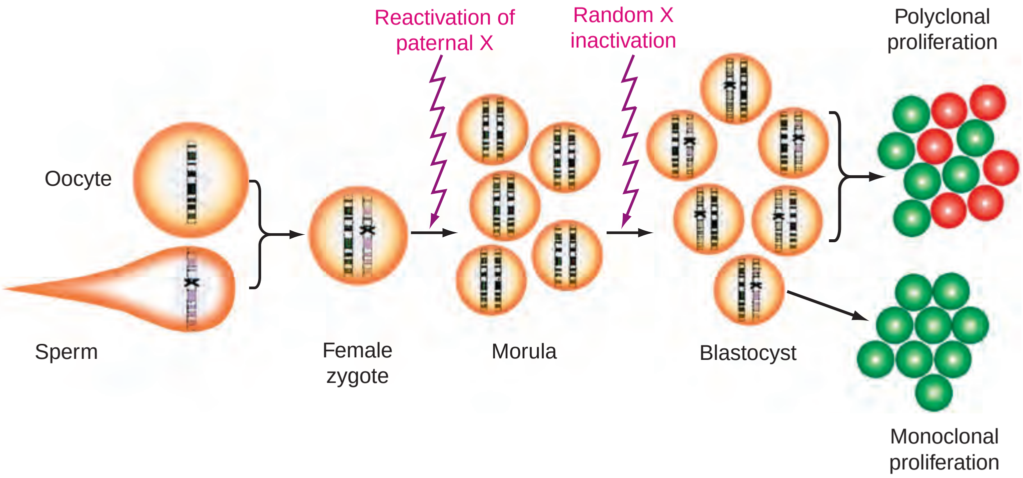

Figure 57.7 X-CHROMOSOME–LINKED ENZYME GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) AS A MARKER TO INVESTIGATE CLONAL DEVELOPMENT OF HUMAN HEMATOPOIETIC DISORDERS. Early in embryogenesis, regions of all but one X chromosome are inactivated in each cell containing two or more X chromosomes. The choice of maternal versus paternal X chromosome for inactivation is random. Once the inactivation occurs, it is fixed and is stably transmitted to daughter cells during mitosis (Lyon hypothesis). Females who are heterozygous for the common B type and the less frequent A type, G6PD (localized on Xq27), are mosaic. This cellular mosaicism is used to study monoclonal versus polyclonal cell proliferation and development of malignant hematopoietic diseases. *(Courtesy Dr. W Raskind, University of Washington, Seattle.)*

The utility of the DNA-based X-chromosome clonal assay is limited to females younger than 60 years because they usually have 1:1 distribution of two-mosaic–cell population. A ratio greater than 3:1 is found in women older than 60 years, probably as a result of stem cell kinetics influenced by X-linked genetic factors. When the ratio of two-cell populations is greater than 3:1, this phenomenon is called a *skewed X-inactivation pattern*. With the HUMARA assay, acquired unequal or skewed X-chromosome inactivation (excessive lyonization) is found in 35% to 40% of women older than 60 years. Thus X-chromosome–based clonality studies must incorporate age-matched controls. More recently acquired somatic mutations using NGS have been useful in documenting clonal hematologic malignancies.

In Utero Mutations and Clonal Origin of Hematologic Malignancies

The observation that monozygotic twins share identical but nonconstitutive and clone-specific fusion gene sequences (e.g., *ETV6-RUNX1*) in pediatric ALL provided the first unambiguous evidence (in 2003) that genetic lesions, generated by chromosomal translocation, arise in utero.[3] These studies initiated by Mel Greaves and his colleagues contributed a wealth of knowledge about founder mutations, subclonal development, clonal origin, and the evolution of disease. The initiating lesion and premalignant clone is shared by the twins as a consequence of intraplacental vascular anastomoses and blood cell chimerism. The twin data were endorsed by backtracking of prenatal-initiating genetic lesions in the archived blood spots, or Guthrie cards, of patients with ALL. These data were interpreted to suggest that *ETV6-RUNX1* was likely a critical initiating lesion for *ETV6-RUNX1*-positive ALL. However, such fusions were detectable in cord blood from newborn infants at rates approximately 100-fold higher than the incidence of ALL, suggesting an obligatory requirement for additional mutations for leukemia development to occur. Over a period of 10 years these results were confirmed and the in utero origin of *MLL*, *BCR-ABL1*, and *RUNX1-RUNXT1* fusion rearrangements further documented, providing direct evidence for a prenatal origin of many childhood leukemias.

Results from genome sequencing of *ETV6-RUNX1* fusion region suggests it arises as a consequence of nonhomologous end-joining in the pro-B-cell stage with possible self-renewal capacity to downstream B-cell precursors. Additional evidence was provided by screening for trisomies in stored cord blood and the data indicated that ~6% of enriched CD34+/CD19+ B progenitor cells carry trisomies frequently seen in hyperdiploid childhood ALL. Using novel SNP as well as other technologies, it has become apparent that ALL has multiple genome copy number variations (CNVs), mostly deletions, and these CNVs are distinctive between a pair of twins, indicating a secondary, postnatal origin.

When genotyping sequencing combined with other molecular technologies of five pairs of monozygotic twins with concordant *ETV6-RUNX1*-positive ALL, Greaves and his colleagues demonstrated that all recurrent CNVs (32 in total) were different within twin pairs providing strong evidence that they are probably secondary events and postnatal in origin in both twins as well as in non-twins with ALL. Another two twin pairs who shared a monochorionic placenta and had Ph-positive ALL, were also studied by Greaves and his colleagues.[3] These studies provided confirmation of the previous observation that *BCR-ABL1* is not sufficient to cause Ph-positive leukemia. Twin A presented with ALL at age 3.8 years and twin B presented at age 4.1 years. Both had an identical *BCR-ABL1* fusion transcript and both received an allogeneic stem cell transplantation from the same matched sibling donor but 7 months later twin B died, whereas twin A remained in good health 8 years following the transplantation. SNP analysis revealed that twin A had a subclone with trisomies for chromosomes 4, 6, 9, 14, 17, and X, tetrasomy 21, and a gain of 22q11.1–q11.23 region, whereas twin B had deletions of *EBF1* and *IKZ1*. These results provide direct evidence that rearrangements additional to *BCR-ABL1* are postnatal in origin, they represent subclonal evolution, and *BCR-ABL1* by itself is not sufficient for development of Ph-positive ALL. Recently two groups have reported, using mathematical models, that some patients' MPNs acquire the *JAK2* mutation in utero.[4]

These mutation-driven natural history studies provide evidence for sequential multistep pathogenesis of hematologic malignancies with sequential accumulation of genetic changes, which may be linear through clonal succession but that clonal evolution in most leukemias is complex and may represent a branching structure, as predicted by Darwin.

Clonal Hematopoiesis of Indeterminate Potential (CHIP) and Age-Related Clonal Hematopoiesis

High-throughput sequencing has provided novel observations which have added to our current understanding of the initial mutations that occur in premalignant stem cells and their clonal development that eventually leads to myeloid malignancies (Chapter 157).

Clonal mosaicism for large chromosomal anomalies (duplications, deletions, and copy number neutral (CN-LOH)), using SNP microarray data from 50,000 subjects in the GENEVA study, indicated that CH is infrequent (<0.5%) from birth until 50 years of age after which its frequency rapidly increases to 2% to 3% of the elderly. It has been estimated that individuals with clonal hematopoiesis (CH) have 10-fold higher risk of developing a subsequent hematologic malignancy. These age-related mutations were confirmed by analysis of mutation acquisition in hematopoietic stem cells, over time, through whole-exome sequencing of single hematopoietic stem cell-derived colonies, which showed that the total number of mutations in healthy individual stem cells increases with age. Therefore, the term CH describes the acquisition of somatic mutations in hematopoietic stem and progenitor cells resulting in clonal expansion in individuals with no overt hematologic disease. Moreover, sequencing of multiple elderly women provided evidence of CH based on X inactivation pattern and recurrent somatic mutation in *TET2* gene. Subsequent analysis of 182 additional elderly women with CH determined that more than 5% of these individuals had mutations in *TET2* (Chapter 157).

Investigation of 82 paired bone marrow and blood samples from carefully selected healthy adult volunteers using a panel of 41 genes known to be mutated in myeloid malignancies, with 1% threshold of detection revealed that bone marrow clones were found in almost 40% of healthy volunteers over 50 years of age. The most frequent mutations included *DNMT3A* and *TET2*. Variant allele frequencies were highly concordant between blood and bone marrow samples.[5]

However, individuals with CH may live for many years and decades without developing hematologic malignancies though they are at increased risk as compared with those without mutations. These studies may explain the higher frequency of myeloid malignancies in the elderly population (Chapter 157).

Loss of Y chromosome

Loss of Y chromosome (LOY) was first described in 1963 in cultured blood leukocytes as a sole cytogenetic abnormality in bone marrow cells which represents one of the most common acquired, post zygotic somatic genomic alterations in elderly men. Approximately 6% of male bone marrow karyotypes from normal individuals and 16% of bone marrow karyotypes with hematologic malignancies show a LOY. The incidence of LOY in bone marrow cells increases proportionally with aging with up to 20% of healthy men over 80 years of age showing LOY using standard G-banding techniques. Mosaic LOY in blood has been reported to be associated with higher risk of all-cause mortality and overall lower life expectancy. LOY has been described most frequently in patients with myelodysplastic disorders and has been reported in MPN, AML, and other myeloid diseases as well as in various solid tumors. Since MDS and MPN are primarily diseases of elderly individuals it is often difficult to separate age-associated LOY from disease-associated LOY. Although the incidence of LOY in MDS is up to 30%, the sole LOY is lower, ranging from 4% to 10%; the WHO does not recognize LOY by itself to be useful in cytogenetically identifying a case of MDS unlike other abnormalities such as del(5q), del(7q), +8, and del(20q).

Recent observations that a higher LOY burden is associated with a higher likelihood for progression to a myeloid malignancy represents the basis for a proposal to include LOY as another form of CH with striking similarities with CHIP. Among 73 studied male patients with sole LOY and a median age of 75 (range 29 to 90), those who had equal or greater than 75% of marrow metaphase cells with LOY had a significantly greater chance of developing a myeloid neoplasm and a higher lifetime incidence of diagnosis of MDS ($P < .0001$). Male individuals with greater than 75% of metaphase cells with LOY also had greater likelihood of having somatic mutations ($P = .0009$) and greater numbers of these mutations ($P = .0002$).[6] The presence of metaphase cells with equal or less than 25% LOY was associated with normal bone marrow morphology and a lower likelihood of progression to MDS. Multivariate analysis showed that these observations are consistent with samples showing 75% or more metaphase cells with LOY are myeloid disease-associated and not related due to aging. Therefore, it has been proposed that LOY represent a marker of CH and as such should be included in the definitions of CHIP in clinical and research settings.

Loss of X chromosome

The relationship between isolated loss of X chromosome (LOX) and aging was first documented in 1995 using interphase FISH method applying to peripheral blood cells of 90 healthy females (age: 1 week to 93 years) with a frequency of 3.2% below 51 years to 5.1% at age 51 to 93 years. This observation was confirmed a few years later in a cohort of 655 females and the frequency of LOX is ranging from 0.07% in patients older than 16 years to 7.3% in individuals older than 65 years. LOX was occasionally reported in BM cells at the frequency of 0.1% of females with the median age of 71.

Acquired trisomy 15 as an isolated abnormality is rarely detected. Approximately 0.1% to 0.2% of elderly patients show +15, frequently in association with LOY. In bone marrow cells, when I-FISH is used, +15 may represent a small clone of up to 24% of nondividing cells but none of these patients developed a myeloid neoplasm after a median follow-up of 28 months (range 0 to 149 months). These observations suggest that +15, like LOY, when present as a small clone is not disease-related but represents an abnormality associated with CH and is most likely age-related.

Chronic Myeloproliferative Neoplasms

The World Health Organization (WHO) characterizes MPNs as clonal stem cell disorders. CML has a unique place among hematologic malignancies and is described separately from the other Ph-negative MPNs.

Chronic Myeloid Leukemia (see Chapter 69)

Knowledge of the origins of CML has accumulated over the last 61 years and serves as a classic example of molecular medicine at its best (Table 57.3). The Ph chromosome is the first example of a specific chromosomal abnormality associated with a malignant disease.[2] *ABL1* and *BCR* genes are the first oncogenes localized at the site of a chromosomal breakpoint in t(9;22)(q34;q11.2). The *BCR-ABL1* fusion leads to a "hybrid" gene, resulting in the production of a dysregulated tyrosine kinase protein. Finally, imatinib mesylate, a specific tyrosine kinase inhibitor (TKI), was the first rationally designed targeted form of cancer therapy.

The Ph chromosome, named in honor of Philadelphia, the city of its discovery, was described for the first time in 1960. It represents a signature genomic rearrangement occurring in more than 95% of patients with CML. Approximately 3% of all pediatric leukemias are Ph-positive CML. The incidence in children increases with age and it is exceptionally rare in infants. The Ph chromosome results from a balanced translocation t(9;22)(q34;q11.2) (Fig. 57.8A–B). The Ph chromosome arises postzygotically, being found only in hematopoietic tissue. The finding of the Ph chromosome in myeloid cells, erythroid

TABLE 57.3 History of Discovery of Philadelphia Chromosome and BCR-ABL1 Fusion

1960	Philadelphia chromosome (Ph) is identified.
1973	Ph is t(9;22)(q34;q11.2).
1983	*ABL1* is translocated from chromosome 9 to chromosome 22.
1984	*BCR* is localized to 22q11.
1987	Ph′ is *BCR-ABL1* fusion.

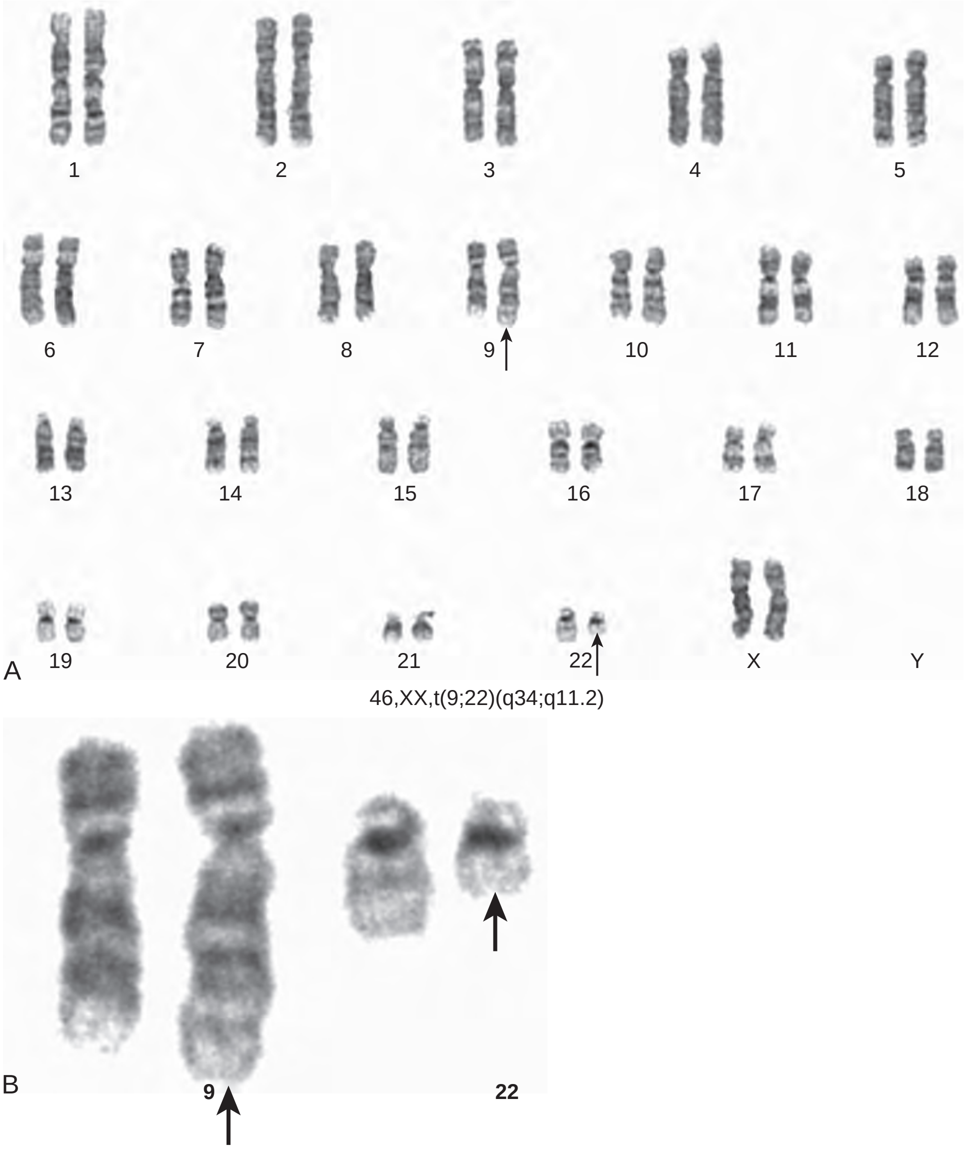

Figure 57.8 (A) The karyotype of a female patient showing a balanced t(9;22)(q34;q11.2), also known as the Ph chromosome. (B) Isolated t(9;22) showing two-thirds of the long arms of chromosome 22 translocated to one homologue of chromosome 9.

cells, eosinophils, monocytes/macrophages, basophils, and B lymphocytes, along with the absence of the Ph chromosome in cultured marrow fibroblasts, supports the concept that the Ph chromosome results from a specific rearrangement in a multipotent hematopoietic stem cell and that it is an acquired rather than an inherited abnormality.[7] Of interest, the Ph chromosome is rarely identified in T cells. T lymphocytes are long-lived cells and may antedate the development of CML. These observations combined with studies exploiting G6PD heterozygosity provide further evidence for the concept that CML is a clonal disease arising in a stem cell capable of differentiation into all hematopoietic cell lineages.

In a review of 1129 Ph-positive patients, the 9;22 translocation was identified in 1036 (92%) cases. Karyotypic analysis of marrow cells in patients with CML is a time-consuming task. However, it demonstrates not only the presence of the Ph chromosome but also the presence of other chromosomal rearrangements (clonal evolution) of clinical significance.

The reciprocal nature of the Ph-positive translocation was confirmed when studies showed that it is the molecular consequence of the translocation of the *ABL1* gene from chromosome 9, band region q34, and subsequent fusion to the breakpoint cluster region (*BCR*) gene on chromosome 22, band q11.2 (Fig. 57.9). This creates a hybrid *BCR-ABL1* gene that is transcribed into a chimeric BCR-ABL1 messenger RNA (mRNA) and translated into a specific chimeric protein.

Three major breakpoint locations along the *BCR* gene on chromosome 22 result in three chimeric proteins. They include $\text{P210}^{\text{BCR-ABL1}}$, $\text{P190}^{\text{BCR-ABL1}}$, and $\text{P230}^{\text{BCR-ABL1}}$ which are associated with three distinct types of leukemia. $\text{P210}^{\text{BCR-ABL}}$ is found in the majority of patients with classic Ph-positive, *BCR-ABL1* fusion-positive CML and approximately 30% of patients with Ph-positive ALL. Expression of $\text{P190}^{\text{BCR-ABL1}}$ is seen in 20% to 30% of adults and 80% of children with Ph-positive ALL. Expression of $\text{P230}^{\text{BCR-ABL1}}$ is associated with a rare indolent chronic neutrophilic leukemia variant and up to 1.6% of CML (approximately 50 patients in the worldwide literature have been described). The most common *BCR-ABL1* isoform results from a fusion of *BCR* exon 13 or 14 (e13/e14) with *ABL1* exon 2 (a2) producing a fusion gene referred to as e13a2 (b2a2) or e14a2(bra2) producing above-mentioned p210 protein. The coiled-coil domain of the *BCR* N terminus facilitates dimerization and constitutive autophosphorylation of the *ABL1* tyrosine kinase domain resulting in subsequent phosphorylation of numerous substrates including the JAK2/STAT CRKL MAPK and P13K/AKT pathways.

Approximately 1% to 2% of Ph-positive patients with CML express both $\text{P210}^{\text{BCR-ABL1}}$ and $\text{P190}^{\text{BCR-ABL1}}$ and their response to TKI therapy

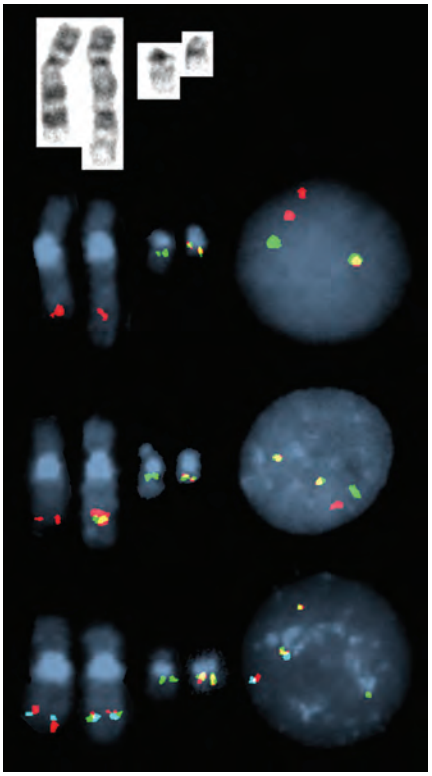

Figure 57.9 CURRENT FISH PROBE STRATEGIES FOR DETECTING *BCR-ABL1* FUSION. Partial karyotype showing the Philadelphia chromosome as a result of t(9;22)(q34;q11.2) *(top row)*. The same chromosomes 9 and 22, as well as a bone marrow nucleus, after hybridization with BCR *(green)* and ABL1 *(red)* using an extra-sensitive dual-color, single-fusion FISH strategy *(second row)*. Chromosomes and a nucleus are counterstained with DAPI *(blue)*. In the extra-sensitive strategy, a part of ABL1 *(red)* remains on der(9) and is shown in interphase nucleus as a smaller red signal, whereas the normal-size ABL1 hybridization signal is seen on normal homolog 9. The other part of ABL1 is on the Ph chromosome and is seen co-localized with BCR as yellow in interphase nucleus. Therefore interphase nuclei will have one normal-size red signal, one smaller-size red signal, one normal-size BCR signal, and co-localization of BCR and ABL1, producing a yellow signal both in interphase cells and metaphase chromosomes. In the dual-color, dual-fusion strategy *(third row)*, there are two co-localized signals on both der(9) and the Ph chromosome, as well as one red signal of ABL1 on chromosome 9 and one green signal of BCR on normal chromosome 22. In the triple-color, dual-fusion strategy, *ASS* gene *(aqua)* is added. It is used to determine whether sequences from der(9) are deleted at the time of the Ph formation. As shown in the fourth row, ASS is localized centromeric from ABL1 on 9q34, and in patients without deletion, ASS is present as two signals in nucleus and on the chromosome 9.

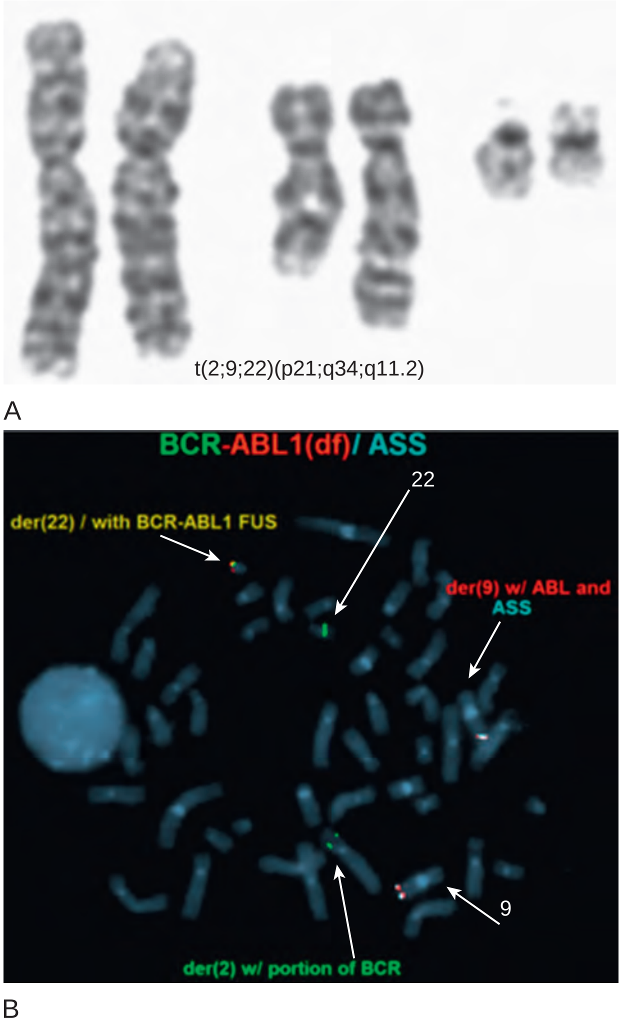

Figure 57.10 (A) Complex Ph translocation. *Top:* A partial karyotype from a patient showing a three-way translocation t(2;9;22) and (B) metaphase FISH *(bottom)* indicating that even in complex karyotype the fusion of *BCR* and *ABL1* takes place on the Ph chromosome or der(22) indicated in *yellow*.

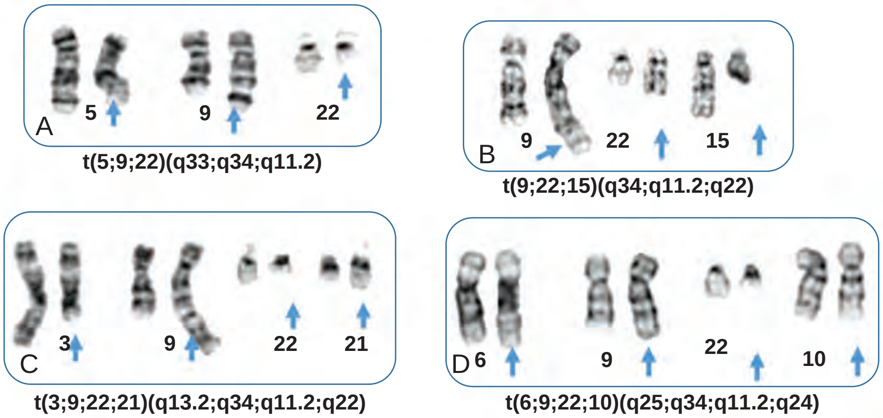
is inferior to patients showing only P210$^{BCR\text{-}ABL1}$. The *BCR-ABL1* fusion is present in both standard and variant forms, in cases where chromosome 9 involvement is cytogenetically not detectable, and when a masked Ph is present. In the majority of patients, the fusion of *ABL1* and *BCR* takes place on chromosome 22 (Fig. 57.10A–B). The *BCR-ABL1* fusion transcript is present in neutrophils, monocytes, eosinophils, erythrocytes, B cells, rarely in T cells, and in CD34+ cells and is associated with increased proliferation of CD34+ myeloid progenitor cells but not of other more mature myeloid precursors.

These observations confirm the hypothesis that CML originates in a multipotent stem cell capable of differentiating to all hematopoietic cell lineages with the exception of T cells. These and other studies provide evidence for the existence of clonal *BCR-ABL1* fusion-negative stage. The formation of *BCR-ABL1* and the Ph chromosome occurs in an already abnormal and genetically unstable clone of pluripotent hematopoietic stem cells. Thus it is the preexisting genetic instability that predisposes to the formation of the Ph chromosome. Once Ph chromosome formation occurs, it confers a further selective growth advantage over normal cells, resulting in overwhelming *BCR-ABL1*-positive, Ph-positive marrow cells at the time of diagnosis of CML.

In 5% to 8% of newly diagnosed patients with CML, the Ph chromosome is present as a 3- or 4-way complex derivative Ph chromosome, always involving chromosomes 9 and 22 as well as an additional one or two chromosomes. In our own laboratory we have observed over many years at least 25 different complex Ph translocations. Three-way translocations are more frequent than 4-way translocations. Some of the examples are the following translocations (Fig. 57.11): t(2;9;22)(p13;q34;q11.2), (9;22;7)((q34;q11.2;p15), t(9;19;22)(q34;p12;q11.2), t(5;9;22) (q35;q34;q11.2), t(9;22;8)(q34;q11.2;p21), t(9;11;22)(q34;p15;p11.2), t(9;22;22) (q34;q11.2;p11.2), t(6;9;22;10)(q25,q34;q11.2;q24), t(7;9;22;22)(q22;q34;q11.2;q13.2), t(6;9;22;11)(q25,q34;q11.2;q13). Most of these complex structural rearrangements are unique but some of them such as t(2;9;22) are recurrent. Moreover, there are less than 1% of CML patients in chronic phase who acquire the t(9;22) clone abnormalities as well as t(8;21), inv(16), t(11q23), t(15;17), and t(3;3) that are associated with AML. In one recent retrospective study among 1382 Ph-positive patients 0.36% of patients had co-occurrence of these abnormalities and most of them progressed to accelerated or myeloid blast crisis.

In about 3% to 5% of patients with CML who are Ph-negative by cytogenetic studies, the clonal and stem cell origin of these hematologic malignancies can still be demonstrated, and molecular analysis reveals the *BCR-ABL1* fusion in approximately 1%



t(5;9;22)(q33;q34;q11.2)

t(9;22;15)(q34;q11.2;q22)

t(3;9;22;21)(q13.2;q34;q11.2;q22)

t(6;9;22;10)(q25;q34;q11.2;q24)

Figure 57.11 PARTIAL KARYOTYPES FROM 4 PATIENTS SHOWING 3- AND 4-WAY Ph TRANSLOCATIONS IN CHRONIC MYELOID LEUKEMIA. *Blue arrows* show abnormal chromosomes. (A) In this t(5;9;22) 3-way translocation a distal segment of the Ph chromosome from 22q was first translocated to chromosome 5, band q33 and the subsequent translocation was between the 5q33 and 9q34 segment. (B) In the t(9;22;15) abnormality there was a traditional first translocation between 9 and 22, followed by the second rearrangement involving 15q22 segment translocated to chromosome 9. (C) In the 4-way translocation involving chromosomes 3, 9, 22, and 21, long arms of chromosome 3 moved to the long arms of chromosome 9 while part of chromosome 22 moved to the long arms of chromosome 21. (D) t(6;9;22;10) has been rarely but recently observed in which a part of 6q moved to the already t(9;22) while part of 10q moved to the long arms of chromosome 6.

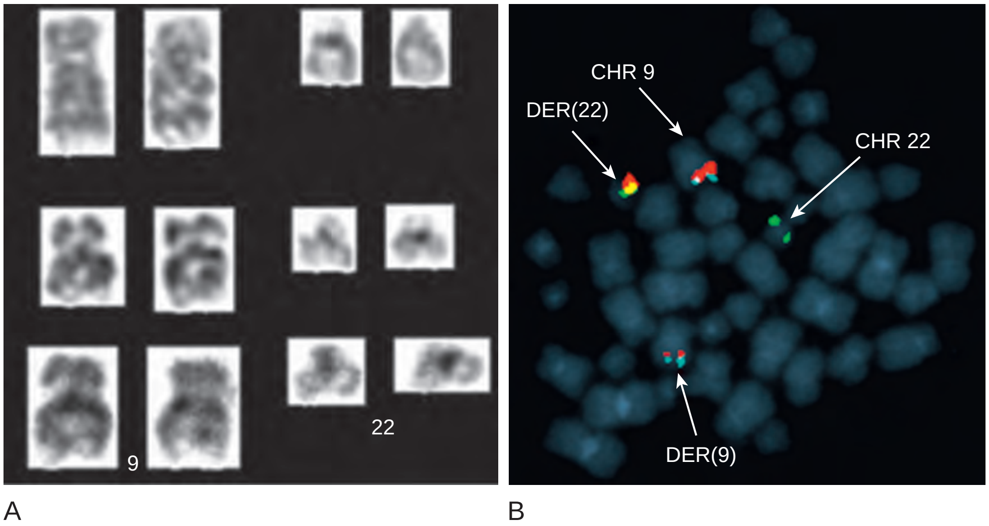


Figure 57.12 *BCR-ABL1* FUSION IN A PATIENT WITH THE Ph-NEGATIVE, NORMAL KARYOTYPE. *Left panel* shows a partial karyotype from three cells showing normal homologs 9 and 22. The *right panel* shows the *BCR-ABL1* fusion *(yellow)* on der (22) and diminished *ABL (red)* on der(9). The fusion has occurred as a result of *ABL1* insertion into *BCR* without apparent chromosomal translocation. Note an intact ASS *(aqua)* on both chromosomes 9.

(Fig. 57.12). These patients have chromosomal insertions resulting in *BCR-ABL1* fusion which can occur in multiple ways. Approximately 70% of cases exhibit *BCR-ABL1* fusion located on a chromosome 22, which was either a cryptic der(22), or "cryptic Ph" or non-cryptic der(22) or "masked Ph." The remaining cases have *BCR-ABL1* fusion located on a cryptic or non-cryptic der(9). Of the 119 such cases reported in literature 77 patients (64.7%) had an insertion-derived *BCR-ABL1* fusion as a cryptic or a masked Ph. This type of *BCR-ABL1* fusion does not influence OS of these CML patients. In the majority of Ph-negative patients, an *ABL1* insertion from chromosome 9 to 22q11.2 results in a *BCR-ABL1* fusion product without reciprocal translocation of sequences from chromosome 22 to chromosome 9. Sizes of the inserts can vary, which may be closely related to the morphological appearance of the chromosomes with the *BCR-ABL1* or those involved chromosomes without the *BCR-ABL1*. Intensive FISH mapping using many probes targeting *ABL1*, *BCR*, and their flanking regions determined that a classic t(9;22) usually involves an exchange of approximately 10 MB of 9q (from the *ABL1* to the 9q telomere) and ~25 MB of 22q (from *BCR* to the 22q telomere).

Approximately 2% of patients truly are Ph-negative and *BCR-ABL* fusion-negative. These patients may not have CML but rather another MPN (Chapter 71). The concept that the *BCR-ABL1* fusion plays a central role in the pathogenesis of CML is strongly supported by two lines of evidence: (a) retroviral transduction experiments in which P210$^{BCR-ABL1}$ is expressed in murine marrow cells, resulting in an MPN resembling CML, and (b) the fact that imatinib, a TKI, selectively inhibits the BCR-ABL1 fusion protein in mice and specifically inhibits the growth of human Ph-positive cells in vitro and in vivo. Although considered necessary, *BCR-ABL1* may not be the initial event or be sufficient to cause the malignant transformation resulting in CML (see earlier section on clonal origin).

PCR analysis can determine the exact breakpoints of DNA fusion products. Reverse transcriptase PCR (RT-PCR) and Northern blot analysis allow detection of *BCR-ABL1* transcripts at the RNA level. Current FISH studies can detect *BCR-ABL1* fusion at diagnosis

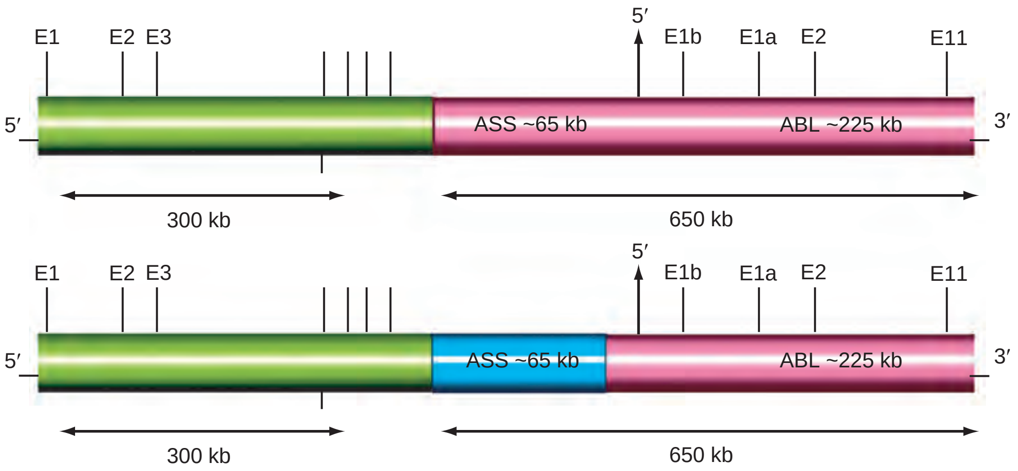

Figure 57.13 SCHEMATIC REPRESENTATION OF THE MOST FREQUENTLY USED BCR-ABL PROBES. Dual-color/single-fusion extra-sensitive probe strategy, as indicated in text, uses a 650-kb probe in which two loci, *ABL* and *ASS*, both are labeled in red. *BCR-ABL* fusion-positive nuclei show three red signals: one small red signal on der(9), one red signal on normal homologue 9, and a third red signal in fusion with *BCR*. When a triple-color probe is applied, the *ASS* locus usually is labeled in aqua and the BCR-ABL fusion-positive cells show two aqua signals, unless there is deletion of der(9). The most useful application of triple-color probe is documentation of deletion of derivative chromosome 9.

using a dual-color *BCR-ABL1* ES probe or *BCR-ABL1* dual-fusion probe (see Fig. 57.12, see also Fig. 57.9). A triple-color *BCR-ABL1-ASS* probe is used for detection of deletions on both chromosomes 9 and 22 (Fig. 57.13). Approximately 12% to 15% of patients with CML have large deletions adjacent to the Ph chromosome translocation breakpoint on the derivative 9 chromosome. These deletions are heterogeneous and may involve both chromosomes 9 and 22 (majority of cases), only chromosome 9 (8% of patients with deletions), or only chromosome 22 (4% of cases with deletions). Moreover, deletion size is variable, ranging from 0.5 Mb to greater than 10 Mb. A more refined study applying SNP microarrays revealed three common deleted regions: (1) a 162-kb loss at 9q34, (2) a 138-kb deletion at 22q11.2, and (3) a 102-kb deletion at 22q11.2. It appears that the partial deletion of the *ABL1-BCR* fusion on derivative 9 chromosome occurs as a part of the same process as the formation of the *BCR-ABL1* translocation. Before imatinib therapy, these deletions were associated with an adverse prognosis; however, in a study of 521 patients with CML, the cumulative incidence of complete cytogenetic responses and major molecular responses and the overall survival (OS) were comparable after 5 years of follow-up between CML patients with and without the del(9q).

At diagnosis, conventional cytogenetics remains the gold standard because the chromosome analysis will identify not only the t(9;22) but also other chromosomal abnormalities that may indicate accelerated or blast phase of the disease or clonal proliferation of Ph-negative cells.

Imatinib mesylate (Gleevec) has revolutionized therapy for CML and, for most patients, has transformed a deadly disease into a chronic disorder that is compatible with normal life. The standard method for monitoring a patient's response to therapy is conventional cytogenetic analysis of cells obtained from a marrow aspirate. In the phase III international Randomized and STI-571 (IRIS) study, 89% of patients had Ph-negative marrow aspirates as determined by conventional cytogenetics after 5 years of treatment. However, conventional cytogenetics has limited sensitivity. The degree of MRD is determined to be an important prognostic factor for patients with CML on therapy. Patients with CML without a discernible Ph chromosome detected by conventional cytogenetics analysis may still harbor up to 10^{10} leukemic cells.

Interphase FISH does not depend on the cycling status of cells, and use of double-fusion probes has reduced false-positive results to approximately 1%. However, if peripheral blood cells rather than marrow aspirate cells are used to monitor MRD, the high percentage of *BCR-ABL1* fusion-negative lymphoid cells may underrepresent the actual residual tumor load. In most direct comparison studies, interphase FISH of peripheral blood compared with conventional cytogenetics of marrow in patients who are treated with imatinib showed good correlations ($r = 0.91$ to 0.97). Real-time quantitative PCR (RQ-PCR) is by far the most sensitive method for detecting MRD. It provides an accurate measure of the total leukemia cell mass and the degree to which *BCR-ABL1* transcripts are reduced by therapy, and it correlates with progression-free survival.

The goal of therapy in CML is to achieve a molecular remission as measured by the reduction or elimination of *BCR-ABL1* transcripts. In the IRIS study, at 5-year follow-up, complete cytogenetic response combined with major molecular response at 12 months was associated with a 97% progression-free survival rate. This compares with an 89% progression-free survival for those with complete cytogenetic response but without a major molecular response. Current international recommendations for optimal molecular monitoring of patients receiving imatinib treatment includes an RQ-PCR assay expressing the *BCR-ABL1* transcript levels on an internationally agreed upon scale. The term major molecular response corresponds to ≤0.0% BCR-ABL1, whereas the designation complete molecular response should be used only for patients with undetectable *BCR-ABL1*, where the limit of detection is confirmed to be at least a 4.5 log reduction from baseline levels. The two major obstacles to successful imatinib-based therapy for patients with Ph-positive, *BCR-ABL1* fusion-positive CML are the persistence of *BCR-ABL1* fusion-positive cells and relapse of the disease because of emergence of resistance to imatinib. Acquired resistance to imatinib treatment can be due to two events: amplification of *BCR-ABL1* fusion product (Fig. 57.14) and mutations in the ABL kinase domain. Currently, 100 different ABL1 kinase domain mutations have been described, although only about 15 are common and account for more than 85% of all mutations detected.

Patients with CML who cannot tolerate or are resistant to imatinib may benefit from the second and now third generation of TKIs (Chapter 69) such as dasatinib, nilotinib, bosutinib, and ponatinib. These agents bind to the ABL kinase domain in a matter distinct from that of imatinib and thereby retain activity against nearly all imatinib-resistant mutations. Recent meta-analysis revealed ABL mutation rates with imatinib 9.7%, dasatinib 1.7%, nilotinib 3.3%. The most common specific mutations were T315I, E255k, and M315I. T315I mutations constitute 58% of dasatinib-related mutations and 13% of imatinib-related mutations. These mutations inhibit the binding of the TKIs, hindering the treatment of patients with CML. The introduction of ponatinib, a new formulation of TKI, has been shown to overcome resistance incurred by the T315I mutation (see Chapter 69).

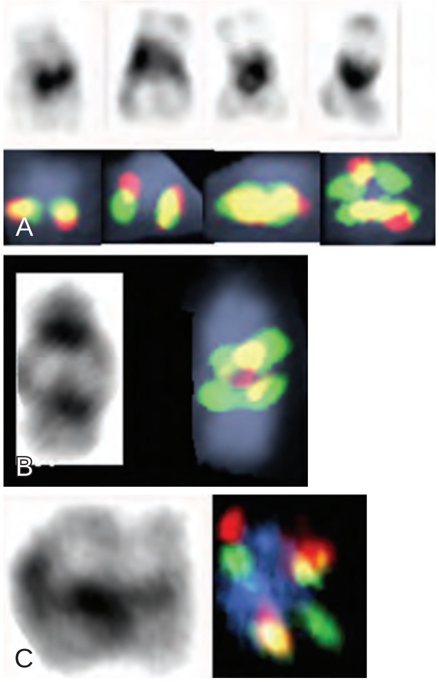

Figure 57.14 EXAMPLES OF UNUSUAL Ph CHROMOSOME ASSOCIATED WITH IMATINIB RESISTANCE AND BLAST CRISIS OF CHRONIC MYELOGENOUS LEUKEMIA. (A) Amplification of the Ph chromosome *(top row)* and the BCR-ABL fusion in a patient treated for 3 months with imatinib. The patient developed five copies of the Ph chromosome and five copies of the BCR-ABL fusion *(yellow)*. (B) G-banding of dicentric Ph chromosome *(left)* dic der(22)t(9;22)(q34;q11.2) and after FISH studies *(right)* showing two copies of BCR-ABL fusion. (C) G-banding of isoderivative Ph, ider(22)t(9;22)(q34;q11.2) *(left)* and after FISH studies showing two copies of BCR-ABL fusion *(yellow)* on the end of both arms. *FISH*, Fluorescence in situ hybridization.

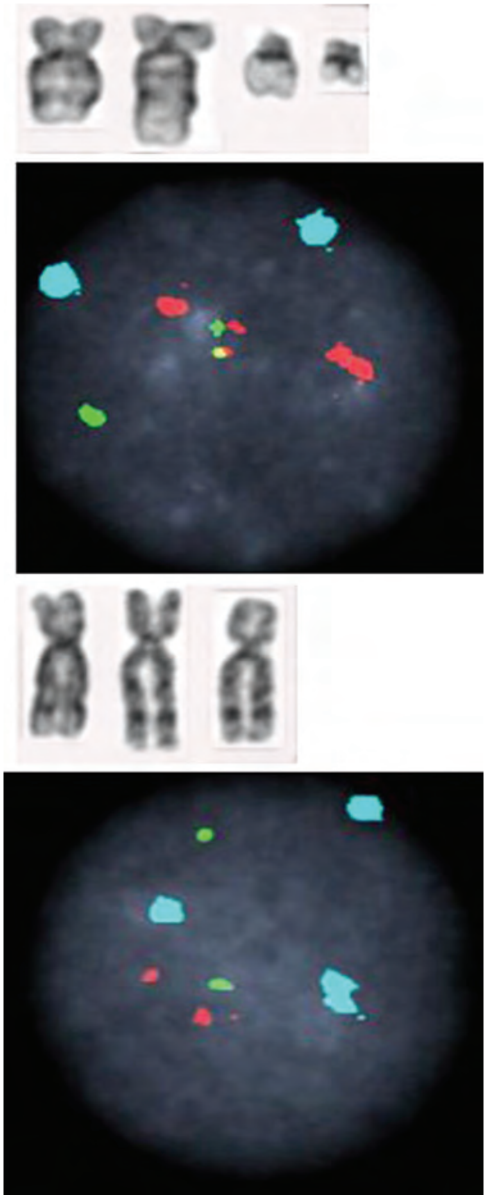

Figure 57.15 TWO DIFFERENT CELL POPULATIONS FROM A PATIENT TREATED WITH IMATINIB. One population shows t(9;22) (*top row*, partial G-banded karyotype) and the BCR-ABL fusion signal *(yellow, second row)* as well as disomy 8 *(aqua)*. In contrast, the second population shows trisomy 8 (*third row*, partial G-banded karyotype) in the BCR-ABL fusion-negative cells *(fourth row)*, showing disomy for the *BCR (green)*, ABL *(red)*, as well as trisomy for chromosome 8 *(aqua)* (see text for details).

Between 5% and 8% of patients undergoing treatment with imatinib will develop additional chromosomal abnormalities (ACAs) such as trisomy 8, monosomy 7, del(20q), and other anomalies in *BCR-ABL1* fusion-negative cells. Imatinib may induce chromosomal abnormalities in BCR-*ABL1*$^{-}$ cells. Alternatively, imatinib may uncover chromosomal abnormalities present before therapy after significant reduction of Ph-positive cells has occurred (Fig. 57.15). Presence of +8 and other chromosomal anomalies in Ph-negative cells in patients treated with imatinib suggests that CML has a multistep pathogenesis and that clonal Ph-negative cells precede the development of the Ph-positive clone (Fig. 57.16). This important observation about the pathogenesis of CML demonstrates the power of conventional cytogenetics, even in the era of molecular assays, and should be used at least annually while patients are undergoing TKI treatment. This hypothesis that clonal development occurs in Ph-negative cells before development of the Ph chromosome was recently confirmed using NGS by targeting 25 genes frequently mutated in myeloid disorders. Ph-negative clones were analyzed in 14 patients who developed clonal cytogenetic abnormalities during TKI treatment. Mutations affecting *DNMT3A*, *EZH2*, *RUNX1*, *TET2*, *TP53*, *U2AF1*, and *ZRSR2* were detected in 43% of these patients. In two patients, the mutations were also found in corresponding Ph-positive diagnostic samples. Moreover, somatic mutations in addition to *BCR-ABL1* affecting *ASXL1*, *DNMT3A*, *RUNX1*, and *TET2* genes are found in 33% of patients. When individual hematopoietic colonies were analyzed from patients with CML at diagnosis, most mutations were present in the Ph-positive cells. By contrast, NGS of subsequent samples during TKI treatment revealed that one *DNMT3A* mutation occurred in Ph-negative cells that was also present in Ph-positive cells at diagnosis, strongly implying that *DNMT3A* preceded the appearance of the *BCR-ABL1* rearrangement which provides support for the initial hypothesis that *BCR-ABL1* and the formation of the Ph chromosome were not the initiating events in the pathogenesis of CML. Another example of clonal evolution in MPNs evolving over time is the co-occurrence of the *JAK2V617F* mutation and *BCR-ABL1*. These rare patients usually have a long (10 to 20 years) history of *JAK2V617F*+ polycythemia vera (PV) before *BCR-ABL1* and the Ph chromosome is acquired. Single cell genotyping revealed that both *JAK2V617F* and *BCR-ABL1* can occur concurrently in hematopoietic stem cells and that *JAK2V617F*+ occurs before the acquisition of *BCR-ABL1*. The contribution of *BCR-ABL1* to disease progression appears to be greater than that of *JAK2V617F*, since these patients display a clinical phenotype that is consistent with CML rather than PV. Recent studies have demonstrated the presence of somatic mutations in *TET2*, *DMNT3A*, and *ASXL1* in both diagnostic and/or follow up remission CML specimens implying evolution within the Ph-negative clone and indicating that these mutations are early events

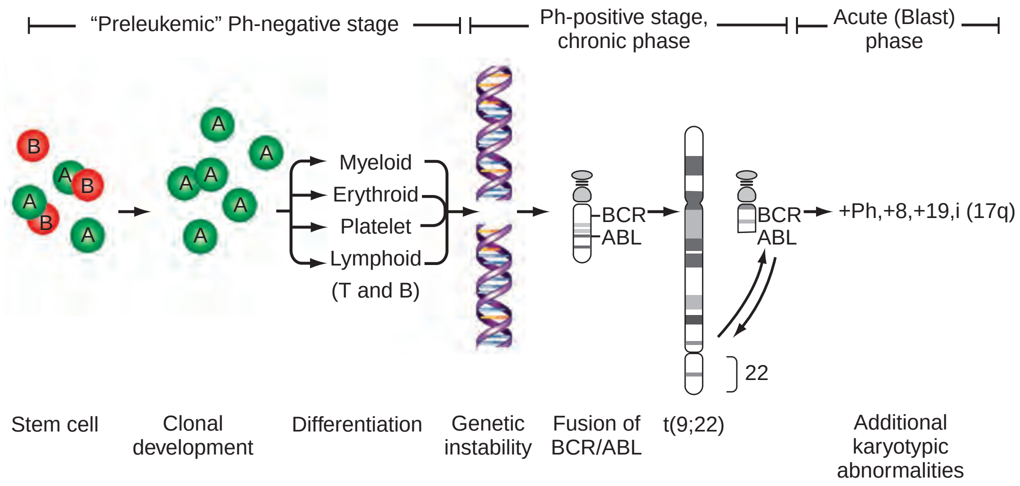

Figure 57.16 HYPOTHETICAL MODEL OF MULTISTEP PATHOGENESIS OF Ph-POSITIVE CHRONIC MYELOGENOUS LEUKEMIA. The first detectable event is a clonal proliferation of cells that are capable of differentiating to all hematopoietic lineages. These cells are genetically unstable and give rise to BCR-ABL fusion and the Ph chromosome. The blast crisis is characterized by nonrandom abnormalities occurring in a genetically unstable Ph-positive clone. At least six events can be delineated. *(Courtesy Dr. W Raskind, University of Washington, Seattle.)*

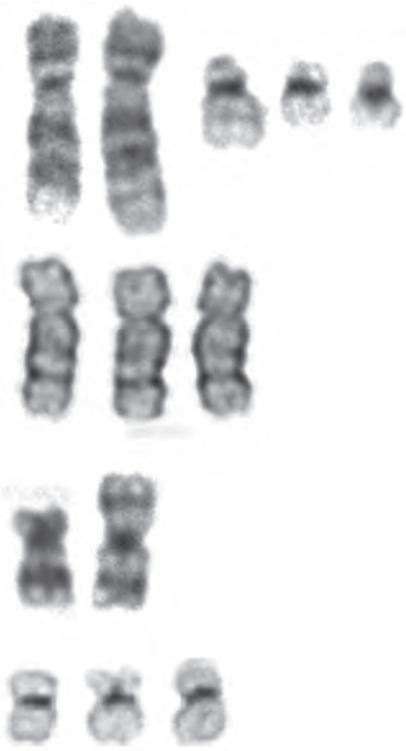

Figure 57.17 THE FOUR MOST FREQUENT ABNORMALITIES ASSOCIATED WITH THE BLAST CRISIS OF CHRONIC MYELOGENOUS LEUKEMIA. Duplication of the Ph chromosome *(top row)* is identified in about 30% of patients, trisomy 8 *(second row)* is found in 30%, isochromosome of the long arms of chromosome 17 *(third row)* is found in 20%, and gain of chromosome 19 *(fourth row)* is seen in approximately 12% of patients with blast crisis of chronic myeloid leukemia.

which preceded formation of the *BCR-ABL1* gene. The mechanism of transformation to advanced-phase CML is complex and varied and remains poorly understood.[8] In myeloid blast crisis (70%) of CML patients show karyotypic evolution, that is, new chromosomal abnormalities in very distinct patterns in addition to the Ph chromosome. The most common abnormalities include gain of chromosome 8 (33%) or +19 (12%), gain of a second Ph chromosome (30%), i(17q)(20%), alone or in combination, to produce modal chromosome numbers of 47 to 50 (Figs. 57.17 and 57.18). In males, LOY is frequently observed. Isochromosome 17q occurs almost exclusively in myeloid blast crisis. Other less frequently observed abnormalities include monosomy of chromosomes 7 and 17, and trisomy of chromosomes 17 and 21. In addition to these common karyotypic evolutions, additional chromosomal aberrations specific for AML—for example, t(8;21) (Fig. 57.19), inv(16), t(3;21)(q26;q22), and most frequently, inv(3q)/t(3;3), resulting in the overexpression of *MECOM (EVI1)*—have been observed. Simultaneous presence of t(9;22) and inv(3) at diagnosis or following TKI therapy appears to be associated with a lack of response to treatment and a clinical course is similar to that of cases with inv(3) without any other chromosomal abnormality. In patients treated with TKI, these ACAs have been classified into two groups based on their impact on survival. ACAs in the Good prognostic group include trisomy 8, LOY, and an extra copy of the Ph chromosome. The second group includes chromosomal abnormalities that are associated with a relatively poor prognosis including i(17q), −7/del(7q), and 3q26.2 rearrangements. The concurrent presence of two or more ACAs was associated with an inferior survival. A prospective study of 1551 imatinib-treated chronic phase patients (German CML-study IV) defined more precisely a high-risk and a low-risk group based on the presence of ACAs. High-risk chromosome abnormalities and their impact on survival included +9,+Ph, i(17q),+17,+19, 3q26.2, 11q23, −7/del(7q), and a complex karyotype, while the low-risk group included all other karyotypic changes. High-risk abnormalities were observed in 6% of patient during chronic phase but in 61% of patients who progressed to blast crisis while low-risk chromosome abnormalities were observed in 21% during CP and in 2.8% of patients who progressed. Most importantly, this study demonstrated that the combination of high-risk cytogenetic abnormalities and a low-level blast cell count (1% to 5%) was associated with disease progression and death from CML. Therefore, additional high-risk chromosomal abnormalities are an early marker of CML progression even when present in patients with low numbers of blast cells.

Complete cytogenetic remission for patients in accelerated phase or blast crisis CML treated with imatinib is rarely accompanied by a normal karyotype; however, 6% to 17% of these patients may have some cytogenetic response (see box on Genetic Testing for Chronic Myeloid Leukemia).

High-resolution cytogenomic studies have demonstrated that in contrast to the chronic phase CML (which is characterized only by genomic imbalances in or around *BCR* and *ABL1*, specifically deletions), during the blast phase, many additional genomic imbalances

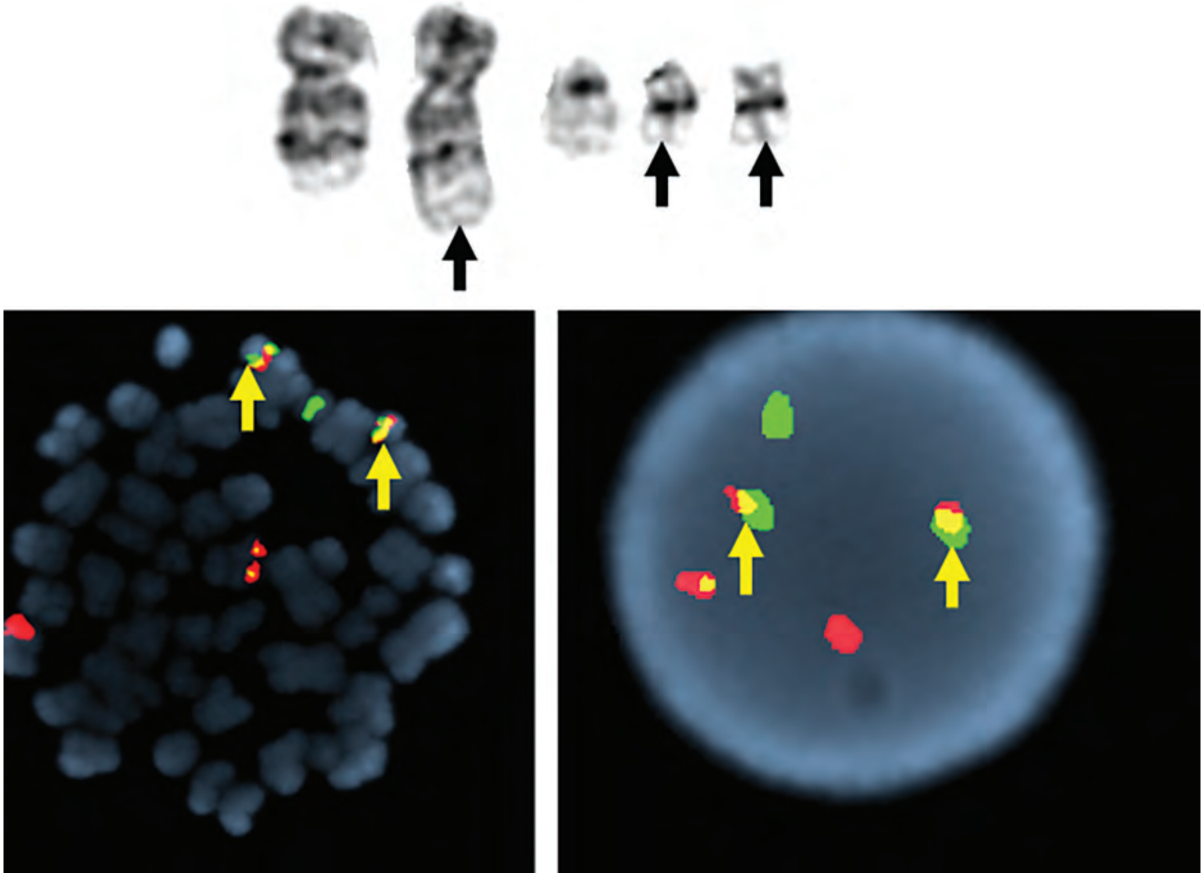

Figure 57.18 BLAST CRISIS OF CHRONIC MYELOID LEUKEMIA. A partial karyotype at the diagnosis of the blast stage of CML was 47,XX,t(9;22)(q34;q11.2 +der(22)t(9;22). The partial karyotype shows two copies of the Ph chromosome as well as one copy on 9q+ *(black arrows)*. Bottom left panel shows two copies of the *BCR-ABL1* fusion on the two Ph chromosomes after FISH hybridization with the dual-color extra sensitive BCR-ABL FISH probe *(yellow arrows)*. The bottom right panel shows bone marrow interphase cells with two fusion signals *(yellow) (yellow arrows)*. Note a tiny bit of yellow signal at the edge of a big red (ABL) signal, consistent with the ES probe to reduce the number of false positive cells. *CML*, Chronic myeloid leukemia; *FISH*, fluorescence in situ hybridization.

GENETIC TESTING FOR CHRONIC MYELOID LEUKEMIA

At diagnosis of CML, perform quantitative cytogenetic analysis using the bone marrow aspirate, which is the sine qua non because peripheral blood cells rarely contain sufficient numbers of mitotic cells at the time of presentation. If the bone marrow aspirate is a "dry tap," perform interphase FISH using a BCR-ABL1 extra-sensitive dual-fusion color probe. According to the ELN 2020 and British Society of Haematology 2020 recommendations, a full bone marrow karyotype is important also to determine the phase of the disease. Their recommendations also include mandatory molecular work to identify the BCR-ABL1 fusion transcript type for molecular monitoring to guide future management. To monitor patients with CML during therapy, use FISH of blood or bone marrow to track changes in the percentage of cells with BCR-ABL1 fusion at 3-month intervals. If the molecular assay demonstrates BCR-ABL1, but the Ph cannot be identified by cytogenetics, a FISH test is required. Once the patient is in complete cytogenetic and FISH remission, the consensus recommendation is to perform real-time quantitative polymerase chain reaction and to follow the patient at 3-month intervals until molecular remission is achieved. According to ELN 2020 recommendations, greater than 10% BCR-ABL1 at 3 months indicates treatment failure. BCR-ABL1 transcript level at less than 0.1% is defined as major molecular response remission. Early indicators of progression are the appearance of additional chromosomal abnormalities and somatic mutations. At relapse, perform a cytogenetic analysis to assess the karyotype of the malignant clone and to determine if a new chromosomally abnormal clone has developed or a new subclone has evolved from the Philadelphia chromosome–positive clone.

occur. Using aCGH, 44 patients in chronic phase CML as well as 11 in myeloid and in lymphoid blast crisis were investigated, and a spectrum of recurrent genomic imbalances was associated with disease progression, including losses at 1p36, 5q21, 9p21, and 9q34 and gains at 1q, 8q24, 9q34, 16p, and 22q11. The most common mutations in myeloid blast phase involve tumor suppressor gene *TP53* (about 25% of cases) and the *RUNX1* in about 40% of cases. Moreover, the *MYC* oncogene has been recently linked to *BCR-ABL1* activity and CML progression to myeloid blast crisis. Recently, mutations in genes frequently found in Ph-negative MPNs such as *CBL*, *TET2*, *ASXL11*, and *IDH1/2* were also identified in patients in accelerated/blast phase. Additionally, deletions of *RB1*, gain of function mutations in *GATA-2* and *RAS* are just some of the spectrum of cytogenomic changes characterizing progression of CML.

Patients with CML may present initially in lymphoid blast crisis mimicking Ph-positive B-cell ALL. Although both the CML and Ph-positive ALL (see later) are driven by the constitutively active *BCR-ABL1* tyrosine kinase, their prognoses differ significantly and it is important to differentiate these two entities. Cytogenomic analysis of 78 CML patients in lymphoid blast crisis demonstrated a unique signature of genomic deletions within the Ig heavy-chain and *TCR* genes, indicating that their presence is essential for the development of a malignant clone with a lymphoid phenotype. Moreover, 50% of patients in lymphoid blast crisis had mutations in cyclin-dependent kinase inhibitor *CDKN2A*, 25% to 35% in *RUNX1*, and ~15% to 25% have mutation in the *BCOR* gene, which interacts with histone deacetylates, a known apoptosis regulator. One of the most important

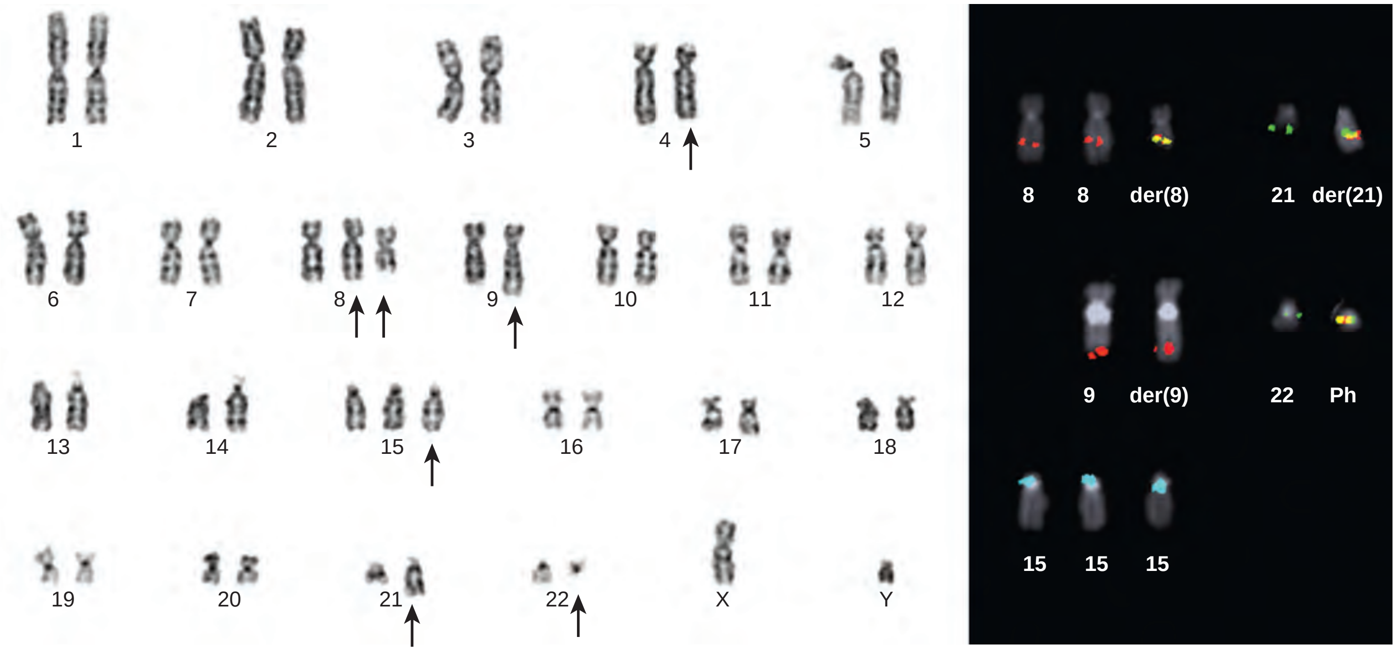

Figure 57.19 SIMULTANEOUS DETECTION OF t(9;22) AND t(8;21) IN A PATIENT WITH BC-CML. A karyotype *(left)* from a patient with chronic myelogenous leukemia who failed three tyrosine kinase inhibitor treatments and progressed into blast crisis showing 46,XY, del(4)(q31q33), t(8;21)(q22;q22), +8, t(9;22)(q34;q11.2), +15. Metaphase FISH studies *(right panel)* confirmed that the BCR-ABL1 fusion-positive cells *(middle row, yellow* co-localization), the patient had RUN1-RUNXT1 fusion as a result of t(8;21) [*yellow* signals on der(8) and der(21)] and a gain of chromosome 8 *(top row)* as well as trisomy 15 *(bottom row)* as shown using centromeric FISH probe specific for chromosome 15 *(aqua)*. *CML*, Chronic myeloid leukemia; *FISH*, fluorescence in situ hybridization.

differences between lymphoid and myeloid blast crisis is the exclusive interaction with STAT proteins. STAT1 is activated mainly by p190, while STAT3 and STAT5 are preferentially activated by the P210 isoform.

The precise causes and mechanisms responsible for CML progression are still elusive and current thinking is that progression of CML is the result of increased and complex genomic instability combined with heterogeneity of numerous coexisting mutations and signaling disruptions causing defective or an insufficient ability to repair DNA.

Ph-Negative Chronic Myeloproliferative Neoplasm

Ph-negative MPNs are disorders arising in a single clone of multipotent precursor cells in which one or all myeloid lineages are abnormally amplified. Classic and more frequently encountered Ph-negative MPNs include PV, primary myelofibrosis, and essential thrombocytopenia (ET). Their cytogenetic and genomic profiles are described in Chapters 70–73. However, included in this chapter are Fig. 57.20A and B and 57.21 in order to illustrate the most frequent abnormalities associated with the Ph-negative MPN. Different 9p chromosomal abnormalities result in *JAK2* numerical gain (see Fig. 57.20) while nine examples of 1q gain, associated with disease progression, are shown in Fig. 57.21.

Less frequently encountered similar disorders include chronic neutrophilic leukemia (Chapter 72), hypereosinophilic syndrome/chronic eosinophilic leukemia (Chapter 74), systemic mastocytosis (Chapter 75), atypical CML, and unclassifiable MPNs (Chapters 72–75). Rare recurrent balanced abnormalities in atypical Ph-negative MPNs can involve the *PDGFRB* gene localized at 5q33, *FGFR1* gene on 8p11, and *PDGFRA* gene on 4q12. The best described are t(5;12)(q33;p13), resulting in *ETV6-PDGFRB* fusion protein, and t(8;13)(p11;q12), resulting in the *ZNF198-FGFR1* fusion gene. The disorder known as *8p11 myeloproliferative syndrome* has been classified by WHO as belonging to the group of myeloid/lymphoid neoplasms associated with eosinophilia and gene rearrangements. Some of these diseases are related to fusion genes between *FGFR1* located on 8p11 and various translocations fusing at least 14 different 5′ partner genes to the 3′ part of the *FGFR1* gene that encodes tyrosine kinase domain (Table 57.4). They include *TPR* (1q25), *LRRFIP1* (2q37), *SQSTM1* (5q35) *FGFR10P* (6q27), *TRIM24* (7q34), *CUX1* (7q22), *PLAG1* (8q12), *CEP110* (9q33), *NUP98* (11p15*), FGFR1OP2* (12p11), *CPSF6* (12q15), *ZMYM2* (13q12), *MYO18A* (17q23), *HERVK* (19q13), and *BCR* (22q11) (Fig. 57.22). The most frequent translocation is t(8;13), and cases with the submicroscopic deletion of the 5′ part of the *FGFR1* gene have also been reported, similar to the formation of t(9;22) with deleted sequences from der(9q) and/or 22q identified in CML. The presence of 8p11 abnormalities in both myeloid and lymphoid cells suggests its origin from a common stem cell.

In patients with chronic eosinophilic leukemia/hypereosinophilic syndrome (Chapter 74) the most frequent recurrent abnormality is the cryptic deletion on 4q12 as a result of *FIP1L1-PDGFRA* fusion gene reported to occur in from 3% to 56% of cases. The disparity in frequencies reflects differing levels of stringency criteria in the diagnosis of disorders with hypereosinophilia as well as different technologies used for detection of *FIP1L1-PDGFRA* fusion. An investigation of 376 patients with persistent unexplained hypereosinophilia revealed an 11% incidence of the *FIP1L1-PDGFRA* fusion gene detected using highly sensitive RQ-PCR. Patients with *FIP1L1-PDGFRA* fusion are characterized by a male predominance, marrow fibrosis, increased number of mast cells, elevated serum tryptase levels, and a favorable response to low doses of imatinib. Most of these patients have a normal karyotype because a cryptic deletion of *CHIC2* locus on 4q12 which is only 800 kb in size. This abnormality is detectable using a more sensitive FISH technology and RQ-PCR in the majority of cases. Moreover, the commercially available tricolor FISH probe will detect not only deletion 4q12 as a result of *FIP1L1-PDGFRA* but also a rare *BCR-PDGFRA* fusion resulting from the t(4;22)(q12;q11.2) rearrangement (Fig. 57.23). Serial monitoring with RQ-PCR demonstrates exquisite sensitivity of *FIP1L1-PDGFRA*-positive patients to low-dose imatinib treatment (Chapter 74). The *FIP1L1-PDGFRA* has also been detected in histopathologically defined cases of systemic mastocytosis with associated eosinophilia, and in cases of AML and T-cell lymphoblastic lymphoma associated with eosinophilia. In an Italian prospective cohort of 27 patients with *FIP1L1-PDGFRA* who were treated with imatinib, a complete hematologic response was achieved within 1 month and all patients became PCR-negative for *FIP1L1-PDGFRA* after a median of 3 months (range 1 to 10 months). In contrast to CML, very few cases of acquired imatinib resistance have been reported. Those rare reported cases had a mutation in T674I within the ATP-binding domain of PDGFRA, analogous to the T315I mutation in CML.

Although translocations involving *PDGFRB* at 5q32 region have been identified with 22 different fusion partners, they are indeed very rare. Any patient with a 5q31–q33 chromosomal abnormality with or without eosinophilia should be investigated for *PDGFRB* rearrangements by FISH testing (Fig. 57.24).

Once the *PDGFRA, PDGFRB*, and *FGFR1* rearrangements are excluded, the only other recurrent secondary abnormalities include trisomy 8 and trisomy 21 (see box on Genetic Testing for Ph-Negative Myeloproliferative Neoplasms).

GENETIC TESTING FOR Ph-NEGATIVE MYELOPROLIFERATIVE NEOPLASMS

At diagnosis, perform a real-time alleles-specific polymerase chain reaction for JAK2V617F, as well as mutational studies for CALR and MPL. Cytogenetic analysis of marrow cells is recommended for patients with essential thrombocytopenia and polycythemia vera. Unstimulated peripheral blood can be used instead of marrow aspirate for patients with primary myelofibrosis patients. Perform FISH studies with BCR-ABL1 for patients with essential thrombocythemia to exclude the diagnosis of chronic myeloid leukemia. FISH studies can be performed when cytogenetics is uninformative for detection of the most frequent abnormalities: +1q, +8, +9, +9p, del(13)(q14), del(20)(q11q13). A panel of five probes includes CEP9, CDKN2A/B at 9p21, D8Z2 as a centromeric probe for chromosome 8, RB1 for deletion 13q, and D20S108 for deletion of 20q12. For patients with a normal karyotype perform aCGH+SNP testing because 68% of these patients have copy number abnormalities including cnLOH. For diagnostic purposes and to monitor treatment response in patients with hypereosinophilic syndrome, perform FISH using triple-color FIP1L1 probe. For 5q32 rearrangements perform FISH with a PDGFRB FISH probe.

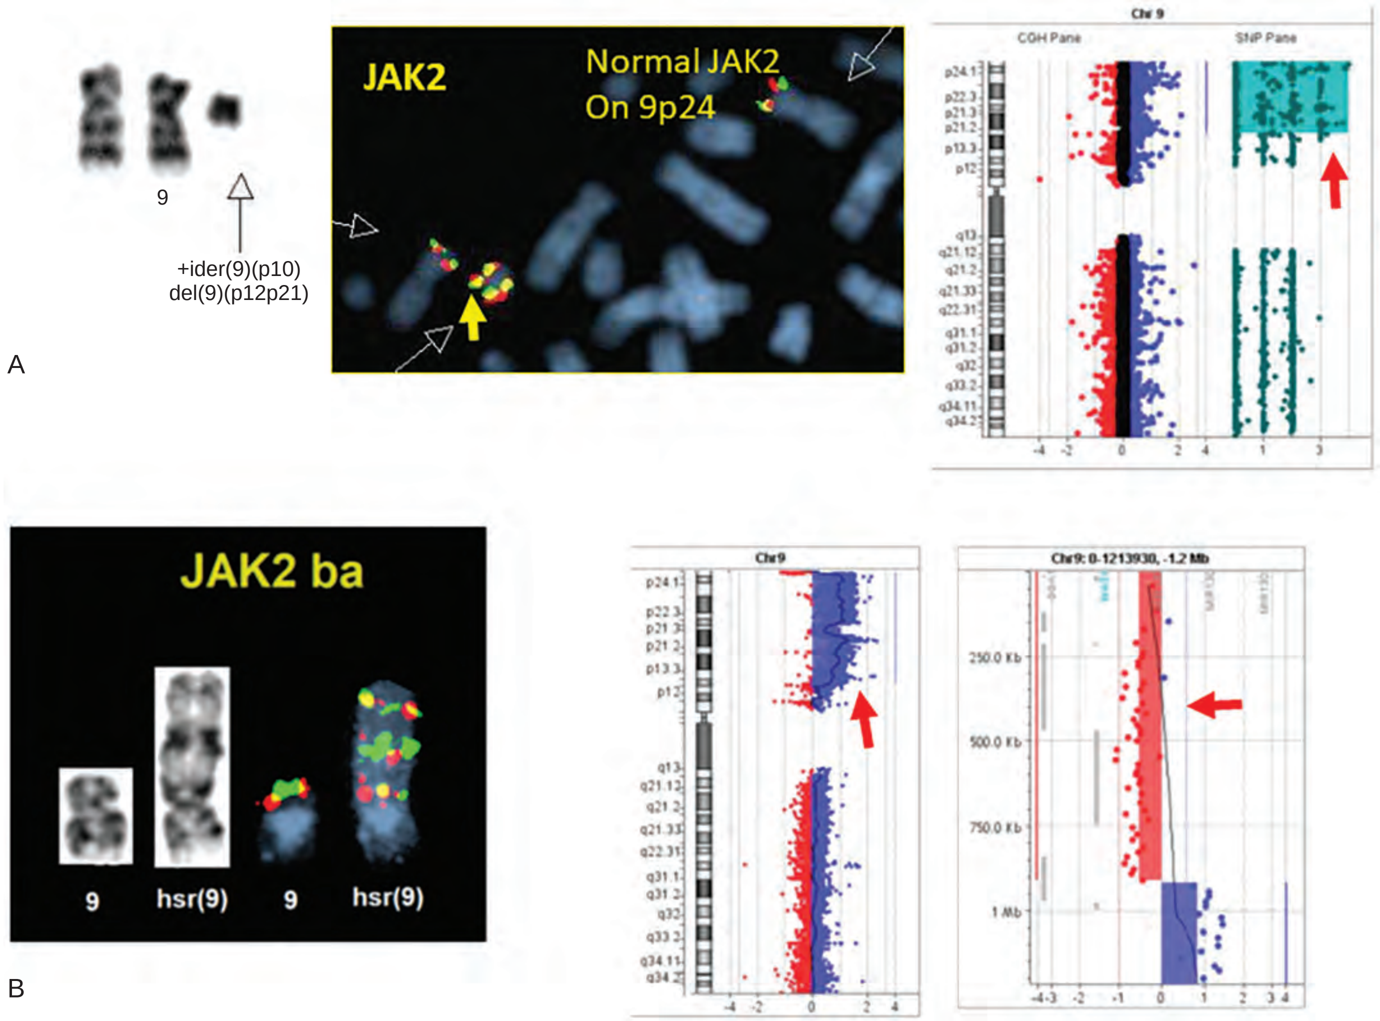

Figure 57.20 TWO DIFFERENT TYPES OF 9P CHROMOSOMAL ABNORMALITIES AND SUBSEQUENT *JAK2* COPY NUMBER ALTERATIONS IN Ph-NEGATIVE MYELOPROLIFERATIVE NEOPLASM. (A) Tetrasomy of *JAK2* in a newly diagnosed patient with myelofibrosis. The initial full karyotype at diagnosis was 47,XX,+mar. Following metaphase FISH evaluation using JAK2 breakapart probe, the karyotype was revised to 47,XX,+ider(9)(p10)del(9)(p12p21) resulting in tetrasomy of *JAK2*. The panel on the right shows the results obtained from array CGH+SNP indicating a gain of 24.7 Mb on the short arms of chromosome 9 including the *JAK2*. (B) Homogenous staining region (HSR) and amplification of *JAK2* in a patient with myelofibrosis. The cytogenetic results showed 20% of cells with sole del(20q) and 80% of cells had a complex karyotype including intrachromosomal complexity such as chromothripsis detected within chromosomes 1, 15, and 20 (not shown) and amplification of 9p (right panel), including *JAK2* and cn LOH of 17p involving TP53 (not shown). *CGH*, Comparative genomic hybridization; *FISH*, fluorescence in situ hybridization; *SNP*, single-nucleotide polymorphism

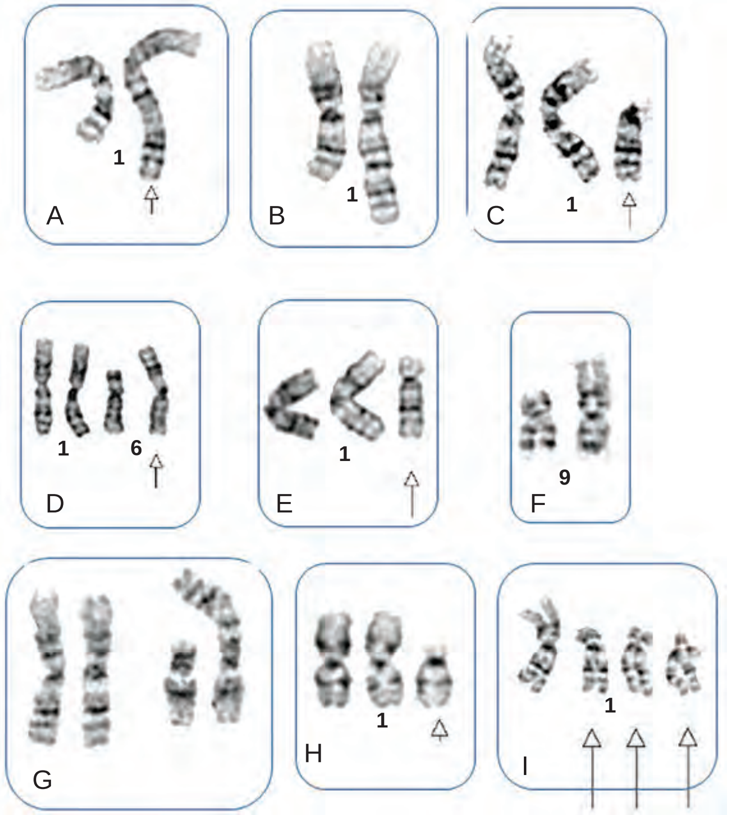

Figure 57.21 NINE TYPES OF 1q GAINS IN PATIENTS WITH Ph-NEGATIVE MYELOPROLIFERATIVE NEOPLASM WHO EITHER HAD +1q AT DIAGNOSIS OR PROGRESSED TO MYELOFIBROSIS AND DEVELOPED +1q. (A and B) Shows different sizes of duplicated 1q segment in two patients: 1q24 shown in (A) is a smaller 1q segment and breakpoint at 1q32 shown in (B) a larger duplicated gain of 1q. (C) Almost an entire long arms of chromosome 1 are translocated to the short arms of chromosome 19 resulting in gain of 1q and loss of 19q. (D) This der(6)t(1;6)(q21;p21.3) rearrangement is a recurrent abnormality both in Ph-negative MPN and MDS and most frequently observed in patients characterized with jumping 1q phenomenon. Often the extra copy of 1q is translocated to the short arms of chromosome 6 and very rarely to the long arm. (E) Another recurrent gain of 1q is the translocation to acrocentric chromosomes such as 22 without apparent loss of any genetic material and is described as +1,der((1;22)(q10;q10). (F) der(9)t(1;9)(p24;p21) is rarely observed in Ph-negative MPN and more frequently in MDS. In this unbalanced translocation there is a loss of terminal band from 9p and a gain of distal 1q segment. (G) der(12)(t(1;12)(q21;p13) is a recurrent abnormality in the (H) +1,del(1)(p13p36.1), (I) der(1)t(1;9)(p13;p13), + der(1)t(1;9)(p13;p13) x2 resulting in tetrasomy for 9p and 1q. *MDS*, Myelodysplastic syndrome.

In the WHO 2016 classification, *mastocytosis* is no longer listed as a Ph-negative MPN (Chapters 56 and 75) but rather as a distinct category, "Mastocytosis." Mastocytosis includes a group of rare and heterogeneous diseases characterized by accumulation of clonal mast cells in one or multiple organs. Over 80% of patients with systemic mastocytosis (Chapter 75) are characterized by *KIT* mutations, specifically in the activation loop of *KIT*, *KIT* D816V. *KIT* is encoded by a 21-exon-containing gene located on the long arms of chromosome 4, 4q12. Other rare *KIT* mutations have been described in adult and pediatric patients. The knowledge of the type and structure of *KIT* mutation is important because the A-loop mutations D816V/H/Y/N disrupt the structure of the receptor, leading permanently to an active conformation and resistance to imatinib. In patients with advanced systemic mastocytosis additional mutations have been observed including *TET*2 (up to 39%), *SRSF2* (up to 36%), *ASXL1* (up to 21%), and *RUNX1* (23%). At diagnosis of mastocytosis patients testing for *KIT* D816V in peripheral blood leukocytes, using highly sensitive and specific PCR-based assays, is necessary to determine the *KIT* allelic burden rapidly, which is now used as a gold standard for assessing disease burden.

MYELODYSPLASTIC SYNDROMES

The MDSs (see Chapters 61 and 65) are a clinically heterogeneous group of hematologic neoplasms with differing biology and clinical manifestations. They have in common a clonal origin, dysplastic cellular morphology, cytopenias, abnormalities of cellular maturation, and an increased propensity to develop acute leukemia (20% to 40%). They predominantly occur in elderly people. Cytogenetic studies can provide both diagnostic and profound prognostic information regarding OS and the risk of transformation to AML. A chromosomally abnormal clone can be detected in 50% to 60% of patients with de novo MDS and in approximately 90% of patients with therapy-related MDS (Table 57.5). There appears to be a correlation between the frequency of chromosomal abnormalities and the severity of disease. Approximately 35% of patients with less aggressive MDS, such as refractory anemia and refractory anemia with ring sideroblasts, have clonal chromosomal rearrangements, whereas approximately 60% to 70% of patients with refractory anemia with excess blasts in transformation have such chromosomal abnormalities. A single or complex chromosomal abnormality may be present initially, and cytogenetic progression may occur during the course of the disease. Even at diagnosis, complex genomic lesions involving five or more different chromosomes are not unusual. Despite the heterogeneity of chromosomal defects (gain, loss, deletion, amplification, rare balanced translocations, transcriptional silencing via methylation, or point mutation), the unifying concept of genetic instability in MDS is hemizygosity of specific genes or chromosomal regions. The heterogeneity of chromosomal abnormalities is overwhelming. However, the most common chromosomal anomalies observed in MDS include gain of 1q, del(5q)/−5, del(7q)/−7, trisomy 8, del(11)(q23), del(12p), +13/del(13q), t(11q23), del(17p), del(20)(q11q13), +21, and idic(X)(q13).

AL, Acute leukemia; *ALL*, acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *CEL*, chronic eosinophilic leukemia; *CML*, chronic myelogenous leukemia; *CMML*, chronic myelomonocytic leukemia; *CMPD*, chronic myeloproliferative disorder; *ET*, essential thrombocytopenia; *MF*, myelofibrosis; *MPD*, myeloproliferative disorder; *MPN*, myeloproliferative neoplasm; *PV*, polycythemia vera; *SM*, systemic mastocytosis.

Until recently guidelines-based indicators (GBI) for MDS patient management did not receive adequate attention. Several population-based studies reported that approximately 25% of MDS patients do receive bone marrow cytogenetic analyses at diagnosis and the lack of chromosome analysis impeded appropriate risk stratification by IPSS-R. GBI indicators represent a standardized best practice performance, outcome, and clinically relevant guidelines for a patient with MDS. According to the diagnostic guidelines the initial work-up must include cytogenetic analysis and molecular diagnostics/NGS/*TP53* evaluation (among other parameters).

In 2012 a new cytogenetic classification of MDS was established that includes five different risk groups (see Chapter 61).

The clinical relevance and the power of conventional cytogenetics in MDS were recognized by the WHO, which documented a strong association between del(5)(q13q33) and 5q− syndrome. The 5q− syndrome is a unique subtype of low-risk MDS with a favorable prognosis, lack of other cytogenetic abnormalities, low risk of leukemic transformation, and more commonly occurs in older females (Fig. 57.25, *second row*). Patients with isolated del(5q) remains the only MDS subtype defined by the genetic abnormality.

Among patients who do not have 5q− syndrome (with or without other chromosomal abnormalities), interstitial deletion of the long arms of chromosome 5 occur in 10% to 15% of patients and are among the most frequent chromosomal abnormalities in MDS (see Fig. 57.25, *second row*). The finding of del(5q) in CD34CD38− stem cells indicates its origin in a stem cell capable of differentiating into myeloid and lymphoid cell lineages. Data on 1432 patients with del(5q) showed a significant amount of heterogeneity in breakpoints. FISH studies delineated a commonly deleted segment that is currently estimated to be 1.5 Mb in size, on 5q31.1. The clustering of genes responsible for growth and differentiation of hematopoietic cells at this site and recurrent nature of −5/del(5q) in MDS caused many investigators to speculate that (a) tumor suppressor gene(s) was/were located in the 5q31 or 5q22–23 band region. To date, the tumor suppressor gene responsible for MDS on 5q has yet to be identified. Because the mechanism causing the interstitial del(5q) is elusive, haploinsufficiency or inactivation caused by methylation, rather than a typical tumor suppressor gene, has been speculated to be involved in this process.

Patients with isolated del(5q) have a more favorable prognosis and have a more prolonged survival than patients with ACAs. Specifically, patients with del(5)(q13q31) live longer than patients with other 5q deletions, indicating that the type of 5q deletion may significantly affect prognosis and response to therapy. Indeed, lenalidomide

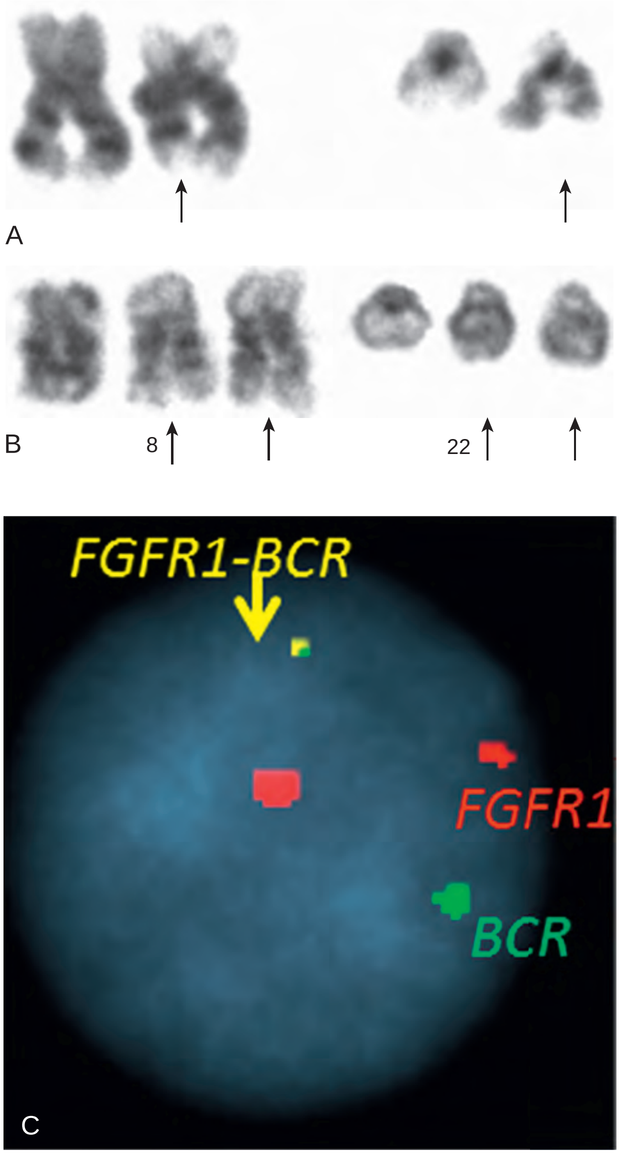

Figure 57.22 (A) A partial karyotype from a patient diagnosed with Ph-negative myeloproliferative neoplasm showing t(8;22)(p11;q11.2). (B) Six months later the patient developed hyperdiploid karyotype, acute lymphoblastic leukemia, and two copies of t(8;22). (C) Interphase FISH confirmed a FGFR1 *(red)*-BCR *(green)* fusion *(yellow)*.

therapy leads to a normal karyotype in 44% of 148 patients with interstitial del(5q) (Chapter 61). Isolated monosomy 7 or 7q deletion occurs in 20% of patients. Frequently, chromosome 7 abnormalities occur with ACA, most commonly rearrangements of 3q or del(12p) (see Fig. 57.25, *third* and *fourth row*). Monosomy 7 is present in all MDS subtypes and is seen predominantly in males. In pediatric patients with constitutional disorders associated with a predisposition to develop AML including Fanconi anemia (FA), congenital neutropenia, neurofibromatosis type 1, Down syndrome (DS), or Kostmann syndrome, −7/del(7q) may be seen as an isolated abnormality (Chapter 30). Therefore the question remains to whether these patients have genetic imprinting and preferentially lose chromosome 7. Unequivocal evidence exists that preferential parental origin of the missing chromosome 7 does not occur; approximately half of the patients have loss of either the maternal or paternal homologue, excluding the genomic imprinting hypothesis. Embryonic origin of partial chromosome 7 deletion in monozygotic twins with juvenile chronic myelomonocytic leukemia has been reported. As shown in Fig. 57.26, acquired cnLOH of 7q is a known recurrent genomic rearrangement in MDS patients not detected cytogenetically but identified using aCGH+SNP, and often detected in patients showing either a normal karyotype or other abnormalities.

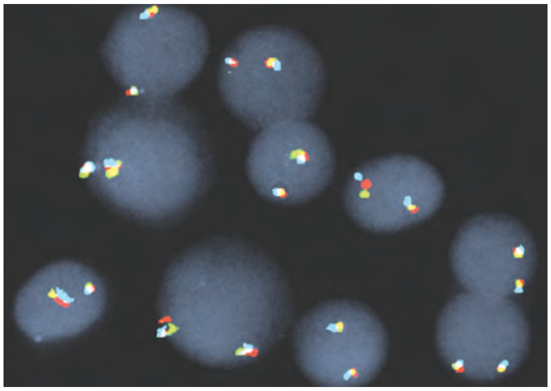

Figure 57.23 BONE MARROW INTERPHASE NUCLEI AFTER FLUORESCENCE IN SITU HYBRIDIZATION STUDIES USING TRICOLOR PROBE FOR CHROMOSOME 4, BAND REGION q12. The *green* color covers an approximately 750-kb region centromeric from FIP1L1. The *red* probe is telomeric of the FIP1L1 gene. The *aqua* color probe begins between exons 15 and 16 of the *PDGFRA* gene and extends toward the 4q telomere. In normal nuclei, as shown here, the probe appears as two tricolor fusions because of close proximity of probes in interphase DNA. Patients with hypereosinophilic syndrome have fusion of FIP1L1 and PDGFRA genes by interstitial deletion and produce one signal with *green-aqua* fusion and a missing orange signal. If the translocation involves the *PDGFRA* gene with loci on other chromosomes, the expected signal pattern is one *orange–green* fusion and one separate aqua signal.

MDS patients with del(7q) as a single abnormality have a distinct clinicopathologic profile with an overall better prognosis than seen in patients with an isolated monosomy 7. Isolated del(7q) is more frequent in patients with less advanced forms of MDS according to the WHO classification or the IPSS-R. They have fewer blasts in the bone marrow than other cytogenetic groups and display a significantly superior survival when compared with patients with isolated monosomy 7. The presence of ACA in patients with del(7q) is associated with shortened OS (see Fig. 57.25, *third row*). Allele typing studies implicated three regions that are most frequently deleted: 7q22, 7q31.1, and 7q31.3. Isolated 7q deletion is a common finding in a variety of myeloid malignancies (MDS, AML, MPN, and others) and as a sole abnormality is present in less than 5% of patients. High-resolution genomic analysis has revealed that among 81 patients with a sole 7q deletion 67 cases had an interstitial deletion while 14 cases showed a terminal 7q deletion. In this cohort, according to the SNP array karyotyping, 85% of patients with interstitial 7q deletion had a commonly deleted regions located at 7q22.1 to 7q31.31. Consequently, there is speculation that a putative myeloid suppressor gene(s) is located in the regions that are frequently deleted. Because prototypic tumor suppressor genes have not been identified in patients with 7q deletions, an alternative explanation may be haploinsufficiency whereby the level of protein is critical, or a complex of two cooperating proteins is affected as a result of inactivation caused by methylation.

Trisomy 8 (see Fig. 57.25, *third row*) is the third most frequent chromosomal abnormality in MDS patients. As a sole abnormality, it is found in 11% of patients with MDS and overall is found in 17% of patients. A significantly higher incidence of trisomy 8 occurs in males than in females. Trisomy 8 is present in all age groups of patients with MDS. Although trisomy 8 is detected in the hematopoietic stem cells of patients with MDS, a sizable fraction of stem cells are disomic but functionally abnormal, suggesting that the acquisition of trisomy 8 is a secondary event. These findings provide evidence for the multistep pathogenesis of MDS, where gain of chromosome 8 is not an early event in the stepwise disease evolution. Although trisomy 8 serves as an intermediate risk factor when detected at diagnosis,

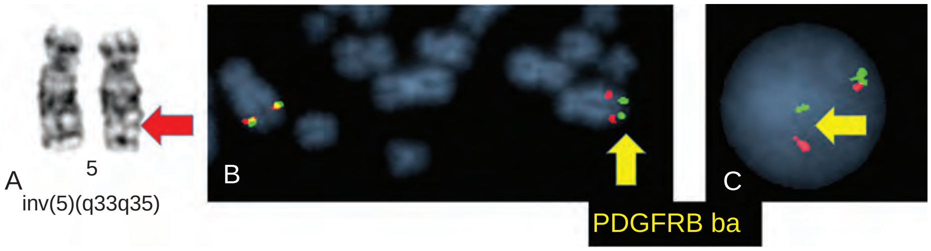

Figure 57.24 A partial karyotype from a patient with Ph-negative MPN showing in (A) panel an inversion of chromosome 5 *(red arrow)* identified cytogenetically in 90% of marrow cells. In panel (B) both chromosomes 5 are shown, after metaphase FISH: the left chromosome 5 has a normal *PDGFRB* while the other homolog 5, with an invasion *(yellow arrow)*, shows the split of the 5′ and 3′ part of the PDGFRB probe, consistent with the rearrangement. The panel (C) shows a bone marrow interphase cell and the yellow arrow points to the split of the red and green signals that reflect rearrangement of the *PDGFRB* gene detected in 28% of non-dividing cells, indicating that this rearrangement in Ph-negative MPN has a higher proliferative capacity than nondividing cells. *FISH*, fluorescence in situ hybridization; *MPN*, myeloproliferative neoplasm.

TABLE 57.5 Recurrent Chromosomal Abnormalities in Primary Myelodysplastic Syndrome

Abnormality	Frequency (%)

Modified from Malcovati L, Hellström-Lindberg E, Bowen D, et al. Diagnosis and treatment of primary myelodysplastic syndromes in adults: recommendations from the European LeukemiaNet. *Blood.* 2013;122:2943.

patients with MDS with trisomy 8 treated with the hypomethylating agent 5-azacitidine have a significantly better survival than patients with other chromosomal abnormalities. Tetrasomy, pentasomy, and hexasomy 8 (polysomy 8) are relatively rare compared to trisomy 8. They have been reported in MDS, AML, or MPN. Tetrasomy 8 was the most common presentation of polysomy 8. In 60.7% of patients, polysomy 8 occurred as part of complex changes (16.2% with 11q23 rearrangements). No cryptic *KMT2A* rearrangements were found in cases when polysomy 8 was the only karyotypic change. Therefore polysomy 8 is a subtype of AML, MDS, and MPN characterized by a high incidence of prior diseases, and poor OS (6 months). Age significantly reduced median survival but associated cytogenetic abnormalities did not modify it. Cytogenetic results further demonstrate an in vitro preferential growth of the cells with a high level of aneuploidy suggesting a selective advantage for polysomy 8 cells.

MDS or MDS/MPN associated with trisomy 11 as a sole abnormality or as a part of noncomplex karyotype has been reported. This rare recurrent abnormality has an overall frequency of approximately 0.3% of MDS patients and is associated with a significantly inferior survival in patients with IPSS intermediate-risk disease ($P = .0002$) but comparable to the poor-risk group ($P = .97$). Trisomy 11 is associated with clinical aggressiveness and represents a high-risk cytogenetic abnormality.

Deletions of 17p are seen in 3% to 4% of MDS and AML patients. These patients often display several other chromosomal rearrangements, including monosomy 17, isochromosome 17q (see Fig. 57.25, *third row*), and unbalanced translocations between chromosome 17 and another chromosome. Approximately 30% of these deletions are related to therapy. The extent of 17p deletion in all cases involves the *TP53* gene. There appears to be a close correlation between dysgranulopoiesis (e.g., pseudo–Pelger-Huet abnormalities) and small vacuoles in neutrophils with 17p abnormalities and *TP53* deletion. The median survival of these patients is poor.

Besides deletion of *TP53*, molecular characterization of MDS with NGS has shown that *TP53* mutant MDS and therapy-related AML have emerged as molecular cohorts with profoundly inferior outcomes regardless of treatment, with a median OS of only 6 to 12 months. In MDS, mutations of *TP53* are commonly seen in patients with complex karyotypes and have a significant negative impact on prognosis. *TP53* mutations are strongly associated with thrombocytopenia, increased blasts, and chromosome 5 abnormalities, isolated del(5q), and complex karyotypes. Presence of *TP53* mutations in patients with a complex karyotype identifies a patient group with an extremely poor prognosis and median OS of 6 months highlighting the unmet need for novel therapeutic approaches in these patients. Recent analysis of 3324 patients with MDS delineated two subsets of patients with distinct phenotypes and outcomes.[9] One-third of *TP53*-mutated patients had monoallelic mutations whereas two-thirds had multiple hits (multi-hit) consistent with biallelic targeting. Established associations with complex karyotype, few co-occurring mutations, high-risk presentation, and poor outcomes were specific for multi-hit patients only. The *TP53* multi-hit state predicted risk of death and leukemic transformation independently of the IPSS-R. Surprisingly, monoallelic patients did not differ from *TP53* wild-type patients in outcomes and response to therapy. These observations show that consideration of *TP53* allelic state is critical for prognostication of MDS patients.

An isodicentric X chromosome in Xq13-idic(X) is a rare but recurrent abnormality that has been associated with refractory anemia with ringed sideroblasts. All MDS patients with idic(X)(q13) are females, most likely because the formation of idic(X) would result in nullisomy for Xq13-qter in males. The median age at the time of diagnosis is 73.5 years. The outcome of idic(X)-positive cases is variable; some investigators report aggressive and rapidly fatal disease and others a relatively favorable clinical course with survival for several years. The fact that idic(X) most often occurs as the sole cytogenetic abnormality suggests that it may be sufficient for leukemogenesis. Using a high-resolution SNP array, the breakpoints on idic(X)(q13) were mapped to two distinct breakpoint clusters, at approximately 70.9 Mb (five cases) and 72.1 Mb (seven cases) on the X chromosome. None of the 11 breakpoints occurred in a gene, strongly indicating that the idic(X)(q13) does not result in a fusion gene. Instead, the functional

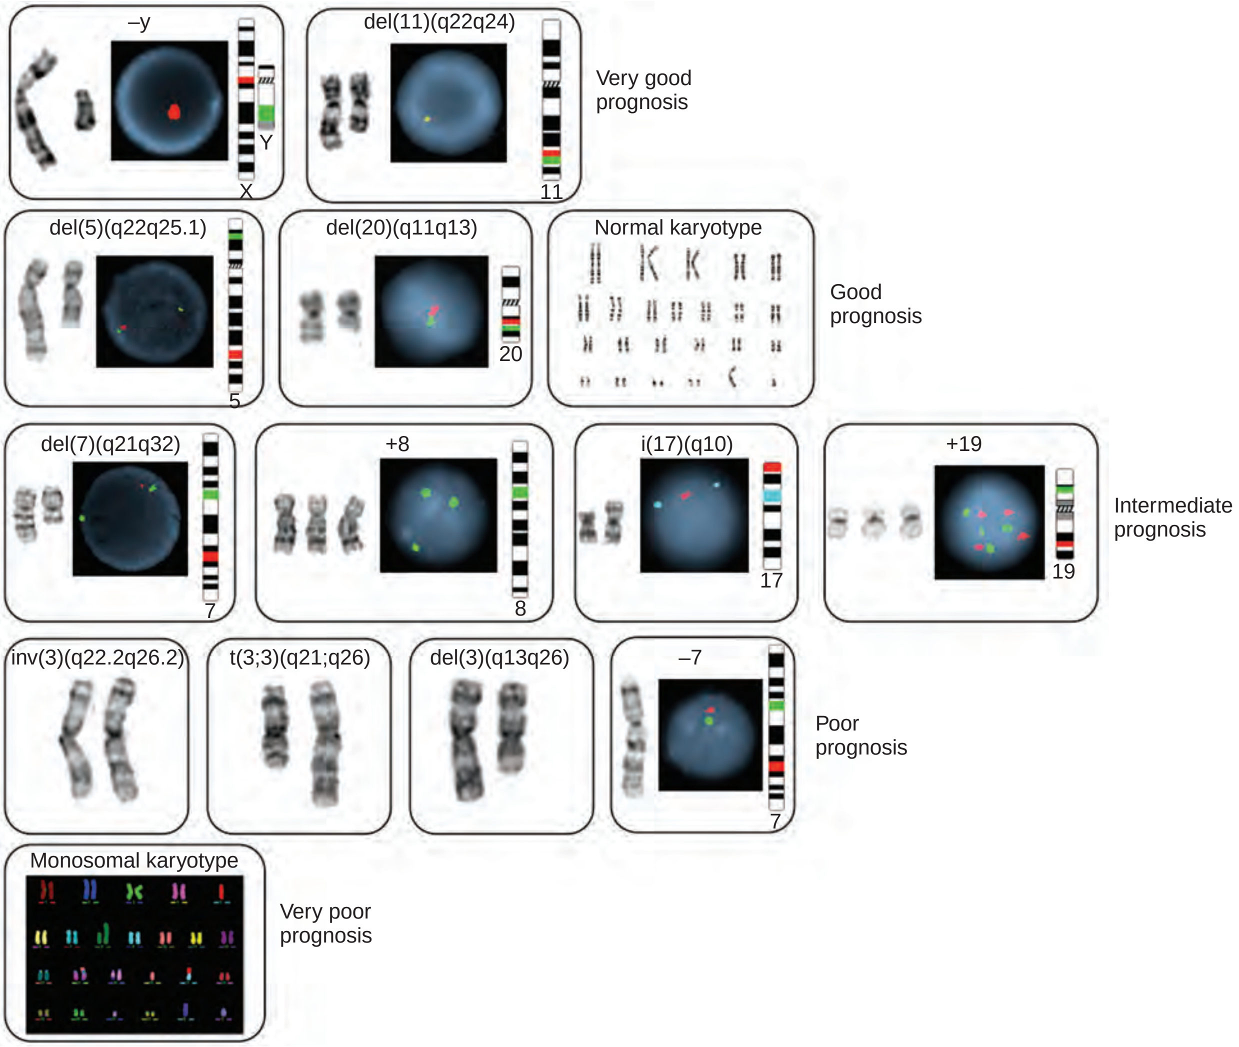

Figure 57.25 PROGNOSTIC SIGNIFICANCE OF THE RECURRENT CHROMOSOMAL ABNORMALITIES IN MYELODYSPLASTIC SYNDROME, ACCORDING TO THE NEW COMPREHENSIVE CYTOGENETIC SCORING SYSTEM.

outcome of the abnormality confers a gene dosage effect because of the concurrent gain of Xpter-q13 and loss of Xq13-qter. This region of the X chromosome is enriched for repeated sequences and most likely, these repeats may facilitate the formation of idic(X). The isodicentric X chromosome was inactive in some patients and active in other patients; hence idic(X) appears to be leukemogenic regardless of X_a or X_i involvement.

Gain of 1q, usually in the form of an unbalanced translocation, is a recurrent abnormality in MDS and appears to be a marker of disease progression. Specifically, the gain of 1q in the form of jumping translocations either at diagnosis or the subsequent acquisition of jumping 1q translocations appears to be associated with imminent transformation to AML in patients after an average of 9 months (Figs. 57.27 and 57.21). As mentioned earlier in the Ph-negative MPN section (Chapters 70 and 72), gain of 1q is also associated with disease progression and is most frequently found at the diagnosis of PV. Once acquired, the patient's prognosis tended to be dependent on the copy number of 1q, indicating that gain of jumping 1q translocations was associated with both disease progression and poor prognosis. Jumping translocations of 1q has also been described in donor cell derived MDS after cord blood transplantation; the average time to developing jumping 1q was less than 2 years. These findings did not provide any common pattern as to the role of the partner chromosomes in unbalanced jumping 1q translocations. However, 81% of recipient breakpoints were localized in pericentric regions whereas the remaining 19% were telomeric fusions. Decondensation of pericentromeric heterochromatin of chromosome 1 together with centromere and repeat DNA sequences interspersed with histones and acetylated sequences may favor illegitimate recombinations leading to jumping 1q translocations. Moreover, exposure to azacitidine has been shown to be associated with alterations of pericentromeric heterochromatin of chromosome 1, as well as an increase in Alu DNA repeats. Hypomethylation of 1q12–21 pericentromeric region of chromosome 1 appears to be at least one aspect of copy number gains of 1q. The mechanism underlying formation of trisomy 1q in MDS has not been investigated but in patients with myelofibrosis we reported that +1q was associated with increased transcripts of *MDM4*, likely leading to further downregulation of *TP53* activity. Elevated *MDM4* levels have been previously found in other hematologic malignancies, including de novo AML. There are numerous other oncogenes that are present on 1q, which could also contribute to disease progression. The overexpression of *CKS1B*, involved in cell cycle regulation, located at band 1q21 has been proposed as the culprit responsible for disease progression in patients with myeloma and gain of 1q (Chapter 91). Therefore, it is possible that in MDS, similar to patients with myelofibrosis with +1q, leads to further dysregulation of the wild-type *TP53* pathway by increasing *MDM4* activity.

The most frequent rearrangement of chromosome 3 involves two bands on chromosome 3—band 3q21 and 3q26 simultaneously—which produces either t(3;3)(q21;q26) or inv(3)(q21q26)

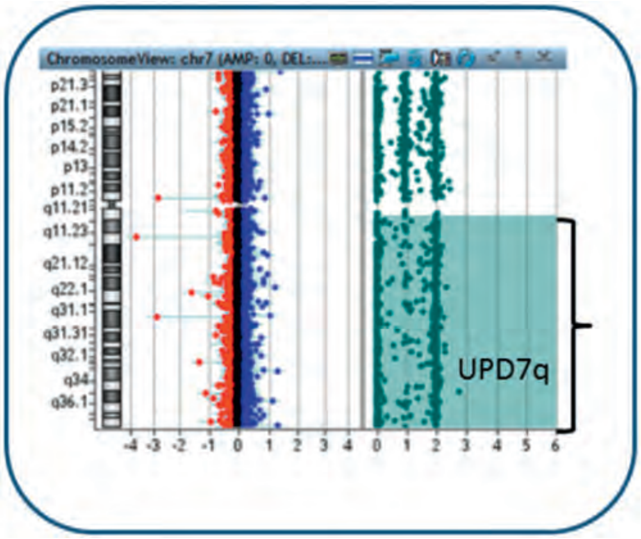

Figure 57.26 ARRAY COMPARATIVE GENOMIC HYBRIDIZATION PLUS SINGLE-NUCLEOTIDE POLYMORPHISM FROM A PATIENT WITH MYELODYSPLASTIC SYNDROME AND NORMAL CHROMOSOME 7. Note acquired uniparental disomy (UPD)/copy-number neutral loss of heterozygosity (cnLOH) of the long arms of chromosome 7, known to be associated with worse prognosis.

(Fig. 57.28A and B). These chromosomal rearrangements are present in de novo and therapy-related MDS, as well as in AML and megakaryoblastic crisis of CML. The incidence of the 3q rearrangements is 2% to 5%. Characteristic clinical features include an elevated platelet count, marked hyperplasia with dysplasia of megakaryocytes, and a poor prognosis with minimal or no response to chemotherapy and a short survival. In addition to similar clinicopathologic features, patients with 3q21q26 share molecular heterogeneity in both the breakpoints and the expression pattern of the genes near these breakpoints (see Fig. 57.28, also Fig. 57.30A.) The chromosomal breakpoints, defined by FISH, in 3q26 are scattered over several hundred kB in either the 5′ or the 3′ region of the *MECOM* (*EVI1* complex locus) gene, whereas the breakpoints in the 3q21 region are restricted to two different smaller genomic clusters approximately 100 kb downstream of the *RPN1* gene. *EVI1* overexpression is observed in the majority of patients, but some patients with the 3q21q26 rearrangement do not have detectable *EVI1* expression, and at least 9% of patients with AML without 3q26 abnormalities overexpress *EVI1*. Therefore the poor prognosis of these patients may be independent of *EVI1* expression, despite the fact that extensive 3q26 breakpoint FISH mapping suggests *EVI1* involvement in numerous novel sporadic and recurrent 3q26 rearrangements. A fusion transcript of *RPN1-EVI1* is rarely observed in patients with 3q21q26 rearrangements. Interestingly, functional genomic studies and allelic-specific analysis revealed experimentally that inv(3)/t(3q) results simultaneously in haploinsufficiency of *GATA2* and upregulation of *MEECOM* as a result of rearrangements in noncoding regulatory sequences of

Figure 57.27 GAIN OF LONG ARMS OF CHROMOSOME 1 IN MYELODYSPLASTIC SYNDROME. Partial karyotypes in these six cases represent examples of gain or duplication of 1q. Gain of 1q in MDS has overlapping features with +1q in Ph-negative MPN and both are associated with rapid progression to AML. (A) Trisomy 1q in the form of der(13) with an extra 1q is translocated to the terminal portion of the long arms of chromosome 13. (B) Gain of 1q in the form of der(6) whereby the entire long arms of 1 are translocated to the short arms of chromosome 6. (C) Two copies of der(6) resulting in tetrasomy 1q in a patient with an advanced myelodysplastic syndrome. (D) Duplication of region 1q12–q21 in a patient with essential thrombocytopenia. (E) Trisomy 1q translocated to the short arms of chromosome 9 resulting in a gain of 9p and 1q in a patient with polycythemia vera (PV) who transformed to myelofibrosis. This is a PV-specific and recurrent abnormality. (F) Trisomy 1q translocated to the terminal portion of the Y chromosome. *AML*, acute myeloid leukemia; *MDS*, myelodysplastic syndrome; *MPN*, myeloproliferative neoplasm.

Figure 57.28 CHROMOSOME 3 ABNORMALITIES IN MYELODYSPLASTIC SYNDROME. (A) A partial karyotype from a patient with MDS showing a recurrent t(3;3)(q21;q26). In this rearrangement metaphase FISH shown on the left, *RPN1 (green)* and a part of *MECOM (red)* gene on 3q21 giving an impression of a "yellow" signal because of their proximity on a metaphase chromosome. The right chromosome 3 shows *RPN1 (green)* at 3q21, part of *RPN1 (green)* and *MECOM (red)* on 3q26 as well as unrearranged *MECOM* translocated from the left chromosome 3 homolog. (B) An unusual chromosome 3 rearrangement in MDS showing a deletion of 3q11–q13 region, followed by inversion with two breakpoints at p21 and q21.2. All three genes *RPN1 (green), MECOM (red)*, and *BCL6 (yellow)* remained in their normal loci. *FISH*, fluorescence in situ hybridization; *MDS*, myelodysplastic syndrome.

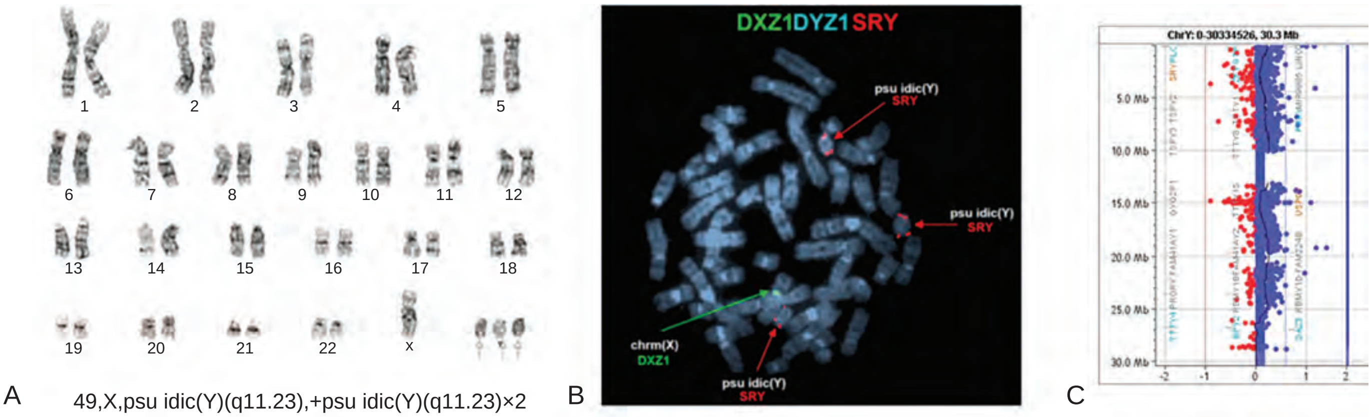

Figure 57.29 PSEUDO ISODICENTRIC Y CHROMOSOME IN MYELODYSPLASTIC SYNDROME. The patient was cytogenetically normal at diagnosis and continued to have a normal karyotype for 4 years during 24 consecutive cytogenetic studies. (A) After 4 years he developed psu idic Y chromosome present in 1 to 3 copies and a loss of normal Y chromosome. (B) Metaphase FISH showed loss of centromere of Y chromosome *(aqua)*, one X chromosome *(green)*, and 2 to 10 copies of SRY gene *(red) (red arrows)* at the telomere of each copy of the psu idic Y chromosome structure. (C) Array CGH+FISH confirmed low copy gain (6%) of Yp11.32 –q12) *(blue)*. *CGH*, Comparative genomic hybridization; *FISH*, fluorescence in situ hybridization.

these genes, indicating the importance of mutations residing outside the coding exome.

A monosomal karyotype (MK), a new cytogenetic category, is defined as a karyotype showing two or more distinct autosomal chromosome monosomies or one single autosomal monosomy (excluding isolated loss of X or Y) in the presence of a structural abnormality (see Fig. 57.25, *bottom row*). Initial reports indicated that MDS with a MK, with or without monosomy for chromosomes 5 and 7, was associated with a poorer prognosis than other complex karyotypes, although later reports could not confirm these results. The reason for this discrepancy may be due to azacitidine treatment with reducing the negative impact of MK in high-risk patients with MDS.

The clinical significance of LOY present in 10% of patients with MDS and approximately 7% of older adult males without MDS was recently elucidated (see section above on LOY in clonal hematopoiesis). Mosaic LOY in blood has been reported to be associated with higher risk of all-cause mortality and overall lower life expectancy. In bone marrow samples containing more than 75% of metaphase cells with a LOY, the observation is associated with MDS. Structural Y chromosome abnormalities are also present in patients with MDS (Fig. 57.29). Older adult males with MDS and LOY who achieve complete hematologic remission regain the Y chromosome in their marrow cells.

The prognosis of patients with MDS is very heterogeneous. In 1997, based on the cytogenetic abnormalities identified in 816 patients with MDS, as well as percentage of blasts and number of cytopenia, an IPSS was proposed. According to the IPSS, 86% of all cytogenetic findings can be explicitly classified according to their prognostic impact. The system is highly reproducible and very simple to use, but it has certain limitations. Moreover, in the remaining 14% of patients the cytogenetic abnormalities have unknown prognostic significance (Fig. 57.30). This limitation underscores two major limitations of cytogenetic classifications of MDS: the profound heterogeneity of acquired cytogenetic aberrations in MDS and the associated challenge of designing a comprehensive cytogenetic scoring system that predicts the prognostic impact of rare abnormalities (Fig. 57.31). A new and comprehensive cytogenetic scoring system based on an international data collection of 2902 patients was reported in 2012 (see Fig. 57.25). Patients included were from the German-Austrian MDS Study Group *(n = 1193)*, the International MDS Risk Analysis Workshop *(n = 816)*, the Spanish Hematological Cytogenetics Working Group *(n = 849)*, and the International Working Group on MDS Cytogenetics *(n = 44)* databases. In total, cytogenetic categories were defined, providing clear prognostic classification for 91% of all patients. All abnormalities were arranged according to OS and development of AML to classify their prognostic impact. The abnormalities were classified into five prognostic subgroups: very good (*n* = 81) included del(11q) and LOY (median OS, 61 months); good *(n = 1809)* included normal karyotype, del(5q), del(12p), and del(20q) (all as single anomaly) and double abnormalities including del(5q) (median OS 49 months); intermediate *(n = 529)* included del(7q), +8, i(17q)(q10), +19, +21, any other single abnormality, independent clones, and double abnormalities not harboring del(5q) or −7/del(7q) (median OS 26 months); poor *(n = 148)* included inv(3)/t(3q)/del(3q), −7, and double abnormalities including −7/del(7q) and complex (three abnormalities; OS of 16 months); and very poor *(n = 197)* included complex karyotypes with more than three abnormalities (OS of 6 months) (see Fig. 57.25. This new scoring system proposed should be viewed as a dynamic model, open to further refinement as the knowledge in karyotypic abnormalities of MDS evolves.

Cytogenetics and FISH studies have relatively similar sensitivities in detecting an abnormal clone among patients with MDS. A FISH test for targeted recurrent abnormalities in MDS should use probes to detect numerical and structural anomalies of chromosome regions 1q, 3q, 5q, 7, 7q31, 8, 11q, 12p, 13q, 17p, 20q, and 21 (see box on Genetic Testing for Myelodysplastic Syndrome and Fig. 57.25).

GENETIC TESTING FOR MYELODYSPLASTIC SYNDROME

Due to the tremendous chromosomal and genomic heterogeneity the best genetic test at diagnosis is conventional cytogenetic studies. It is also required for the IPSS-R prognosis. FISH for detection of P53 single or biallelic deletion will identify a group of patients with very poor prognosis. In patients with a normal karyotype a reflex test is aCGH+SNP for detection of cnLOH, specifically on 7q, allowing greater confidence in detection of genomic change fostering improved patient-specific management.

Detection rate of submicroscopic or cryptic aberrations in MDS patients with normal karyotype is 32.8%. The chromosomal abnormalities detected by SNP-A can influence the prognosis of patients with MDSs, especially in the low-risk group. The patients with multiple chromosomal abnormalities detected by SNP karyotyping had an inferior prognosis, and those with SNP abnormalities (≥3 per patient) were found to be an independent predictor of poor prognosis in patients with MDS. Moreover, SNP karyotyping in MDS revealed chromothripsis (chromosomal shattering) as recurrent genomic abnormality (1.2%), specifically in high-risk MDS cases, and the presence of chromosome 13 chromothripsis is a novel recurrent genomic change in high-risk MDS.

Familial MDS is very rare (Chapters 30 and 61). MDS presenting in children and younger adults is more frequently associated with germline genetic predisposition (Chapter 65). In recognition of the growing subgroup of MDS or acute leukemia associated with germline mutations or familial cases, the revised WHO of myeloid neoplasms now includes a new category: myeloid neoplasms with germline predisposition (Chapter 30). The diagnosis of a germline MDS predisposition disorder carries profound implications for medical management and treatment. Although there is a whole spectrum

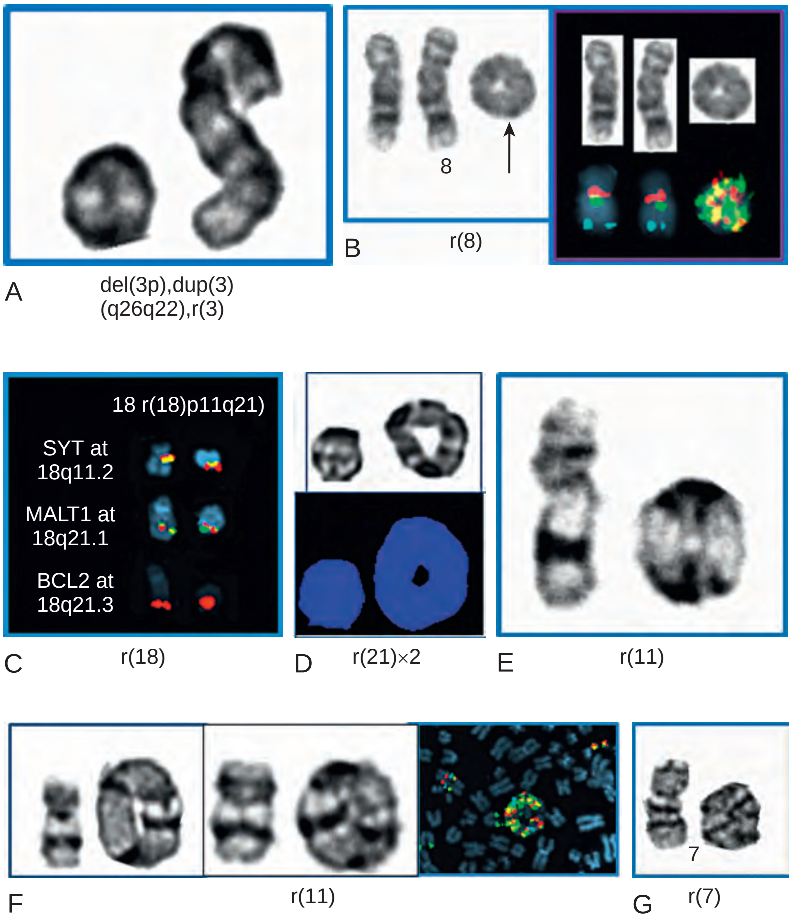

Figure 57.30 RING CHROMOSOMES IN MYELODYSPLASTIC SYNDROME AND OTHER HEMATOLOGIC MALIGNANCIES. (A) Ring 3 of one homolog and deletion 3p and duplication 3q of another homolog 3 in a patient with MDS and a complex karyotype. (B) A gain of ring of chromosome 8 in a patient with acute lymphoblastic leukemia. Metaphase FISH revealed amplification of *FGFR1 (red)* and *D8Z2 (green)* and loss of chromosome 8 region telomeric from 8p12 and below centromere *(green)* resulting in almost total loss of 8p and 8q because *MYC (aqua)* at 8q24 was deleted in r(8). r(18) with breakpoints at p11 and q21 in a patient with acute myeloid leukemia at diagnosis. (C) Metaphase FISH revealed that *SYT*, *MALT1*, and *BCL2* were retained in the ring 18. (D) Two different ring 21, as revealed by multicolor FISH in a patient with hairy cell leukemia and a complex karyotype. (E) Ring 11 in a patient with MDS. (F) Two different ring 11 in a patient with multiple myeloma. Metaphase FISH revealed *MLL* amplification *(yellow)* but not amplification of *CCND1 (red), IGH (green)*, or centromere 11 *(aqua)*. (G) Ring of chromosome 7 in a patient with T-cell leukemia. *TCRB* and *TCRG* are localized at 7p14 and 7q34, respectively. *FISH*, Fluorescence in situ hybridization; *MDS*, myelodysplastic syndrome.

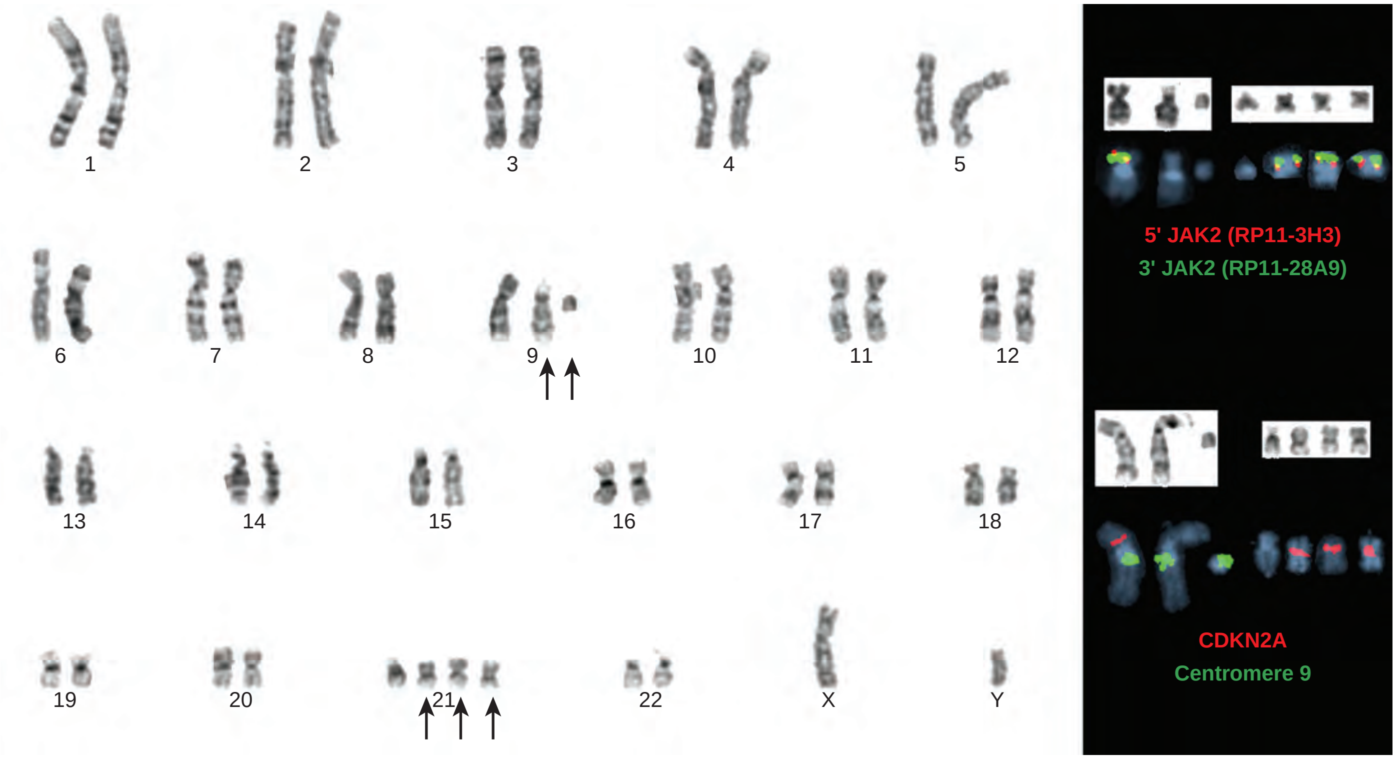

Figure 57.31 A GAIN OF JAK2 IN A PATIENT WITH MYELODYSPLASTIC SYNDROME. A bone marrow karyotype *(left panel)* from a patient with MDS showing a 49,XY add(9)(p12), +der(9)del(9)(p12p24)del(9)(q12q34)der(21)t(9;21)p21p24;p11), +der(21)t(9;21)(p21p24;p11)×2. FISH testing with JAK2 (top part) and CDKN2 and centromere 9 *(bottom panel)* revealed 70% of cells to have a deletion of 9p, including *CDKN2* and four copies of unrearranged *JAK2*, suggesting that in some patients with MDS the underlying mechanism may be a gain of *JAK2*. *FISH*, Fluorescence in situ hybridization; *MDS*, myelodysplastic syndrome.

of germline MDS predisposition conditions a few of those associated with acquired chromosomal abnormalities will be listed here. MDS with germline *GATA2* mutations is frequently associated with monosomy 7/del7q (−7) or trisomy 8, particularly in children and young adults. A study of 426 cases of pediatric MDS patients identified germline *GATA2* mutations in 37% of patients with primary MDS with −7 and 16% of MDS cases with trisomy 8 (Chapter 65). Germline *GATA2* mutations were identified in 72% of adolescents with −7 MDS. In contrast, germline *GATA2* mutations were absent in therapy-related MDS. Germline mutations in *SAMD9* and *SAMD9L* genes are frequently present in patients with bone marrow failure and a high risk for monosomy 7 MDS at a young age and these patients present either with MDS or AML. FA is characterized by genomic instability, hypersensitivity to DNA cross-linking agents, and predisposition to marrow failure, as well as hematologic malignancies and solid tumors (Chapter 30). The cumulative incidence of patients with FA to develop MDS is 40% by age 50 years and 20% by age 40 years for AML (Chapter 30). The incidence of leukemia is even higher in the FANCD1/BRCA2 subtype of FA, with many cases presenting at ages less than 5 years. In the registry of patients with Diamond-Blackfan anemia (DBA) of North America, 2% of DBA patients developed AML by age 45 years. Dyskeratosis congenita (DC) or telomere biology disorders (TBDs) encompass genetically heterogeneous disorders related to impaired telomere maintenance (Chapter 30). These patients often present associated with hematologic complications including bone marrow failure, MDS, and AML. The cumulative incidence of MDS in patients with DC has been estimated to be 2% by age 50 years. *RUNX1* deficiency is the cause of an autosomal dominant familial platelet disorder with predisposition to myeloid leukemia. Familial platelet disorder with predisposition to developing MDS, AML, or lymphoid malignancies such as T-cell leukemia or B-cell malignancies (Chapter 30). Another constitutional abnormality that appears to predispose to MDS/AML is a deletion of band region q22.1 to q22.2 of chromosome 21 (where *RUNX1* gene is located) with a complex phenotype (dysmorphic features, organ malformations, growth delay, and mental retardation), germline *RUNX1* deletion, and congenital thrombocytopenia. Although longitudinal data are limited, lifetime risk for developing a myeloid malignancy in patients with germline *RUNX1* mutations appears to be highly variable and has been estimated to be around 44%, ranging from 11% to 100%. Tables 57.6 and 57.7 shows the acquired recurrent somatic mutations observed in patients with MDS. According to the European Leukemia Net report 52% to 90% of patients with a normal karyotype have at least one genomic point mutation or MDS-related copy number change as detected by combing three technologies: NGS, cytogenetics, and a CGH+SNP. Using SNP array data from 50,000 subjects recruited for genome-wide association studies demonstrated that 0.5% of healthy individuals possessed genomic lesions. In contrast, recent whole-exome sequencing data of DNA from the peripheral blood of 17,182 persons showed clonal mutations leading to clonal outgrowth of hematopoietic cells in 10% of persons over the age of 70 years and in 18.4% among people aged 90 to 108 years. The most commonly mutated such genes were *DMT3A*, *TET2*, and *ASXL1*, which are frequent mutations in MDS and AML. These elderly people with clonal mutations in their peripheral blood did not have MDS or any other hematologic malignancy, indicating that age-related CH is a common premalignant condition and individuals with clonal mutations have an increased risk of developing hematologic malignancy (Chapters 13 and 19).

The widespread use of NGS has identified more than 50 recurrent somatic mutations in patients with MDS leading to the development of a rich mosaic detailing the mutational landscape and genetic determinants of prognostic significance and survival in MDS (Chapters 3, 13, 19, and 61). The only mutation that has diagnostic validity is an acquired mutation in *SF3B1* gene which was recognized by WHO for its potential to establish diagnosis of MDS with ring sideroblasts.

TABLE 57.6 **Recurrently Mutated Genes in Myelodysplastic Syndrome**

RAD21	<5%
SMC1A	<5%
SMC3	<5%

Modified from Spaulding TP, Stockton SS, Savona MR, et al. The evolving role of next generation sequencing in myelodysplastic syndromes. *Br J Haematol*. 2019;188(2):224.

Four lines of evidence support recognition of somatic *SFRB1* mutation as a disease-defining genomic event: (1) its most often an initial (founding) genetic event occurring in the most primitive hematopoietic stem cells (CD34+CD38−CD90+CD45RA-cells), (2) it is a major determinant of the disease phenotype, (3) it has an independent prognostic parameter which influences survival and risk of progression to AML, and (4) it may predict response to specific agents. With the widespread adoption of targeted sequencing panels it is now recognized that more than 80% of MDS patients harbor one or more known recurrent mutation. *TP53* VAF (variable allele frequency) may inform distinct risk subgroups because of lower-risk patients with *TP53* mutations at the time of diagnosis, more than 6% VAF were linked to shorter OS and progression-free survival compared to patients with less than 6% VAF.

ACUTE MYELOID LEUKEMIA

AML refers to a group of heterogeneous diseases with respect to clonality, molecular lesions, chromosomal aberrations, and response to treatment (see Chapters 59, 60, and 63). Initially, using *G6PD* as a marker of clonality, it was determined that AML originates from a single clone and has a multistep pathogenesis. In adults, at the time of diagnosis all hematopoietic cell lineages are clonal. In children younger than 16 years, erythroid cells and platelets often are not part of the leukemic clone.

The application of nucleotide-polymorphism technologies has confirmed the clonal origin of AML and further revealed that most, if not all, patients with AML evolve through a process of constrained clonal evolution. Multicolor metaphase analysis, FISH, CGH arrays, SNP arrays, PCR, and NGS have all greatly improved detection of subclones and established the concept of a clonal hierarchy in AML. To understand the branching evolution of AML development, each mutation must be placed in the context of whether it is a "driver" versus "passenger" and an "initiation" versus "progression" event (Chapter 59). Driver mutations directly affect the biology of the cell, whereas passenger mutations do not. Initiation mutations are present within the founding clone and are found in all AML cells. Progression mutations emerge during leukemic evolution, leading to subclones, and exist in only a fraction of AML cells. Selection pressure, such as chemotherapy, can favor the elimination or outgrowth of different branches within the AML evolutionary hierarchy.

Modern genomic technologies have provided a better understanding of normal and leukemic hematopoiesis (Chapter 3). A subset of AML cases evolve from a preceding clinically overt phase such as MDS by subclonal evolution with an increased number of genomic changes. The founder mutations present in preleukemic cells are retained in AML blasts, implicating them as putative initiating events and establishing clonal expansion as the first step in leukemogenesis. However, some recurrent leukemia-associated somatic mutations, such as *TET2*, have also been linked to multilineage CH in aging healthy individuals. For the majority of de novo AML without any prior clinical symptoms, the cell of origin, biologic consequences of initiating mutations, and order of subsequent mutations remain poorly understood. Today, state-of-the-art AML diagnostics relies on integration of different disciplines including cytogenetics and molecular genetics to provide most optimal diagnosis and management. Initial observations by the International Workshop on Chromosomes in Leukemia asserted that cytogenetic findings may serve as the single most important prognostic marker in AML; these observations were subsequently validated through studies conducted by the Medical Research Council (MRC), the Cancer and Leukemia Group B (CALGB), and the Southwest Oncology Group. Finally, in 2008, the WHO incorporated cytogenetic findings along with morphology, immunologic markers, and molecular genetics into their classification system (Chapter 56). Cytogenetics remains the most powerful independent prognostic factor and provides the framework for risk stratification schemes that have been generally adopted to guide treatment approaches for AML patients. Based on karyotype status, two major groups of AML can be distinguished: (a) those with an abnormal karyotype, which accounts for approximately 52% of patients, and (b) those with a normal karyotype by conventional cytogenetics, which accounts for 48% of patients with AML.

AML is generally considered a medical emergency implying an immediate start of treatment as soon as the diagnosis is made. However, a report from the German Study Alliance Leukemia-Acute Myeloid Leukemia registry investigated 2263 patients and analyzed the relationship between the time from diagnosis to treatment start (TDT) and concluded that the TDT had no prognostic significance on remission rates and OS. They suggested that it may be safe to wait for genetic and other laboratory test results in order to assign patients to the best available treatment option before the start of intensive therapy for AML.

Acute Myeloid Leukemia With a Normal Karyotype

Patients with AML and a normal karyotype who present between the ages of 16 and 60 years carry an intermediate prognosis. However, cytogenetically normal AML is highly heterogeneous at the molecular level, both mutations and overexpression of single genes have been identified, and their complex interactions are frequently utilized to provide more accurate risk stratification schemas. Within the normal cytogenetic category, 45% to 62% of patients with AML have nucleophosmin 1 (*NPM1*) mutations, 25% to 35% have *FLT3* mutations, 5% to 10% have *MLL* tandem duplications, and 8% to 15% have *CEBPA* mutations. The prognosis of patients with a normal karyotype differs depending on the presence of each of these mutations (Table 57.8). Patients with *NPM1* mutations alone have a favorable prognosis, with 60% of patients living longer than 11 years. Even in patients age 60 to 74, the presence of an *NPM1* mutation is an independent predictor of a more favorable outcome. More than 20 different mutations have been described in the C-terminal portion of the protein that lead to loss of tryptophan residues and generation of a nuclear export signal that acts in concert to cause delocalization of *NPM1* from the nucleus to the cytoplasm. Because the functional integrity of *NPM1* is dependent on its ability to shuttle between the nucleus and cytoplasm, this ability is severely compromised in *NPM1*-mutated AML. *NPM1*-mutated AML is associated with distinctive biologic and clinical features including older age, female predominance, multi-lineage involvement, extramedullary disease, high blast percentages and increased white blood cell counts, and lack of CD34 expression. As an isolated molecular abnormality, *NPM1*-mutated AML is associated with a highly favorable prognosis, with complete remission (CR) rates with modern chemotherapy being between 70% and 80%. The most common mutation (type A, accounting for 75% of all mutations) generates an aberrant extra nuclear export signal. Although *NPM1* mutations are heterozygous, hetero/homodimerization with wild-type *NPM1* results in cytoplasmic mislocalization of both mutant and wild-type protein. This alteration in subcellular location perturbs normal *NPM1* function, including the mislocalization and stabilization of critical proteins such as the *TP53* regulator p14ARF. This process also generates a distinct transcriptional signature. *NPM1* mutations are considered to be early events in the pathogenesis of AML. In childhood AML with normal cytogenetics, *NPM1* mutations are relatively uncommon, occurring at a frequency of 8% of cases (Chapter 63).

TABLE 57.8 Gene Mutations in Patients With Acute Myeloid Leukemia and a Normal Karyotype

Gene	Chromosomal Location	Frequency (%) of Patients With Normal Karyotype	Prognosis
NPM1	5q35	45–62	Favorable, increased CR rates and prolonged OS in the absence of FLT3 mutation
FLT3-IDT	13q12	25–35	Unfavorable, specifically when the mutant to WT allelic ratio is high
FLT3-TKD	13q12	7–10	Controversial
CEBPA	19q13.1	15	Favorable
MLL-PTD	11q23	10	Not known
IDH1	2q33.3	15–20	Most likely unfavorable
IDH2	15q26.1	20	Most likely unfavorable
DNMT3A	2p23.2	36	Most likely unfavorable
TET2	4q24	5	Likely unfavorable
ASXL1	20q11.21	9–10	Inferior outcome

CR, Complete remission; *OS*, overall survival.

In contrast, the presence of *FLT3* and *MLL* mutations are associated with an adverse prognosis, and coexistence of *FLT3* and *NPM1* does not improve the prognosis. Internal tandem duplications (ITDs) of the *FLT3* gene confer an increased risk for relapse and death when compared with patients without *FLT3*-ITD. Three types of *FLT3* gene changes are present, ITD of the juxtamembrane domain-coding sequence, a point mutation within the activation loop domain, and the copy-neutral loss of heterozygosity. Although both mutations lead to the constitutive activation of the receptor, only presence of *FLT3*-ITD with high allelic ratio has been associated with an inferior outcome in young patients. This mutation initially develops as a heterozygous mutation and over time the *FLT3*-IDT blasts acquire copy-neutral loss of heterozygosity resulting in homozygous mutated allele and high *FLT3*-ITD allelic ratio. OS of patients with *FLT3*-ITD differs significantly when categorized by the 2017 ELN risk stratification criteria.[10] Therefore, at diagnosis of AML a complete work-up according to ELN recommendations, including assessment of ITD allelic burden is mandatory to select patients eligible for intensive therapy

Intact functioning of the CCAAT/enhancer binding protein (*CEBPA*) gene is essential for normal granulocytic differentiation. It is a lineage-specific transcription factor that is required for the formation of committed myeloid progenitors from multipotent progenitor cells. *CEBPA* executes this function by coupling the direct transcriptional activation of myeloid-specific genes with the arrest of cell proliferation. *CEBPA* is an intron-less gene with mRNA that can be translated into two different AUG codons to give rise to two distinct isoforms, p42 and p30. Only the p42 isoform of *CEBPA* can promote proliferation arrest. *CEBPA* mutations, leading to arrest of differentiation, are seen in 5% to 10% of de novo AML and in up to 15% of normal karyotype AML. Only mutations affecting both alleles, double mutations, confer superior survival as compared to single mutations. Concomitant *GATA1* and *WT1* mutations are seen more often in double mutants while *FLT3-ITD, NPM1, ASXL1*, and *RUNX1* mutations are more commonly associated with single mutations, possibly contributing to their poorer prognosis.

A rare but specific subset of adult AML can be defined by the cytogenetically cryptic *NUP98-NSD1* fusion gene that involves the nucleoporin gene 98 (*NUP98*) on chromosome1, 1p15, and the nonhomeobox gene *NSD1* present on chromosomal band 5q35. *NUP98* encodes a 98-kDa protein of the nuclear pore complex, which is known to fuse with at least 21 different fusion gene partners in chromosomal rearrangements in various hematologic malignancies. NSD1 is thought to function both as a transcriptional co-activator and a co-repressor. Among 293 pediatric and 808 adult cytogenetically normal cases of AML the *NUP98-NSD1* fusion gene was described in 16.1% of pediatric and 2.3% of adult AML cases. Apparently *NUP98-NSD1* has been shown to correlate with *FLT3*-ITD, which is associated with increased blast cell percentages.

TET2 proteins are necessary for the conversion of 5-methylcytosine to 5-hydromethylcytosine and play a role in demethylation processes within the cell. *TET2* mutations have been reported in 10% to 23% of patients with AML with a normal karyotype. The impact of *TET2* mutations on the prognosis and outcome remains poorly defined.

DNMT3A mutations, which affect the DNA methyltransferase enzymes and subsequent epigenetic modulation, have been described in about 27% to 33% of normal karyotype AML and are associated with a worse OS (see earlier section on clonal origin and early mutations).[11]

TABLE 57.9 **The European Leukemia Net 2017 Risk Stratification of Acute Myeloid Leukemia**

Prognostic Group	Subset	CR Rate; Relapse With 3+7 Without HCT	Comments
Favorable	inv(16)/t(16;16) NK and *NPM1+/ FLT3* ITD-NK and *CEBPA* +/+	>80%–90%; 35%–40%	Outcome worse in older patients, with t-AML, KIT mutations, and poor response to initial therapy
Intermediate	Mutated NPM1 and FLIT3-ITD (without adverse-risk genetic lesion), t(9;11)(p21.3;q23.3)/ MLL-KMT2A	50%–80%; 50%–60%	Outcome worse in older patients, with t-AML, and poor initial response
	Cytogenetic abnormalities Not in favorable or adverse group		Outcome worse in older patients, with t-AML, and poor initial response
	FLT3 ITD+		
Adverse	−5, −7, 5q abn, 3q, 17p, 11q (other than 9;11), t(6;9), complex, monosomal karyotype, wild type NMP1 and FLT3-ITD, Mutated RUNX1, Mutated ASXL1 and mutated TP53, insufficient metaphases for analysis	<50%; >90%	Outcome worse in older patients, with t-AML, and poor initial response

AML, Acute myeloid leukemia; *CR*, complete remission; *HCT*, hematopoietic cell transplant; *NK*, normal karyotype, +/+, double mutation.

Currently, a newly diagnosed patient with AML and a normal karyotype should be checked for common mutations such as *FLT3, NPM1, CEBPA, RUNX1, MLL-PTD*, or *EVI1, TET2*, and *DNMT3A*, which may have prognostic and possibly therapeutic implications (Table 57.9).

Integration of NGS and high-density SNP array in a study of 252 patients with de novo AML and normal karyotype showed co-occurrence of mutations and cryptic cytogenetic abnormalities in 58% of which 49% harbored copy-number abnormalities or copy neutral loss of heterozygosity (CN-LOH).[7] Of the 282 cryptic acquired abnormalities, genomic losses were more frequent than gains or CH-LOH (54%, 27%, and 19%, respectively). Losses were distributed virtually across all chromosomes, differently from CN-LOH and gains. Most important, the majority of lesions were not recurrent with the exception of those located on 13q. Losses and CN-LOH were concentrated in chromosomes 1, 2, 5q, 7, 11q, and 13q. Due to their location, and general implications of losses and CN-LOH, these genomic cryptic abnormalities could be acting as a second hit in the leukemogenesis process due to the loss of the wild-type alleles. Initial results are consistent that the presence of two or more genomic lesions has a negative impact on patient outcomes.

Acute Myeloid Leukemia with an Abnormal Karyotype

Among patients with an abnormal karyotype, 25% have balanced translocations and 27% showed unbalanced abnormalities or a complex karyotype.

The pretreatment AML karyotype constitutes an independent prognostic determinant for attainment of CR and risk for relapse and survival. Four broad cytogenetic risk categories of AML are useful in clinical practice: favorable, intermediate, unfavorable, and unknown (Figs. 57.32, 57.33 and Table 57.9). It is important to perform appropriate cytogenetic and FISH studies to establish the correct cytogenetic risk category. Table 57.10 lists 72 of approximately 250 recurrent chromosomal translocations observed in leukemias, including AML and excluding *MLL* translocations (see later) (see Fig. 57.40). Because of their specific association with distinct subtypes of leukemia, some AML-specific translocations have been incorporated into the WHO classification as criteria for subclassification of AML, including t(8;21) (Fig. 57.34), t(15;17), inv(16) (Fig. 57.35), and 11q23 rearrangements, regardless of the morphology or percentage of blast cells.

Two specific cytogenetic types of AML—t(8;21)(q22;q22) and inv(16)(p13q22) or t(16;16)(p13;q22) (see Fig. 57.35)—are called *core-binding factor (CBF)* AMLs and are usually grouped together due to similarities in their molecular and prognostic features. However, the morphologic features of these two AML subtypes are very different, suggesting that individual approaches may enhance clinical benefits in future studies. Patients with t(8;21) exhibit large myeloid blasts with abundant basophilic cytoplasm, numerous azurophilic granules, and occasional Auer rods. Patients with 16q22 abnormalities show increased numbers of eosinophils to varying degrees, and at all stages of maturation. The immature eosinophilic granules are larger than normal and may contain purple-violet cytoplasmic granules. The t(8;21) subtype may be present alone, although 30% to 35% of patients also display LOY in males and LOX in females. Another 20% of patients with t(8;21) have a deletion of 9q12–23, including a commonly deleted segment that spans 7 to 8 Mb. Trisomies for chromosomes 4 and 8 together with t(8;21) are observed in 6% to 10% of patients. Virtually all patients with t(8;21) achieve CR with induction chemotherapy. Additional cytogenetic abnormalities, irrespective of their nature or complexity, do not have a deleterious effect on rates of remission, relative risk of relapse, and OS. t(8;21) interrupts two genes—*RUNX1* (*CBFA2*) on chromosome 21, band q22, in intron 5, and *RUNX1T1 (ETO)* [eight, twenty-one gene], on chromosome 8, band q22—and joins them to form a new chimeric gene on the abnormal der(8) chromosome. *RUNX1* is a gene on chromosome 21, also known as *CBFA2* because it encodes for a DNA-binding component of CBF and binds DNA through a specific sequence called the *runt domain*. The *RUNX1* gene locus on chromosome 21 spans 120 kb; the *RUNX1T1* gene on chromosome 8 is distributed over 87 kb.

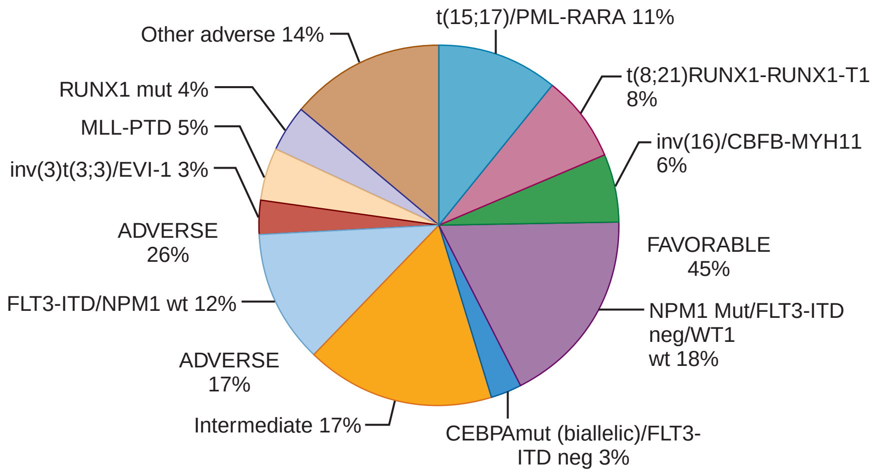

Figure 57.32 INTEGRATION OF CYTOGENETIC ABNORMALITIES AND MOLECULAR MARKERS TO REFINE RISK GROUPS IN ACUTE MYELOID LEUKEMIA. *(Reprinted from Smith ML, Hills RK, Grimwade D. Independent prognostic variables in acute myeloid leukaemia. Blood Rev. 2001;25:39; with permission.)*

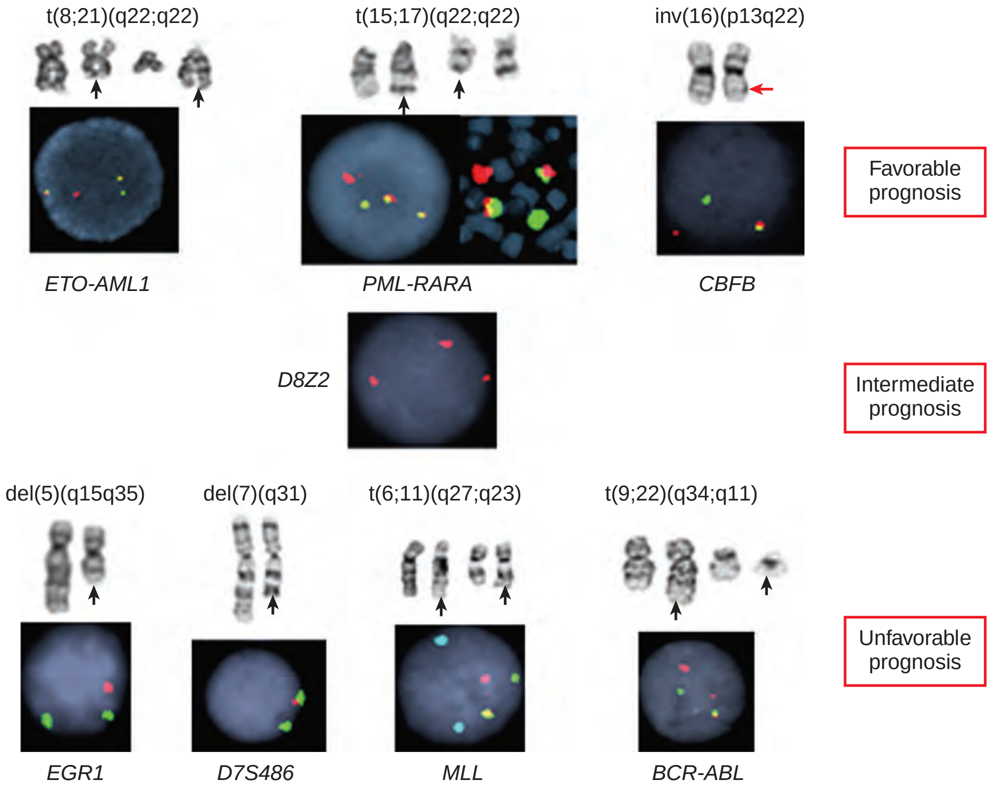

Figure 57.33 PROGNOSTIC CYTOGENETIC RISK CATEGORIES IN ACUTE MYELOID LEUKEMIA. Favorable prognosis includes t(8;21) and ETO-AML1 fusion, t(15;17) and PML-RARA fusion, and inv(16) and rearrangements of *CBFB* on 16q22. Trisomy 8 is associated with intermediate prognosis. Unfavorable cytogenetic risk categories include monosomy 5/del(5q), −7/del(7q), and translocations of 11q23 and *MLL*, represented here by t(6;11), and the Philadelphia chromosome.

The *RUNX1* gene has been identified in more than 39 chromosomal translocations in leukemia and plays a critical role during hematopoiesis (see different *RUNX1* chromosomal partners: http://atlasgeneticsoncology.org/Genes/AML1ID52.html). The fusion gene is located on the partner chromosome in the majority of *RUNX1* translocations. Its disruption is associated with the development of myeloid and lymphoid leukemias. Therefore *RUNX1* is viewed as a master regulatory switch that controls development of a definitive hematopoietic lineage. Moreover, the *RUNX1* transcription factor is critical for proliferation and differentiation of hematopoietic stem cells. Haploinsufficiency of *RUNX1* has been linked to a propensity to develop AML, and biallelic nonsense mutations in the *RUNX1* gene have been identified with primitive forms of AML(M0 subtype). The RUNX1T1 protein belongs to the ETO family of proteins involved in protein–protein interactions but not in protein-DNA interactions.

In the hybrid RUNX1-RUNXT1 protein, the C-terminus of RUNX1 is replaced by the entire RUNXT1 protein. The main functional characteristic of RUNX1-RUNX1T1 chimeric protein is its

ability to bind DNA containing RUNX1 binding sites and thereby exert a dominant negative inhibition of the endogenous RUNX1 protein. The exact role of the RUNX1-RUNX1T1 fusion protein in determining the onset and progression of AML is not fully understood; however, accumulating evidence indicates that even a point mutation in the RUNX1 protein, responsible for assembling and organizing the machinery for hematopoietic gene expression at multiple sites in target genes, results in a block of differentiation of myeloid progenitors to granulocytes. *RUNX1* mutations are present in 46% of patients with AML with the M0 subtype and in 80% of patients with trisomy 13 AML. As mentioned earlier, the *FLT3* gene is localized on chromosome 13, and *RUNX1* mutations and trisomy 13 are associated with a fivefold increase in *FLT3* transcript levels as compared with patients without trisomy 13. The exact relationship

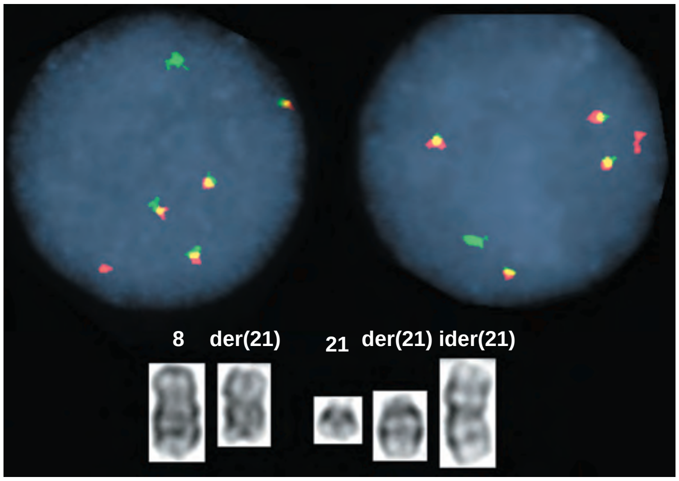

Figure 57.34 DUPLICATION OF T(8;21). Four copies of ETO-AML1 (RUNX) fusion *(yellow)* shown in two interphase cells *(top)* from a patient with acute myeloid leukemia and t(8;21) *(bottom)* karyotype, as well as ider(21). This formation is equivalent to the Ph duplication in the blast crisis of chronic myelogenous leukemia because of duplication of der(21) without accompanying t(8;21).

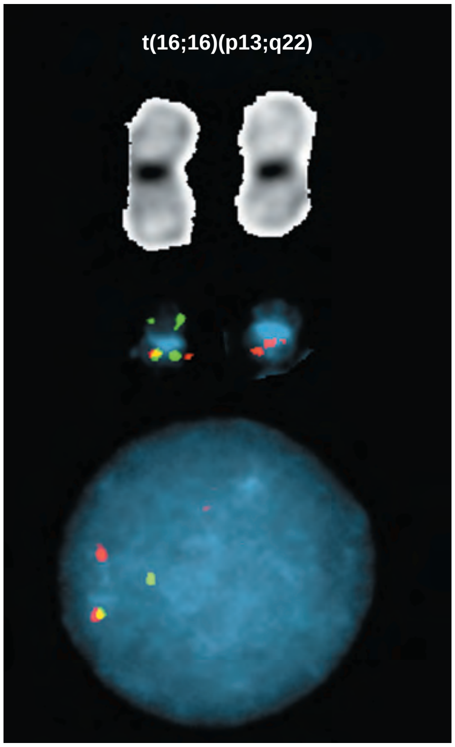

Figure 57.35 Partial G-banded karyotype from a patient with M4 acute myeloid leukemia showing t(16;16) *(top)*, after FISH study using a break-apart CBFB probe (at 16q22), demonstrating that the 5′ end *(red)* of the gene remains on 16q of one chromosome 16, whereas the 3′ end *(green)* translocated to the short arms of the other chromosome 16. Separation of 5′ and 3′ ends as single signals is indicated in the bone marrow nucleus *(bottom)*. *FISH*, Fluorescence in situ hybridization.

between *FLT3* and *RUNX1* in leukemogenesis remains unknown. Multiple copies of *RUNX1/RUNXT1* fusion have been demonstrated (see Fig. 57.34). The t(8;21) is the most common translocation in pediatric patients with AML (10% to 20%) (Chapter 63). Prenatal origin of t(8;21) AML has been established for approximately 50% of pediatric AML patients using Guthrie card analysis.

Although 60% to 70% of patients with t(8;21) achieve complete and long-term remission with modern chemotherapy regimens, monitoring MRD using t(8;21) marker has proven to be useful in identifying patients at a high risk for relapse. Multiparametric approaches, such as flow cytometry, RQ-PCR, and interphase FISH, are complementary methods and provide useful information concerning MRD and relapse kinetics. It should be noted that 18% of healthy individuals have *RUN1-RUNXT1* transcripts detectable by PCR and the fusion transcripts have been detected in 40% of cord blood samples, suggesting that *RUNX1-RUNXT1* by itself may not have overt leukemia-initiating properties.

In patients with 16q22 abnormalities such as inv(16)(p13;q22) and t(16;16)(p13;q22), the marrow contains an increased percentage of abnormal eosinophils (see Fig. 57.35). Combined May-Grünwald-Giemsa staining with FISH demonstrates that the abnormal eosinophils possess inv(16) and therefore belong to the leukemic clone. Trisomy 22 is a frequent accompanying abnormality. Both inv(16) (see Fig. 57.35, *top right*) and t(16;16) (see Fig. 57.35, middle) are abnormalities of the *CBFβ* gene at 16q22 and are associated with M4Eo subtype, as was characterized previously by the FAB AML classification system. Both rearrangements result in fusion of *CBFβ* and *MYH11 (myosin heavy-chain) gene of 16p13. The exact role of the resulting hybrid protein, CBFβ- SMMHC* (smooth muscle myosin heavy chain), is unknown, but is likely involved in impaired hematopoietic differentiation. Both t(8;21) and inv(16) result in abnormal repression of CBF target genes. CBF is a heterodimeric transcription factor complex that consists of three distinct DNA-binding CBFα subunits—*RUNX1, RUNX2*, and *RUNX3*—and a common *CBFβ* subunit, which is non-DNA-binding. The binding affinity of *RUNX1* subunit to the DNA promoter sequences is significantly increased by association with CBFβ, which does not directly interact with DNA and protects the *RUNX1* subunit from proteolysis. The breakpoints in t(8;21) affect *RUNX1* exon 5 and R*UNX1T1* exon 2. The breakpoint in *MYH11* involved in inv(16) and t(16;16) is variable and gives rise to at least 10 different fusion variants. In contrast, the breakpoints in CBFβ at 16q22 are at intron 5. Both translocations are associated with a favorable prognosis, but they exhibit different leukemic cell morphology.

Approximately 4% of patients with *CBFβ-MYH11* rearrangement lack a cytogenetically detectable inv(16) or t(16;16). Cytogenetic detection of inv(16) may be difficult, and interphase FISH with a dual-color CBFβ probe at diagnosis is a crucial genetic test. *CBFβ-MYH11* fusion can be found by either RT-PCR or FISH in AML patients without eosinophilia; therefore *CBFβ* testing should be included in the standard AML testing panel. The presence of additional abnormalities, such as trisomy 8, do not adversely affect clinical outcomes.

The *CBFβ-MYH11* chimeric fusion can be detected in utero approximately 10 years before development of childhood leukemia. This observation suggests that formation of *CBFβ-MYH11* alone is not sufficient to cause leukemia and that subsequent genetic events must occur before clinically recognizable AML. CBF AML is associated with a favorable CR rate, OS, and lower relapse risk than patients with cytogenetically normal AML. However, a retrospective analysis of 113 patients with CBF AML demonstrated that patients with inv(16) at diagnosis were less likely to have any normal metaphases when compared with patients with t(8;21). Moreover, the identification of an increasing number of normal metaphase cells increased the risk for relapse and negatively affected the survival of patients with inv(16); identifying at least one normal metaphase at diagnosis and 19 with inv(16) had a significant impact on 5-year survival (60% versus 14%, $P = .00005$). These factors, along with age, were the only independent variables associated with refractory disease and higher relapse. Nevertheless, CBF AML has been defined as a favorable genetic group by National Comprehensive Cancer Network (NCCN) and ELN guidelines. NCCN guidelines have classified t(8;21) and inv(16) AMLs with c-*KIT* mutations as having intermediate risk disease, whereas the ELN has provided no further recommendations for those with c-*KIT* mutations. Mutations in the *KIT* gene are the most recurrent molecular abnormalities, occurring in 15% to 46% of CBF

AML, and are associated with a higher risk for relapse. The mutation frequency was similar for pediatric and adult patients with t(8;21) whereas pediatric patients with inv(16) AML tend to have a higher frequency of *KIT* mutations than adult patients. Approximately 5% to 10% of CBF AML patients, mostly those with t(8;21), have concurrent systemic mastocytosis with *KIT* mutations and a good prognosis (Chapter 75).

The cKIT mutations are clustered within exon 17 which encodes the *KIT* activation loop (A-loop) in the kinase domain, and in exon 8, which encodes an evolutionarily highly conserved region in the extracellular portion of the *KIT* receptor. KIT17 mutations occur almost exclusively at codon D816 in patients with inv(16), and at codons D816 or N8822 in patients with t(8;21). *KIT* mutations represent not only a prognostic indicator but also a potential therapeutic target for TKI therapy. In adults the mutation frequency in exon 17 is significantly higher in t(8;21) than in inv(16) patients with AML (35.6% vs. 6.9%, respectively, $P < .0001$), whereas the mutation frequency in exon 8 is significantly lower in t(8;21) than inv(16) patients with AML (4.4% vs. 18.8%, respectively, $P = .0003$). The prognostic value of *KIT* mutations in CBF AML remains debatable. The incidence, characteristics, and prognostic effects of *KIT* mutations are different for each subgroup. It appears that mutations in exon 17 have a strong adverse impact on the relapse and survival of adult patients with t(8;21) AML.

Other activating mutations associated with CBF AML include *FLT3*, *CBL*, *NRAS* or *KRAS*, and *ASXL2*. *FLT3* point mutations (most common D835) are frequently associated with inv(16) (6% to 24%) and 6% of patients have *CBL* mutations associated with improved OS. *NRAS*- and *KRAS*-activating mutations are preferentially observed in inv(16) and do not impact prognosis. *ASXL2* mutations (11.5%) are exclusively associated with t(8;21) and were not observed in inv(16) patients. The ASXL2 protein is involved in epigenetic regulation of gene transcription and seemingly confers a worse prognosis but these results need more extensive validation. *RUNX1* mutations present in about 5% to 15% of patients with M0 AML, are mutually exclusive when t(8;21) and inv(16) are present. As mentioned earlier, there are 47 recurrent abnormalities involving the 21q22 chromosomal site where *RUNX1* is localized. Some of the more frequent rearrangements are discussed here.

The t(16;21)(q24;q22) is a rare but recurrent chromosomal abnormality associated with therapy-related AML. FISH and RT-PCR methods have demonstrated fusion of *RUNX1* on 21q22 and *CBFA2T3* on chromosome 16, which produces an *RUNX1/CBFA2T3* fusion gene on chromosome 16. The breakpoints of both t(8;21) and t(16;21) occur within the same intron of the *RUNX1* gene. *RUNX1/CBFA2T3* fusion results in the production of a protein that is very similar to the RUNX1/RUNX1T1 protein in t(8;21).

The (16;21)(p11;q22) chromosomal rearrangement is rare and associated with M1-M2 AML. A proportion of these patients may have additional abnormalities. This translocation fuses the *FUS/ERG TLS/FUS* gene on chromosome 16, band p11, to the *ERG* gene on chromosome 22, band q22. The *ERG* gene is a member of the E twenty-six (ETS) family of transcription factors and is a sequence-specific transcriptional activator. The presence of a fusion transcript is detected by RT-PCR, at the time of diagnosis, at relapse, and during remission. These observations are consistent with the impression that patients with t(16;21) have a poor prognosis and may benefit from early detection of this chimeric gene to determine the need for more aggressive therapy.

AML with intrachromosomal amplification of chromosome 21 (iAMP21) is a rare entity (~0.1%). It occurs in pediatric B-cell ALL (~2%) (see below ALL) and as such was recognized by the current WHO classification as a provisional entity in 2017. In adult AML, iAMP21 is most often identified using FISH technology. Interphase cells showing 5 or more copies of *RUNX1* gene, that are localized on chromosome 21q22, are considered positive. Most of the adult AML patients with iAMP21 have a complex karyotype and the most frequent additional abnormalities include −5/del(5q), −7(del7q), −17/del(17p). High copy numbers of *RUNX1* are identified as homogenous staining of region 21(q22), extra copies of chromosome 21 and/or i(21q) insertion of 21q22, double minutes (DM), and ring or marker chromosomes. AML iAMP21 differs in several ways from B-cell ALL: (a) AML patients with iAMP21 are almost all adults (median age 65 years old), (b) they are almost always associated with a complex karyotype, (c) they show a high frequency of *TP53* deletion/mutation, (d) often they present with pancytopenia, and (e) these patients are highly refractory to standard AML-induction therapy. The regions predominantly amplified span chromosome 21q22.1q22.3 and these chromosomal segments range in size from 11.8 to 40 Mb. Since most patients with AML iAMP21 have a deletion/mutation of *TP53*, a very complex karyotype, and genomic instability chromothripsis appears to be an underlying mechanism of pathogenesis.

The t(15;17)(q22;q21) involves the promyelocytic leukemia (*PML*) gene on chromosome 15, band q22, and *RARA* on chromosome 17, band q21. This abnormality constitutes the genetic basis for approximately 95% of all cases of APL (Fig. 57.36).[12] The remaining 5% of cases possess nine rare variant translocations: t(11;17)(q23;q21)/*ZBTB16-RARA* and *MLL-RARA*, t(11;17)

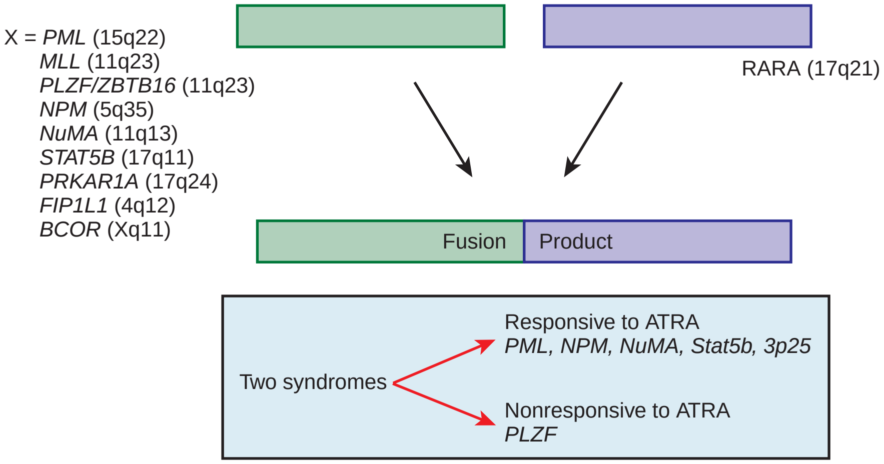

Figure 57.36 MOLECULAR CYTOGENETIC DEFECTS IN ACUTE PROMYELOCYTIC LEUKEMIA ARE RESPONSIBLE FOR DIFFERENT RESPONSE TO ALL-*TRANS* RETINOIC ACID DIFFERENTIATION THERAPY. Patients with t(11;17)(q23(q22) and PLZF(ZBTB16)-RARA fusion do not respond to all-*trans* retinoic acid (ATRA) differentiation therapy, whereas patients with classic t(15;17) and other four cytogenetic variants have exquisite sensitivity to differentiate in response to all-trans retinoic acid. *(From Cheng L, Zhang DY, eds. Molecular Genetic Pathology. Totowa, NJ: Humana Press, a part of Springer Science; 2008.)*

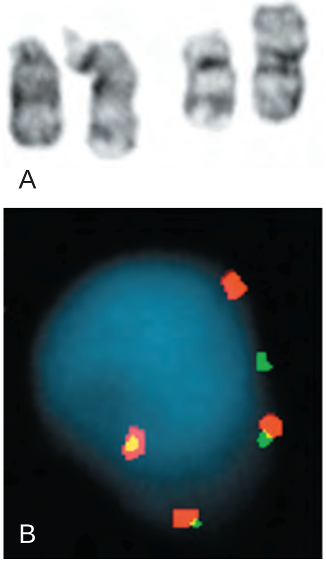

Figure 57.37 ISOCHROMOSOME 17 IN ACUTE PROMYELOCYTIC LEUKEMIA WITH A GAIN OF PML-RARA FUSION. (A) Partial karyotype from a patient with acute promyelocytic leukemia, showing ider(17) t(15;17)(q22;q21). The karyotype shows isochromosome for the long arms of chromosome 17 and deletion of the short arms. (B) FISH studies revealed three copies of PML-RARA fusion in bone marrow nucleus, confirming that the first event in the pathogenesis was PML-RARA fusion and the subsequent event was a structural rearrangement of isochromosome. *FISH*, Fluorescence in situ hybridization.

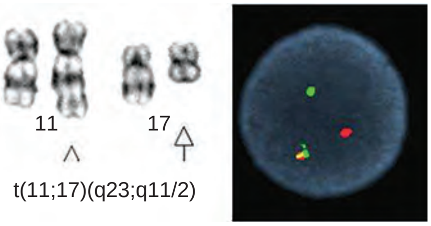

Figure 57.38 A variant of APL showing in 90% of marrow cells a balanced translocation between the long arms of chromosomes 11 and 17. This is a variant APL translocation involving *KMT2A* and *STATB* at 17q11 chromosomal site. Interphase bone marrow nuclei after FISH showed 78% of cells with a split in KMT2A dual color breakapart probe, between the 5′ *(green)* and 3′ *(red)*. *APL*, acute promyelocytic leukemia; *FISH*, Fluorescence in situ hybridization.

(q23;q21)/*NUMA1-RARA*, t(5;17)(q35;q21)/*NPM1-RARA*, t(2;17)(q32.3;q21)/*NABP1-RARA*, t(17;17)(q21.2;q21.2)/*STATB-RARA*) (Fig. 57.37) or del(17)(q21.2q21), iso (17q) (Fig. 57.38) t(4;17)(q12;q21) *FIP1L1/RARA*, t(X;17)(p11.2;q21)/*BCOR-RARA*, and cryptic *PRKAR1A-RARA* detected in a patient with a normal karyotype. Therefore APL, which accounts for 10% to 15% of AML cases, is associated with several different genetic rearrangements fusing the *RARA* gene with a different partner gene. Based on these genomic rearrangements, a FISH assay, using a breakapart probe strategy with dual-color *RARA*, can identify two different clinical syndromes: those responsive to all-*trans* retinoic acid (ATRA) (more than 99%) therapy and those carrying a *ZBTB16-RARA* or *STAT5B-RARA* fusion gene, which are not responsive to ATRA and are naturally resistant to arsenic trioxide (ATO) therapy. Patients with promyelocytes that have exquisite sensitivity to differentiate in response to ATRA treatment have one of the other six RARA fusion rearrangements (see Fig. 57.36). ATRA resistance is heterogeneous and commonly involves mutations in the RARA ligand-biding domain of the fusion protein. FISH studies have also identified patients with cryptic translocations and unusual chromosomal variants (see Fig. 57.36). It is important to recognize patients who will or will not respond to ATRA so that appropriate therapy can be administered.

The t(15;17) is often the only chromosomal abnormality present in 70% to 100% of APL bone marrow metaphase cells. The most frequent additional abnormality is trisomy 8, but this abnormality does not influence the rate of CR. The *RARA* gene is a nuclear hormone receptor, spanning 7.5 kb, and contains nine exons. The breakpoint occurs almost exclusively in intron 2 of the *RARA* gene. The *PML* gene locus spans 35 kb and contains nine exons coding for mRNA of 4.6, 3.0, and 2.1 kb. The breakpoints in *PML* occur in three distinct clusters leading to mRNAs of different length. The existence of different breakpoint regions in the *PML* gene and the presence of alternative splicing of PML transcripts are responsible for the heterogeneity of *PML RARA* junctions and variants.

APL is a disease characterized by accumulation of cells blocked at the promyelocytic stage of granulocytic differentiation. APL accounts for only 5% to 8% of pediatric AML, and 95% of children with APL show a classic t(15;17). However, almost 35% of pediatric APL have *FLT3-ITD* mutations. The clinical signs of these additional mutations on relapse rate and OS is not yet apparent.

Our current understanding of the molecular pathogenesis of APL is that *PML-RARA* behaves as a potent transcriptional repressor and that supra physiologic doses of retinoic acid can overcome this repression. In the presence of retinoic acid, *PML-RARA* behaves as a transcriptional activator. In patients with variant *ZBTB16-RARA*, an additional co-repressor complex binding site is present, and histone deacetylase inhibitors are used to restore sensitivity to retinoic acid. It appears that *PML-RARA* fusion-induced differentiation arrest of leukemic blasts and increased self-renewal of progenitors are two distinct features of APL and are probably driven by two different gene programs. The *RARA* fusion protein has a dual action, activating transcription of a number of genes and repressing transcription of others. *PML-RARA* and *ZBTB16-RARA* repress several DNA repair genes and activate the Wnt signaling and NOTCH pathways leading to increased stem cell renewal. Many of the genes targeted by retinoid acid are known to play a key role in regulating myeloid cell proliferation and differentiation. Therefore it is possible that inhibition of their expression by RARA fusion proteins may lead to differentiation blockade. A rare translocation (11;12)(p15;q13) has been identified in ∼10 patients, with morphological and immunophenotypic features of APL. This chromosomal translocation results in a fusion between *nucleoporin* (*NUP*)*98 and RARG* gene (RAR gamma) and these patients do not respond to treatment with ATRA and ATO. The common characteristic of these very rare patients is the presence of *RARG* rearrangement. Some partner proteins can bind to different DNA-binding domains of *RARG* to form fusion proteins such *as PML–RARG*, *CPSF6–RARG*, and *NPM1–RARG–NPM1*.

Rapid confirmation of APL diagnosis is mandatory and should be performed, if possible, on a bone marrow specimen, using ELN recommendations.[12] Accurate identification of the APL-associated genomic lesion at diagnosis is important because APL is a medical emergency that is frequently associated with an abrupt onset, high risk for early death (10% to 20%), and a potential for high cure rate (>80%) if appropriate treatment is rapidly initiated, based on its definitive diagnosis.

Although the *PML-RARA* rearrangement is the main pathogenetic event in APL other recurrent somatic mutations in genes including *FLT3*, *WT1*, *NRAS*, *KRAS*, *ARID1B*, and *ARID1A* have been observed. Recent data indicate that FLT3-ITD mutations do not confer a worse prognosis in patients receiving ATRA plus ATO. Comparing the initial mutational status of patients who relapsed during the course of disease and those in CR the number of concomitant mutations per patient was significantly higher in the group of patients who relapsed ($P < .0001$) indicating an accumulation of genetic alterations during disease progression. The treatment outcome in patients with newly diagnosed APL improved dramatically with the introduction of ATRA and ATO. ATRA activates transcription of blocked genes and degrades PML-RARA while ATO degrades PML-RARA by promoting apoptosis and has a pro-oxidant effect. Despite remarkable scientific advances over the past two decades high-risk patients and patients exhibiting uncharacteristic translocations remain problematic. The initial workup should include conventional karyotyping, FISH studies, RT-PCR, and anti-PML antibodies. Longitudinal monitoring of disease with RQ-PCR and FISH is currently recommended to provide assessment of MRD and early intervention if relapse should occur.

Less than 1% of patients with AML have a Ph chromosome (see Fig. 57.33, *bottom right*) and it remains a controversial entity as it is not listed in the WHO 2016 classification as a separate entity. Ph-positive (Ph+) AML may be cytogenetically distinguished from the myeloid blast crisis of CML by monosomy 7 (also frequently found in Ph+ ALL) and inv(16). Moreover, mutations found in 40% to 60% of AML as well as in Ph+ AML have not been described in Ph+ CML. All Ph+ AML examined to date showed a unique loss of Ig genes with a specific genomic signature, suggesting a distinct biologic entity. Both P210$^{BCR\text{-}ABL1}$ and P190$^{BCR\text{-}ABL1}$ were observed, but P190 appears to be prevalent. Before TKI therapy, the median survival of the Ph+ AML was 9 months; this has improved to a median survival of 18 months (range 6 to 71) with the use of imatinib therapy. In rare patients with AML, late appearance of a Ph chromosome either as a sole abnormality or in a clone showing t(8;21) is taken as evidence that the Ph chromosome in these patients is a secondary event. The late-appearing Ph chromosome in AML is characterized by P190$^{BCR\text{-}ABL1}$ protein. The coexistence of the Ph chromosome and inv(16) is a rare but recurrent finding in both CML and AML. In CML the fusion transcript is P210$^{BCR\text{-}ABL1}$, whereas in AML the fusion transcript is P190$^{BCR\text{-}ABL1}$. The presence of both the Ph chromosome and inv(16) in AML is associated with a favorable prognosis, whereas in CML, the coexistence of *BCR-ABL1* and *CBFB-MYH11* is predictive of rapid evolution to blast crisis. Rare AML patients may present with inv(3)(q21;q26.6)/*GATA2-MECOM* fusion and a subclone showing the Ph chromosome/*BCR-ABL1*.

Using extra-sensitive *BCR-ABL1* FISH probe Ph+ AML expressing P190$^{BCR\text{-}ABL1}$ protein may be recognized, and distinguished from the Ph+ CML because it is characterized by a second co-localized “fusion” signal, since the breakpoint on chromosome 22 in AML is more centromeric with two signals being closer to each other giving an impression of two fusion signals.

The *KMT2A* [lysine (K)-specific methyltransferase 2A], (*MLL*) gene at 11q23.3 is responsible for 95% of all 11q23 translocations, including both those in patients with AML and ALL (Figs. 57.39 and 57.40 and Table 57.11). *KMT2A* (previously known as *MLL*) is a large, 90-kb gene containing 36 exons coding for a 431-kDa protein. The protein contains AT hooks, which are known to regulate transcription by inducing changes in DNA conformation that permit the association of transcription factors with regulatory regions of DNA. *KMT2A* rearrangements occur in approximately 70% of infant and 10% of adult therapy-related leukemias. As of January 2021 102 direct *KMT2A*/*MLL*-gene fusions, 11 *KMT2A* rearrangements but not in-frame translocations, an additional 11 cases where the partner

(H) der(11)dic(1;11)(q12;q23) in a patient with myelofibrosis transforming to acute myeloid leukemia. (I) der(14)t(11;14)(q23;q23), resulting in trisomy for part of the long arms of chromosome 11. (J) t(4;11)(q23;q23) in pediatric acute lymphoblastic leukemia. (K) t(6;11)(q27;q23) in pediatric acute lymphoblastic leukemia. (L) t(11;19)(q23;p13) in pediatric acute lymphoblastic leukemia and after FISH study, showing separation of *MLL* breakapart probe where the 5′ end of the *MLL (green)* remains on der(11) and the 3′ end *(red)* is translocated to 19p. (M) t(9;11)(p22;q23) in pediatric acute myeloid leukemia and after metaphase FISH study *(right)*, showing that the 3′ end of the *MLL (red)* is translocated to 9p but the 5′ end *(green)* remains on der(11). *FISH*, fluorescence in situ hybridization.

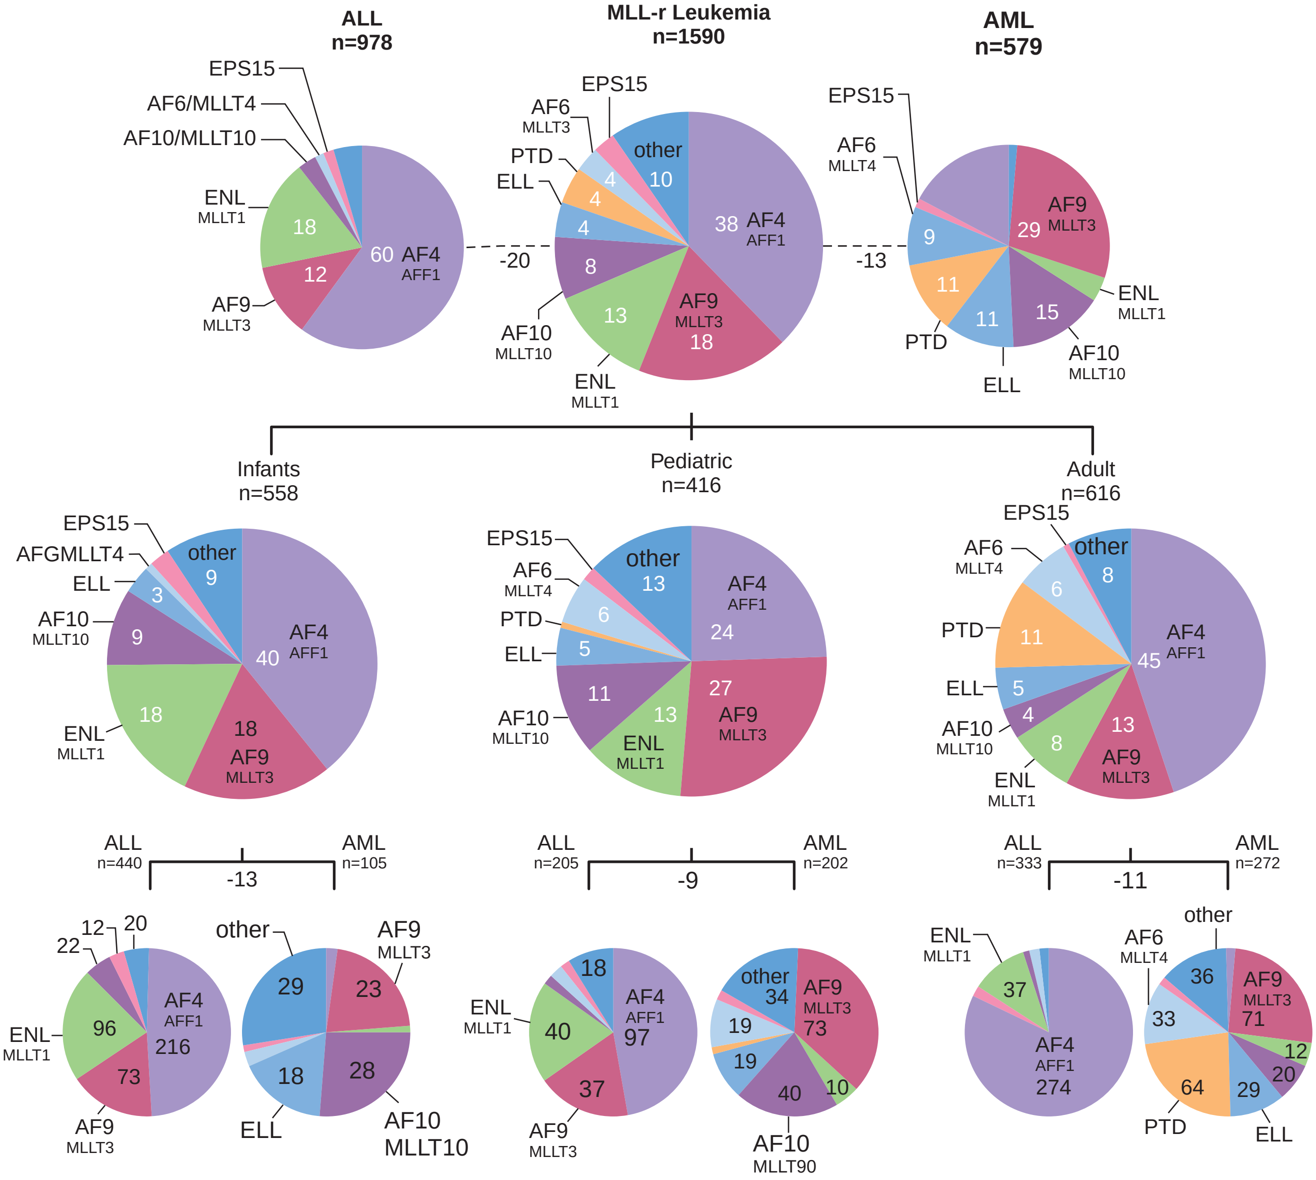

Figure 57.40 THE MLL RECOMBINOME IN ACUTE LEUKEMIA. Classification of patients according to age classes and disease type. (*Top*) Frequency of most frequent translocation partner groups in the investigated patient cohort of *MLL*-rearranged acute leukemia patients ($n = 1590$). This patient cohort was divided into ALL *(left)* and AML patients *(right)*. Gene names are written in black, and percentages are indicated as white numbers. Thirty-three patients could not be classified into the ALL or the AML disease types, respectively. *(Middle)* TPG frequencies for the infant, pediatric, and adult patient group. *(Bottom)* Subdivision of all three age groups into ALL and AML patients. Negative numbers refer again to the number of patients who were neither classified to the ALL nor to the AML subgroup. *ALL*, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *TPG*, translocation partner group. *(Reproduced with permission from Meyer C, Hofmann J, Burmeister T, et al. The MLL recombinome of acute leukemias in 2013. Leukemia. 27:2165, 2013.)*

gene is not directly fused, and 35 additional cases where the partner gene is not characterized at the molecular level have been identified (personal communication with Dr. Claus Meyer in January 2021).[13] In nearly all direct and reciprocal *KMT2A* recombinomes, the 3′ portion of the *KMT2A* gene is retained causing a direct fusion of the 5′ *KMT2A* gene portion with a portion localized telomeric to *KMT2A*. Of note, an abnormal FISH signal pattern, using dual-color, break-apart FISH, shows an abnormal signal pattern arising from 3′ *KMT2A* deletions in up to 28% of cases, and very rarely a gain of 3′ *KMT2A* portion of the gene, usually as a result of an additional derivative partner chromosome.

The five most frequent rearrangements of the 11q23/*KMT2A* gene in adult AML occur either with a translocation partner gene such as t(9;11)/KMT2A-*MLLT3 (MLL-AF9)* occurring in 24% of cases (see Figs. 57.40), (6;11)(q27;q23)/*KMT2A-MLLT4*, in 10% of cases, t(11;19)(q23;p13.3)/*KMT2A-MLLT1* in 4%, t(11;19)(q23;p13.1/*KMT2A-ELL* (*MLL-ELL*) in 12%, t(10;11)((p12;q23)/*KMT2A-MLLT10* in 9% of patents, or derived from *KMT2A* gene internal duplication *(KMT2A-PTDs)* of the amino-terminus region of the gene (see Fig. 57.39).

The BCR for about 96% of patients is localized between *KMT2A* exon 8 and 14. A novel, second (minor) BCR was reported in 2019, and was localized between *MLL* intron 21 and exon 24 (with a clear preference for *MLL* intron 21-23. -23, and includes a novel *KMT2A/MLL* fusion with *USP2. USP2* is localized about 1 Mpb telomeric to *KMT2A/MLL* at 11q23.3 and transcriptionally oriented in the direction of the chromosome 11 centromere and thereby classifying all as fusions ($n = 17$) and intrachromosomal inversions. Additionally 4 novel translocations include *USP8* gene as a partner. *KMT2/MLL-USP2* and *KMT2A/MLL-USP8* alleles seems to be restricted to the minor BCR. A breakpoint in *MLL* intron 11 is associated with a worse prognosis than those patients with upstream breakpoints. The

breakpoint in *MLL* intron 11 causes a *cis to trans* conversion and switches the MLL protein from a transcriptional activator/maintenance factor to a transcriptional repressor.

KMT2A rearrangements are initiated by DNA damage, which induces DNA repair via the nonhomologous-end-joining DNA repair mechanism. These genetic recombination events produce five different rearrangements: (1) reciprocal chromosomal translocations which fuse the 5′ –*MLL* gene portion with the corresponding gene; (2) partial tandem repeats, frequently in AML; (3) inversions or deletions on 11p and 11q in which inversions lead to reciprocal *KMT2A* fusions whereas deletions cause fusion of the 5′ KMT2A directly to another gene located further downstream (*ARHGEF12, BCL9L, CBL* and *CEP164*); and (4) complex *KMT2A* rearrangements involving three- or four-way translocations resulting in more than two fusion alleles as well as in *KMT2A* amplification (Fig. 57.41). About 15% of *KMT2A* recombinations represent in-frame fusions that can be readily expressed into a fusion protein and 85% are out-of-frame fusions and express a 5′ truncated MLL protein.

The t(9;11), which has been associated with a more favorable outcome in adult and pediatric AML, is distinguished as a separate entity in the latest WHO classification and ELN risk stratification recommendation (Fig. 57.42). Other frequent *KMT2A* translocations are t(6;11)(q27;q23) involving *MLLT4(AF6)* and t(11;19)(q23;p13.3) involving *MLLT1 (ENL)*. A partial tandem duplication of the amino-terminus region of the *KMT2A* gene is associated in patients with or without trisomy 11 (see Fig. 57.39B, C, and F).

The *KMT2A* gene is encoded by 37 exons. It is recruited to the promoters of select cell-cycle regulatory genes, suggesting its role in cell-cycle control. KMT2A protein regulates gene expression and cell cycle control via chromatin modification. Translocation of 11q23 cluster within an 8.3-kb region that encompasses exons 8 to 14 of *KMT2A* fuses the N-terminal portion of *KMT2A*, which contains the AT hook and methyltransferase domains, to numerous different proteins. In infant and in therapy-related AML, the *KMT2A* genomic breakpoints cluster at the 3′ end, near exon 12. In childhood and adult de novo AML, the breakpoints usually occur in the 5′ end, between exons 9 and 10. The most frequent *KMT2A* rearrangements in pediatric and adult patients as well as in ALL and AML are summarized in Fig. 57.39.

Patients with AML and *KMT2A* rearrangements have a poor prognosis despite treatment with aggressive chemotherapy. As mentioned earlier in this chapter, identical *KMT2A* rearrangements have been detected in three pairs of monozygotic infant twins, indicating in utero *KMT2A* rearrangement that results in clinical manifestations developing sometime during the first year of life. The contribution of various *KMT2A* fusion partners to transformation has been recently clarified for some fusion partners. Survival associated with the rare

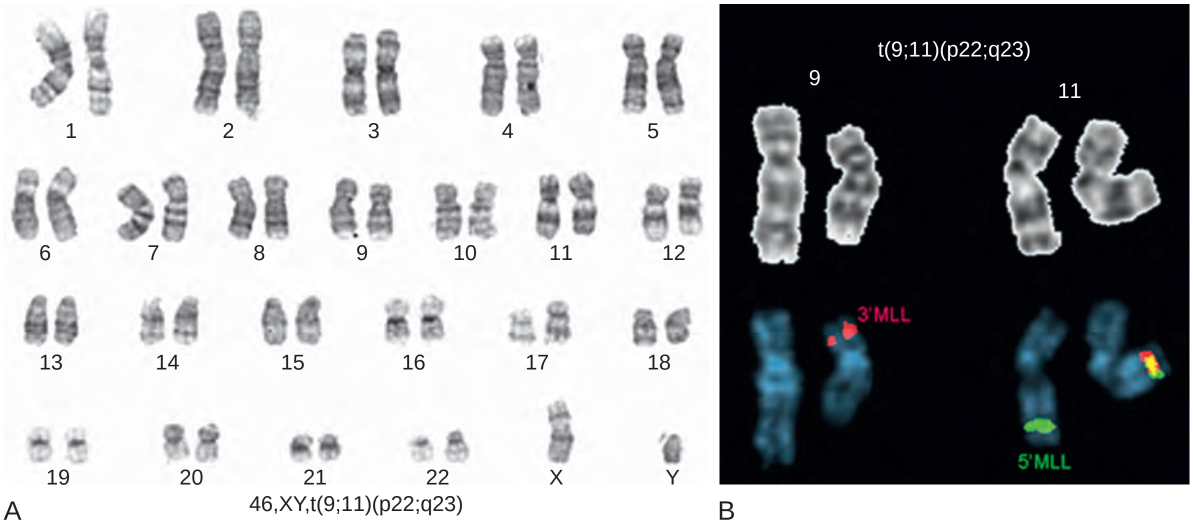

Figure 57.41 THE MOST FREQUENT *MLL* TRANSLOCATION IS t(9;11)(p22;q23). (A) The G-banded karyotype and (B) a partial karyotype, from another metaphase, after hybridization with dual color "breakapart" MLL probe showing the 5′ *MLL (green)* being retained on 11q23 and the 3′ *MLL (red)* moved as a result of the translocation to 9p22. This translocation results in a fusion of *MLLT3-AF9*.

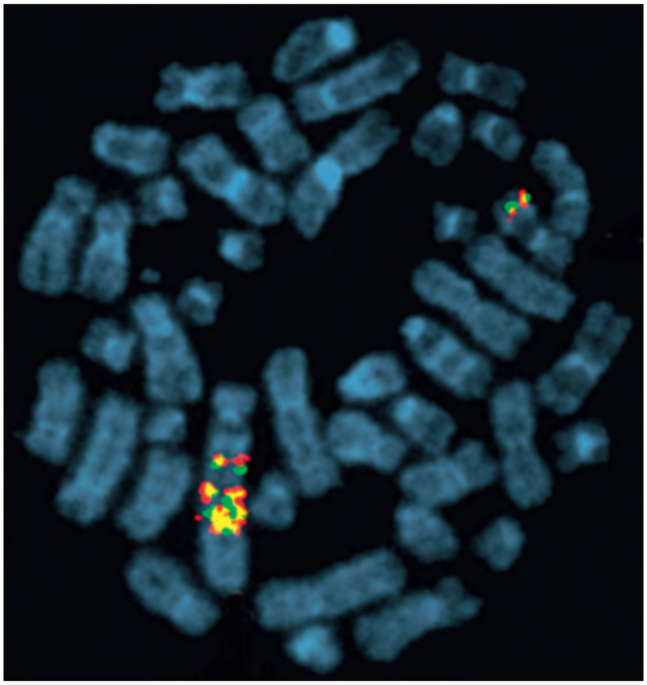

Figure 57.42 MLL AMPLIFICATION. Metaphase cell from a patient with acute myeloid leukemia after DAPI staining *(blue)* showing *MLL* amplification *(yellow)* along the abnormal chromosome 11. At least 15 copies of *MLL* amplicon were inserted into an abnormal chromosome 11. A normal copy of chromosome 11 with one copy of *MLL* is shown on the right side of the metaphase.

t(1;11)(q21;q23) translocation was favorable, in contrast to very poor outcomes with the more frequent t(4;11), t(10;11), and t(6;11) translocations. Even now, novel translocations, such as the one shown in Fig. 57.43, are still being identified and their prognostic implications are currently unknown.

ACAs occur in about 46% of adult AML patients with *KMT2A* rearrangements and most frequently involve trisomy 8 (23%), trisomy 21 (14%), and greater than 3 or more abnormalities (12%), but other additional chromosomal changes such as abnormalities of chromosomes 7 and 5 are not uncommon.

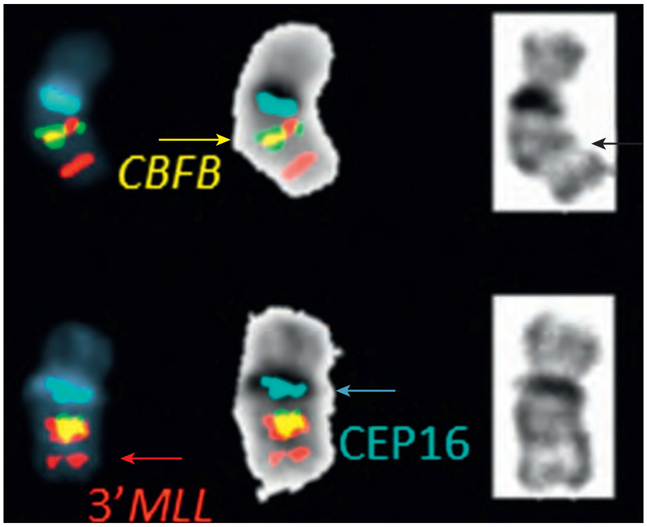

Figure 57.43 A NOVEL MLL PARTNER. A partial karyotype showing an abnormal chromosome 16 from two different metaphase cells from a patient with acute myeloid leukemia showing t(11;16)(q23;q23) karyotype as a sole abnormality. On the *left* is chromosome 16 stained with DAPI *(blue)* after metaphase FISH with three probes: centromere 16 in *aqua, CBFB* "breakapart" probe in *yellow*, and 3′ *MLL* in *red*. *Middle panel* is an "inverted" DAPI image and on the *right* is the G-banding of an abnormal chromosome 16. As a result of t(11;16) a part of 11q23 was translocated to 16 and the 3′ moved at 16q23.

In neonatal leukemia, defined as occurring within the first 28 days of life, most, if not all are congenital and very rare. In two thirds of patients the disease manifests as an AML and the remainder include ALL, specifically of B lineage, some with mixed phenotype or blastic plasmacytoid dendritic cell neoplasms (BPDCN). The most frequently observed cytogenomic abnormalities include t(4;11)(q21.3;q23.3)/*KMT2A-AFF1*, t(1;22)(p13.3;q13.1)/*RBM15-MKL1*, and t(8;16)((p11.2;p13.3)/ *KAT6A-CREBBP*. Intrauterine origin with transmission from one twin to the other via inter-uterine placental sharing has been reported in cases of AML with t(9;11) abnormality as well as in cases of ALL with t(11;19), (4;11) and t(1;11).

The rarity of these patients suggests that fetal and progenitor cell hematopoiesis are not inherently susceptible to leukemic transformation. This is supported by the observation that NGS shows a relatively "silent" mutational landscape and the key molecular event, *KMT2A* rearrangement alone, may be sufficient for development of leukemia in some cases.

Gene expression studies have demonstrated clear differences in the expression of lineage-associated genes, between *KMT2A* rearranged AML and ALL but there appears to be a core gene expression profile found in all *MLL*-rearranged leukemias, independent of the lineage.

AML patients with the partial tandem duplication within *KMT2A* (*KMT2A*-PTD) show internal duplication spanning exon 3 to 9, exon 3 to 10, or exon 3 to 11. *KMT2A*-PTD in AML occurs in 3% to 11% of adult de novo AML and is more frequently present in AML, and as mentioned above, with normal cytogenetics (57%) and AML with trisomy 11 (7%) as a sole cytogenetic abnormality. The most frequently mutated genes which accompany *KMT2A*-PTD AML include *DNMT3A* (39%), *FLT3*-ITD (35%), *IDH2* (21%), and RUNX1 (20%). The prognostic impact of *KMT2A*-PTD on OS and event-free survival (EFS) is similar to wild-type *KMT2A* AML. However, concomitant presence of *DNMT3* and *NRAS* mutations appears to be associated with an adverse clinical outcome.

t(8;16)(p11;p13)/MYST3-CREBBP rearrangements are a distinct pediatric subtype of AML with 97% of cases showing FAB subgroup M4 or M5 (Fig. 57.44). This specific association has also been observed in adult AML. Gene expression analysis revealed that t(8;16) cases clustered strongly together with, but separate from, *MLL* rearranged AML.

t(6;9)(p23.3;q34.1) is a rare cytogenetic abnormality, found in approximately 1% of AML cases, and subsequently reported to be associated with AML and marrow basophilia (Fig. 57.45). Basophilic leukemia is now recognized by the WHO classification as a separate entity. In addition to t(6;9), other chromosomal abnormalities such as t(8;21)(q22;q22), del(12)(p11–13), t(X;6),(p11;q23), and t(2;6)(q23;p22) may be associated with basophilic leukemia. As a result of t(6;9), the 3′ end of the *NUP214*, nuclear pore complex protein 214 kDa, gene located on chromosome 9, band q34, is fused to the 5′ end of the DEK gene located on chromosome 6, band p23. The resulting *DEK-NUP214* fusion gene is a derivative of chromosome 6. The translocation breakpoints occur in exon 6 in the *NUP214* gene and in exon 2 in the *DEK* gene. As a result, the presence of the *DEK-NUP214* fusion can be identified by PCR but not by dual-color FISH probes. Approximately 70% of patients with *DEK-NUP214* have an *FLT3* tandem duplication.

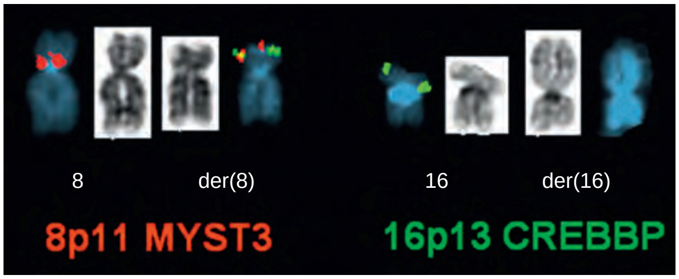

Figure 57.44 THE t(8;16). A partial karyotype from a patient with acute myeloid leukemia showing a t(8;16)(p11;p13) which results in fusion of *MYST3 (red)* and *CREBBP (green)*.

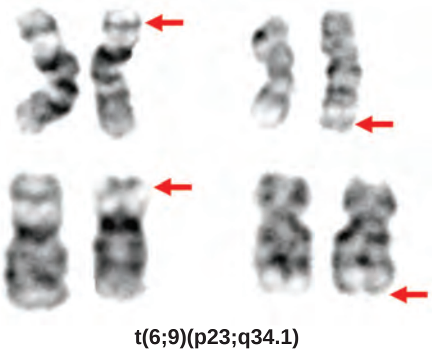

Figure 57.45 MARROW BASOPHILIA WITH CHARACTERISTIC t(6;9). t(6;9)(p23;q24). Shown as partial karyotype from 2 metaphase cells from a patient with acute myeloid leukemia and marrow basophilia. This translocation results in a fusion between *NUP214* gene on 9p34 (chromosomes on the right) t and *DEK* gene on 6p23, chromosome pair shown on the left *(red arrows)*.

inv(3)(q21q26.2) or t(3;3)(q21;q26.2) (see Fig. 57.28) is a distinct subtype of AML with recurrent chromosome abnormalities according to 2016 WHO classification, occurring in about 1% to 2.5% of all AML cases. Each rearrangement is associated with the juxtaposition of the *RPN1* (ribophosphorin 1 located on 3q21) gene with the transcription factor MECOM (*EVI1*, located in the 3q26.2 band). Two alternative forms exist, one generated from *EVI1*, the other *MECOM* (*MDS1* and *EVI1* complex locus) through intergenic splicing with *MDS1*, a gene located 140 kb upstream of *EVI1*. Both rearrangements may present as de novo or secondary AML and are characterized by normal or increased platelet counts and abnormal megakaryocytopoiesis. These abnormalities are also observed in MDS, blast crisis of CML, as well as in Ph-negative MPNs. De novo AML associated with t(3;3)/inv(3) is an aggressive form of leukemia with minimal responses to chemotherapy and poor clinical outcomes. Rare patients with an inversion on both chromosome 3 have been described and the second inv(3) appears to be a secondary event that carries an even worse prognosis. Patients with double inv(3)(q21q26.2) are associated with monosomy7/del(7q) or complex karyotype. Moreover, the second inv(3) is a result of an acquired copy neutral loss of heterozygosity, a somatic event occurring as a part of mitotic recombination of 3q. These patients have a rapidly progressive disease. Breakpoints in band 3q21 are distributed in a 235-kb region centromeric to and including the *RPN1* locus, whereas those in band 3q26.2 are scattered over a 900-kb region located on each side of and including the MECOM (*EVI1)* locus. There are a few cluster breakpoints within 3q21 region. The first BCR of about 30 kb is located 15 kb centromeric of the *RPN1* gene and the other breakpoints are centromeric to the first one, located up to 60 kb. In contrast to most of the translocations and inversions associated with de novo AML, that lead to the fusion genes, inv(3)/t(3;3) does not generate a chimeric gene, but rather induces gene overexpression. Approximately 68% of reported patients with inv(3)/t(3;3) have one ACA, including −7/del(7q) present in 75% of cases.

Resistance to therapy in patients with inv(3)/t(3;3) is linked to the inappropriate activation of the *EVI1* as a consequence of the 3q structural rearrangement. *EVI1* is a hematopoietic stemness factor and is a transcription factor with chromatin-remodeling activity. *EVI1* is also expressed in approximately 11% of patients with AML in the absence of 3q aberrations and represents an independent adverse prognostic factor. *EVI1* is activated as a consequence of inv(3)/t(3;3) via structural repositioning of a distal *GATA2* enhancer from 3q21 to the *EVI1* locus at 3q26. Relocation of the enhancer additionally confers reduced and monoallelic *GATA2* expression. Besides deregulated expression of *EVI1*, a molecular hallmark of patients with 3q structural rearrangements, 98% of these patients harbor mutations in genes activating RAS/receptor tyrosine kinase signaling pathways including hemizygous mutations in *GATA2*, heterozygous alterations in *RUNX1*, *SF3B1*, and genes encoding epigenetic modifiers. Chromosomal rearrangements involving 3q26.2 often lead to *EVI1/MECOM* rearrangements and induce *EVI*1 overexpression. More than 30 *MECOM* partner genes have been identified with the following abnormalities being the most common: inv(3)(q21q26.2 or t(3;3)(q21;q26.2)/EVI1*(MECOM)-GATA2* ~60%, t(3;21)(q26.2;q22)/*MECOM-RUNX1*(~15%) (associated with therapy-related MDS/AML), t(3;12)(q26.2;p13)/*MECOM-ETV6* (6%), and t(2;3)(p15–23;q26.2)/?-*MECOM* (6%), t(3;8)(q26.2;q24) often leads to *MECOM-MYC* rearrangement and is commonly associated with disease progression or therapy-related myeloid neoplasms with a dismal outcome.

t(3;5)(q25;q35*), NPM1/MLF1:* translocation (3;5)(q25;q35) is present in approximately 0.5% cases of AML and is associated with an intermediate prognosis, it is observed in all age groups, but more commonly in younger patients. These patients have shown to have a 34% survival rate after 10 years. In younger patients, this translocation is usually the sole karyotypic abnormality, whereas older patients may demonstrate a more complex karyotype. This translocation generates an *NPM1/MLF1* chimeric gene, which includes approximately half of the 24-kb *NPM1* gene, localized on 5q35, extending from exons 1 to 6, juxtaposed to virtually the entire 35-kb *MLF1* gene, localized on 3q25, starting at exon 2. The chimeric *NPM1/MLF1* fusion protein totals 426 amino acids with 175 amino acids from *NPM1* fused to 251 amino acids from *MLF1*, which excludes only the initial 16 amino acids from *MLF1* in this chimeric protein. In approximately 88% of patients with t(3;5) the translocation results in *NPM1/MLF1* fusion. In some patients with balanced t(3;5) the fusion is not apparent because of the variant 3;5 translocations that may include multiple genes at 3q21–25 and 5q31–35.

The presence of a hyperdiploid karyotype in *acute erythroleukemia* occurs in 47% to 56% of patients, along with a loss of genetic material in chromosomes 5, 7, and 18. An MK was identified in 43% of cases in one series. Balanced translocations are rare in erythroleukemia, although rare cases of *KMT2A* rearrangements have been reported. The frequent occurrence of a complex karyotype with abnormalities of chromosomes 5, 7, and 17 may be one reason for the poor prognosis associated with acute erythroleukemia. Mutations frequently seen in other subgroups of AML (such as *FLT3*, *KIT*, or *RAS* mutations) have not been reported in acute erythroleukemia. In pediatric patients, acute erythroleukemia is very rare. Congenital erythroleukemia is exceedingly rare with only six cases reported in the literature. The mutational spectrum of adult and childhood acute erythroleukemia allows classification of this entity into 5 distinct transcriptional profiles which are the strongest predictors of outcome: in adults *TP53*-mutated, *NPM1*-mutated, *KMT2A*-mutated and rearranged, and *DDX41*-mutated; and pediatric *NUP98* rearranged. Patients with *NPM1* mutations and *HOXB9* overexpression are associated with a favorable prognosis, and *TP53*, *FLT3*, and *RB1* alterations are associated with poor survival.

Pure erythroid leukemia represents a neoplastic proliferation of immature cells committed exclusively to the erythroid lineage with no evidence of a significant myeloblastic component. Pure erythroid leukemia is extremely rare and is frequently associated with complex cytogenetic abnormalities. The uncontrolled proliferation of immature erythroid precursors comprises at least 80% of the marrow. A complex karyotype is present in 83% of cases and the median OS is 2.9 months. Compared with AML with more than 50% erythroblasts, PEL demonstrate a higher incidence of poor-risk chromosomal abnormalities. Within the complex karyotype monosomy 7 appears to be the most frequent abnormality.

The M7 or megakaryocytic subtype of AML is a rare clonal disease, with an estimated frequency of 1% among AMLs, arising in a multipotent stem cell capable of differentiating along the megakaryocytic and granulocytic pathways. This acute leukemia subtype has a variety of genetic and morphologic characteristics. The M7 subtype is more frequent in children than in adults. In adults, megakaryocytic leukemia is frequently observed as a secondary leukemia after chemotherapy or leukemic transformation of several chronic MPNs, including CML. Approximately 65% of acute megakaryocytic leukemias are associated with marrow fibrosis. After multivariate analysis, the AML megakaryocytic subtype is an independent predictor of increased mortality. Approximately 50% of patients with M7 AML have chromosomal abnormalities at diagnosis. No specific chromosomal abnormality is associated with the adult form but observed abnormalities include 3q21 to 3q26 rearrangements, partial or total deletion of chromosomes 5 and 7, gain of chromosomes 8 and 19, and t(9;22). Adult patients with megakaryocytic leukemia are also characterized by mutations in *TP53*, *DMNT3A, RB1*, and genes in cohesion, and *ASXL* family.

Two manifestations of childhood megakaryocytic leukemia have been observed. First is constitutional trisomy 21 association with *GATA1* (located on X chromosome) mutation (Chapters 29, 30, 63). Young children with constitutional trisomy 21, median age at diagnosis 6.5 days, are more than 100 times more likely to develop megakaryocytic leukemia than normal children. However, children with constitutional trisomy 21 and megakaryocytic leukemia have a more favorable prognosis as compared with patients without constitutional trisomy 21. In these patients with constitutional trisomy 21, a second event includes somatic mutations of the transcription factor *GATA1* which leads to the third event of malignant transformation. The presence of +21 is sufficient to cause an increased number of megakaryocytes *in utero* but not sufficient to cause leukemia. However, the mutations in *GATA1* lead to production of the shortened GATA1 protein that lacks the first 83 amino acids and together with constitutional +21 leads to transient myeloproliferative disorder (TMD). TMD is a self-limiting preleukemic condition seen at birth in up to 30% of constitutional +21 neonates. Although the majority of TMD cases undergo a spontaneous remission, 10% to 20% of clinically significant cases progress to megakaryocytic leukemia within 4 years. This progression is associated with acquisition of additional mutations resulting in malignant transformation of the residual *GATA1* mutant clone. The second form of childhood acute megakaryocytic leukemia involves t(1;22)(p13;q13) encoding the OTT-MAL (*RBM15-MKL1*) fusion protein in infants without constitutional trisomy 21 (Fig. 57.46). It is a very rare abnormality, described in about 40 cases worldwide (about 5% of infant AML cases), and associated with infantile M7 and with children younger than 3 years of age. Detection of t(1;22) is diagnostic. Another fusion protein often seen in pediatric non-constitutional +21 patients is inv(16)(p13.3q24.3) leading to the chimeric protein *CBFA2T3-GLIS2*. This translocation is observed in 18.6% of pediatric acute megakaryocytic leukemia patients and associated with a worse overall and reduced EFS. It has not been detected in adult patients but it has been identified in other pediatric patients with AML. The translocation (11;15)(p15;q35) /*NUP98-JARIDIA (KDM5a)* is observed in 8% to 12% of pediatric megakaryocytic leukemia patients and does not carry any statistically significant prognostic risk although these patients tend to show lower survival rates than those with other chromosomal fusions. Patients expressing *NUP98-KDM5a* also have frequently mutated *RB1*, *KMT2A* rearrangements, and *RAS* mutations. These children

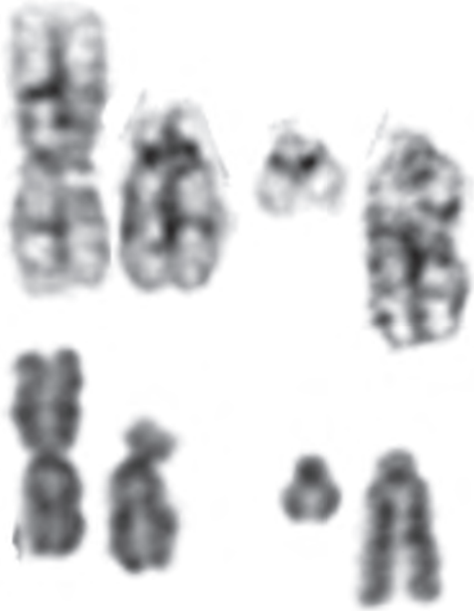

Figure 57.46 MEGAKARYOCYTIC LEUKEMIA WITH T(1;22). Partial karyotype from two metaphase cells from a 4-week-old baby with M7 megakaryocytic leukemia showing a diagnostic t(1;22)(p13;q13) abnormality.

acquire diverse chromosomal abnormalities, most notably tetrasomy 21 and trisomy 8 and *KMT2A* rearrangements (17.4%). Pediatric non-constitutional +21 acute megakaryocytic leukemia is a heterogenous malignancy comprised of distinct subsets of subgroups with varying outcome.

The t(1;22) rearrangement has been observed in a set of monozygotic twins, suggesting an *in utero* origin in some cases. To date there are 16 cases of *GATA1* mutation-related transient MPDs and M7 AML in phenotypically and cytogenetically normal children. Thirteen of the 16 children were diagnosed during the first few months of life and in six cases, the blasts disappeared spontaneously without chemotherapy and the patients did not develop M7 AML. Gene expression profiling has provided the insight into the molecular pathogenesis of M7 leukemia in children with and without constitutional trisomy 21. These patients have distinct molecular phenotypes, with increased expression of chromosome 21 genes in patients with constitutional trisomy 21 as compared with M7 leukemia patients without constitutional trisomy 21. The *RUNX1* gene, localized on chromosome 21 which is essential for normal megakaryocytopoiesis, is expressed at lower levels in children with constitutional trisomy 21 and M7 leukemia, indicating a mechanism that may contribute to a block in differentiation.

Down Syndrome–Associated Acute Myeloid Leukemia

The myeloid leukemia of DS (Chapters 29, 30, and 63) was given a special WHO subclassification (ML-DS) because of its unique clinical and biologic features. These erythromegakaryoblastic leukemias are diagnosed before the age of 5 years and often present with thrombocytopenia and/or myelodysplasia. ML-DS is always preceded by the neonatal preleukemic syndrome, transient abnormal myelopoiesis (TAM; also known as transient MPD) that may, or may not, be clinically apparent. Unlike acute megakaryoblastic leukemias in patients without DS, these patients usually respond well to therapy with most patients being cured. Genetically, ML-DS is characterized by an acquired mutation in the *GATA1* gene (90%). The mutation in *GATA1* is necessary but insufficient for development of ML-DS. Virtually all cases of TAM and ML-DS have N-terminal truncating *GATA1* mutations. *GATA1* mutations are present at birth in both neonates with DS with TAM and, through retrospective analysis of neonatal blood spots, also in children with ML-DS without a previous history of TAM. It is not clear at what stage in fetal development *GATA1* mutations arise; the earliest point in gestation at which mutations have been identified is 21 weeks. *GATA1* mutations disappear when TAM (or ML-DS) enters remission, indicating that they are acquired.

Monosomal Karyotype

MK is defined by the presence of at least two separate autosomal monosomies or one monosomy plus one or more structural abnormalities. The overall frequency of MK in AML varies between 6% and 20%. In a study of 1058 patients with AML and an abnormal karyotype, 30% had MK (see Fig. 57.33, *bottom row*). AML with MK is frequently associated with other adverse risk cytogenetic abnormalities, such as inv(3), −5 or del(5q), −7 or del(7q), abnormal (12p), −18/del(18q), abnormal (17p), and a complex karyotype. The frequency of these recurrent monosomies are: −7 and −17 in 6%, −18 in 5%, −5 and −21 in 4%, −20 in 3%, −3, −12, and 22 in 2%, and loss of chromosomes 2, 4, 9, 13, and 19 in 1% of cases. MK is a strong prognostic predictor of poor outcome compared with a traditionally defined complex karyotype. Responses to induction therapy and OS of patients who have AML with MK are dismal: CR rates of 32% and a 4-year survival of 9%. MK in a study of 248 patients with AML was found to be associated in more than 50% of patients with deletion of P53, whereas in another study of newly diagnosed 369 patients with AML, MK predicted an adverse treatment outcome and was associated with multidrug-resistance. A low frequency of mutations such as *FLT3* and *NPM1* are found in patients with MK AML.

Gain or Loss of Chromosomes in Acute Myeloid Leukemia

Approximately 15% to 20% of patients with AML have a numerical gain or loss of a single chromosome as the sole primary karyotypic abnormality. Each of the autosomes and sex chromosomes can contribute to the numerical changes. The most common trisomies in decreasing order of frequency are gain of chromosome 8 (Figs. 57.47

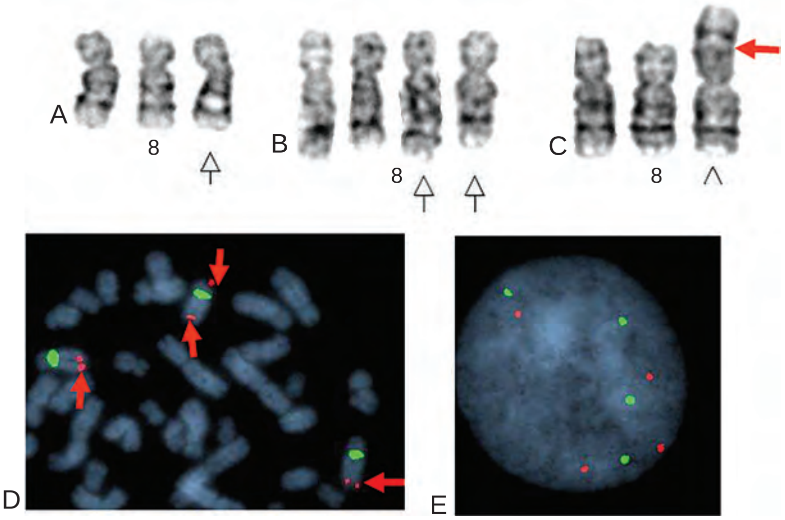

Figure 57.47 GAIN OF CHROMOSOME 8 DETECTED AT RELAPSE OF ACUTE MYELOID LEUKEMIA. All evaluated cells had a gain of chromosome 8. Four related cell populations evolved: (A) 35% of cells had +8, (B) 25% of cells had tetrasomy 8, (C) 35% of cells had a gain of an isochromosome of 8q and a deleted 17p and loss of TP53 (not shown). The i(8q) is a novel abnormality not previously observed in multiple testing from the diagnosis (a year earlier) but del (17p) was observed in 11% of cells at diagnosis, indicating genomic instability as a result of TP53 deletion. (D) Shows a metaphase cell after FISH with two homolog 8 and the presence of i(8q) *(two red arrows)*. (E) Shows an interphase FISH with 4 red signals (MYC at 8q24) and 4 centromeres *(green)* indicating a cell with tetrasomy 8 detected in 58% of cells while 11% had 3 copies of #8 whereas 24% of cells had 4 copies of MYC and 3 copies of centromere 8 consistent with i(8q).

Figure 57.48 STRUCTURALLY ABERRANT CHROMOSOMES 8 AND 11 IN A NEWLY DIAGNOSED PATIENT WITH ACUTE MYELOID LEUKEMIA. (A) 90% of cells had a loss of Y chromosome and a gain of an aberrant chromosome 8 in two copies. The derivative chromosome 8 first resulted from an unbalanced translocation between the long arms of chr(8) and chr(11) which entirely replicated itself leading to a gain of chr(8) and four copies of 11q. (B) A partial karyotype from another cell showing two copies of der(8)t(8;11). (C) Additionally, 10% of cells showed an alternative aberrant chromosome 8 present in one copy with a gain of an additional aberrant copy in the form of an isoderivative chr(8). Ider(8)t(8;11) was produced from an unbalanced translocation between 8q and 11q and a subsequent replication of the proximal region leading to two identical arms of the aberrant chromosome, resulting in four copies of 8q, and five copies of 11q. (D) Partial gains of 8q and 11q are rare recurrent abnormalities found in myeloid malignancies. According to the 2017 ELN recommendations, these results are associated with an intermediate-adverse risk category. (D) Array testing detected trisomy and tetrasomy of chromosome 8 (a ~146.4 Mb gain 8p23.3q24.3) and partial gain of the long arm of chromosome 11q (~35.2 Mb 11q22.1q25) *(blue)*.

and 57.48), 11, 13, 22, 21, 14, and 9 and most common monosomies include −5, −17, and −7. The gain of chromosome 8, the most frequent abnormality seen in AML, is a sole abnormality in 6.3% of cases and overall occurs in 16% of cases. The incidence of +8 detected by FISH varies between 19% and 25% of AML cases. The prognosis of AML with +8 depends on whether +8 occurs as an isolated abnormality or accompanies other cytogenetic aberrations. In the latter situation, +8 does not appear to adversely affect the favorable outcome of patients with t(15;17), inv(16)t(16;16), and t(8,21). By contrast, patients with +8 and a complex karyotype and/or an unfavorable aberration such as del(5q) or −7 usually have a very poor outcome. Isolated +8 has been considered to be associated with either intermediate or unfavorable prognosis.

MYC Amplicon in Acute Myeloid Leukemia

In normal cells, *MYC* gene is localized on chromosome 8, band region q24.21. Less than 1% of hematologic malignancies have genomic amplification and they are usually associated with an elderly age and poor prognosis. Genomic amplifications are cytogenetically identified as homogeneous staining regions (HSR), DM, and ring chromosomes. Gene amplification(s) in hematologic malignancies is a rare entity (<1%). Using a comprehensive and high-resolution genomic method, analysis of 23 patients with *MYC*-amplification revealed amplicon heterogeneity in 65% of these patients and in 48% deletions of 8q24 segment was observed. Moreover, amplification of 8q24 region has been observed in a ring structure suggesting that 8q24 amplicon architecture is shared between different chromosomal structures. Discovery of neocentromere in these patients may represent scattered acentric DM as well as HSR resulting in mitotic stabilization, and providing an adaptive advantage of leukemia cells harboring 8q24 amplicon.

Deletion of 17p often results in the loss of tumor suppressor *TP53* gene on band p13.1, which has been reported in 5% to 9% of adult AML patients. The abnormalities of 17p are often associated with other chromosomal aberrations such as del(5q), −5, −7, but is an independent poor-risk prognostic factor.

TP53 mutations are more common in older patients and those who have previously received alkylating agents. These patients have an increased number of CD34+ cells, suggesting that the loss of *TP53* function could cause cell cycle arrest. Based on genomic classification of 1540 AML patients treated in different intensive chemotherapy trials, the *TP53*-mutation-positive subgroup of patients consisted of complex cytogenetic alterations or isolated chromosome losses or gains and were associated with an adverse prognosis. Therefore, it has been proposed that testing for deletion and mutation of *TP53* should be included in the ELN and WHO classification system of AML (Figs. 57.49 and 57.50).

Acute Myeloid Leukemia With Complex Karyotype

Any karyotype with at least three chromosomal aberrations, regardless of their type and the individual chromosomes involved, is designated as “complex” in the absence of the WHO-designated recurrent genetic abnormalities. Several studies have shown that patients with t(8;21), t(16;16)/inv(16) and t(15;17) constitute a separate biologic and clinical entity even if they contain additional abnormalities, because these additional cytogenetic abnormalities do not adversely affect the clinical outcome. Therefore the category of AML patients with a complex karyotype exclude patients with t(8;21),inv(16)/t(16;16) and t (15;17). Approximately, 10% to 12% of AML patients have three or more chromosome abnormalities whereas 8% to 9% have five or more abnormalities. The incidence of a complex karyotype increases with age. In patients with AML, age 18 to 60, 6% to 8% have three or more chromosomal abnormalities whereas 17% to 19% of patients older than 60 have a complex karyotype. In three large series of AML patients with a complex karyotype analyzed using multicolor FISH, more than 90% of patients had at least five abnormalities, with a median number of chromosomal aberrations being between 6 and 10. Approximately 80% of all patients with a complex karyotype have deletion 5q, followed by deletions 17p and 7q, occurring in approximately 50% of cases. At least 85% of all patients with AML with a complex karyotype showed one of these three deletions. The prognosis of patients with a complex karyotype is generally very poor. Among

Figure 57.49 COMMON MUTATIONS IN DE NOVO AND SECONDARY ACUTE MYELOID LEUKEMIA. A number of clonal blood disorders with a myeloid phenotype are represented. Each of these disorders is characterized by recurrent mutations in specific genes, some of which are shared between several different phenotypes (e.g., *TET2*). All of these disorders can transform to secondary AML upon acquisition of additional somatic mutations. When AML arises in the absence of an antecedent clonal blood disorder, it is known as primary AML. *aCML*, Atypical CML; *AML*, acute myeloid leukemia; *CML*, chronic myeloid leukemia; *ET*, essential thrombocytopenia; *IMF*, idiopathic myelofibrosis; *PV*, polycythemia vera; *SM*, systemic mastocytosis. *(Reprinted with permission from Grove CS, Vassiliou GS. Driver mutations in acute myeloid leukemia. Curr Opin. 2020;27:49.)*

patients with AML above the age of 60, which constitute the majority of patients with complex karyotype, only 10% to 44% of those who harbor three or more chromosomal abnormalities achieve a CR, which usually is of very short duration (median 6 to 8 months). CR rates of karyotypically complex patients are slightly higher in younger patients. The number of chromosomal abnormalities is central to the definition of a complex karyotype. Adult patients with *hyperdiploidy* with 49 to 65 chromosomes is a rare abnormality in AML, less than 2%, and by definition is included in a subgroup of patients with complex karyotypes, irrespective of the structural abnormalities involved. Patients with only numerical gains should be classified as belonging to the intermediate risk group of patients with AML.

Complex karyotype AML occurs in a heterogeneous group of patients that almost never is associated with mutations in *NPM1* nor with biallelic *CEBPA* genes and infrequently with mutations in *FLT3*, *IDH1/IDH2*, *DNMT3A*, and *TET2*. In sharp contrast, this subgroup of AML patients are characterized by chromosomal aneuploidy, by structural rearrangements and ~70% demonstrate point mutations in *TP53* gene. Most of the patients with *TP53* deletions are accompanied by *TP53* mutations in the remaining allele leading to the complete loss of the *TP53* activity. Heterozygous *TP53* mutations are also common.

Acute Myeloid Leukemia in Children (Chapter 63)

The Children Oncology Group (COG)–National Cancer Institute (NCI) TARGET AML Initiative has characterized the genomic landscape of almost 1000 pediatric AML patients.[14] This extensive effort revealed similarities and unique differences between adult and pediatric AML. The most important observation was that the overall frequency of myeloid malignancy gene mutations is lower in pediatric AML than that in adult patients. The mutational burden increases with age, with fusions and copy number alterations being more common in younger patients while smaller sequence variants are more frequent in older patients. Mutations in *DNMT3A*, *IDH1/2*, *NPM1*, and *TP53* are less common in pediatric patients while co-occurring *NUP98* and *FLT3* or *WT1* mutations were demonstrated to affect pediatric AML outcomes. The TARGET initiative also revealed some "novel" pediatric-specific chromosomal copy number changes including focal deletions of *MBNL1* gene (3q25.2) and *ELF1* (13q14.11). Although the TARGET pediatric study did not report *PML-RARA* fusion-positive children, about 5% to 10% of pediatric AML patients harbor *PML-RARA* fusion. However, in about 10% of these patients who are morphologically diagnosed as APL, RARA rearrangements could not be identified which suggests that these children should be classified as a subclass of AML rather than APL. The impact of cytogenetics on outcome in a pediatric group of patients with AML (excluding APL) demonstrated about 80% OS at 10 years in patients with *CBFA2T3* AML. Within these groups, t(16;21)(q24;q22) resulting in *CBFA2T3-GLIS2* fusion is an exclusive pediatric cytogenetic abnormality which leads to a strong downregulation of *GATA1*. It is currently thought that pediatric acute megakaryocytic leukemia associated with DS (+21 constitutional) targets *ERG* and *GATA1* genes but that the *CBFA2T3-GLIS2* fusion is able alone to maintain both high ERG and low GATA1.

In contrast to *CBFA2T3* AML, pediatric patients with *MLL(KMT2A)* abnormalities had an intermediate prognosis (61% OS at 10 years) with no evidence of heterogeneity according to the translocation partner of *MLL*. Additional abnormalities among the 11q23 leukemias have diverse prognoses; trisomy 8 is an independent favorable, whereas trisomy 19 is considered an adverse prognostic factor in the *MLL* rearranged group of pediatric patients. Approximately 10% to 15% of children and adolescents and 30% to 60% of infants have *KMT2A* AML. Most of the *KMT2A* fusion-positive AMLs are considered an aggressive form of AML, although the outcome is overall neutral (fusion specific impact on prognosis) and notably t(9;11)(p22;q23)/ and ins(10;11)(p12;q23q13) are more prevalent in children than adults. *MLL10* (10p12.31) is the fourth common gene fusion partner and is predominantly observed in pediatric AML, although it has been reported in B- and T-cell ALL. In infant patients with t(9;11) the patients present with ALL rather than AML, and the phenotype usually changes into typical myelomonocytic AML with increasing age of patients. *FLT3*-ITD alterations are found in about 10% to 20% of newly diagnosed pediatric AML patients and is an independent prognostic factor for poor outcome particularly for patients with high ITD allelic ratios and/or loss of the wild-type allele leading to copy number-neutral ITD homozygosity.

Recurrent fusions involving *NUP98* (11p15) with over 30 different partner chromosomes have been identified in approximately 4% to 9% of pediatric AML patients. *NUP98-KMT5A* fusions are more prevalent in children below 3 years of age. Clinically *NUP98* rearrangements are associated with normal karyotype AML and most frequently occur in the myelomonocytic subtype with the exception of *NUP98-KDM5A* fusions [t(11;12)(p15.4;p13–33)] which are enriched in acute megakaryocytic leukemia occurring in approximately 10% of such cases. The presence of a *NUP98-KDM5A* fusions in megakaryocytic leukemia is associated with a poor prognosis with an EFS of 25%. The *NUP98* fusions are associated with a poor prognosis in acute erythroleukemia, with 20% of children with this rare form of AML. Isolated *NUP98* rearrangements are not independently prognostic but the combination of *NSD1-NUP98*/ [t(5;11)(q35.2;p15.4)] fusion and concomitant *FLT3*ITD mutation is strongly associated with a poor outcome.

Acute Myeloid Leukemia in the Elderly

The biology of AML changes with age (Chapters 19, 59, 60, and 157). The spectrum of cytogenetic abnormalities in older adults includes a higher percentage of abnormalities involving −5/del(5q), −7/del(7q), and 17p and a lower incidence of translocations associated with a favorable prognosis. Older patients with a complex karyotype have an extremely poor prognosis, with only 26% achieving CR owing to high rates of resistant disease. Multidrug resistance is present in 57% of patients over 75 years of age and in 33% of patients with AML younger than 56 years of age. The OS rate in older adult patients with AML is only 2% at 5 years. The biology of AML in the elderly patients may be a consequence of the age of hematopoietic stem cells, shortened telomere length (associated with older cells), presence of fewer normal stem cells to compete with the malignant clones and repopulate marrow following chemotherapy and as mentioned earlier, the increased frequency of age-related somatic mutations present in over 10% of healthy individuals over 70 years of age (Chapters 19, 59, 60, and 157).

Chromothripsis in Acute Myeloid Leukemia

Chromothripsis describes a process whereby hundreds of genomic rearrangements have been acquired as a result of a single catastrophic event. A chromosomal region or a chromosome or telomere belonging to other chromosomes is shattered into hundreds of pieces; some but not all are stitched together by the DNA repair machinery in a mosaic patchwork of genomic fragments. Cells not only survive this crisis but emerge with a genomic landscape that confers a selective advantage, thereby promoting further malignant evolution. In addition to the clustering of structural variants, multiple base-pair mutations can also be acquired in a single mitotic explosion, called *kataegis*. This process drives cytosine-specific mutagenesis in regions flanking sites of genomic rearrangement, and can result in the rapid occurrence of up to 20 base-pair substitutions. The best methodology to identify chromothripsis is high-resolution array SNP karyotyping using at least three of five criteria: (1) Regularity of oscillating copy-number states. In chromothripsis, the copy number value should typically oscillate between two or occasionally three states; (2) the presence of "interspersed regions with loss and retention of heterozygosity," which means that the segments in the highest copy number state should retain heterozygosity; (3) clustering of breakpoints, 5 to 10 breakpoints should be observed within 50 kb genomic interval; (4) more than 10 breakpoints within a minimum segment size of 10 kb; and (5) 0.3 kb as signal distance between adjacent segments. Using these criteria, chromothripsis has been identified in 6.5% of 395 newly diagnosed AML and these patients are older, higher risk, lower WBC, *TP53* loss and/or mutations, while *FLT3* and *NPM1* mutations were mutually exclusive with chromothripsis. Chromothripsis-positive patients with AML (and MDS) have a poor OS, particularly those with deletion 5q31.1 to 5q33.1, containing key genes involved in DNA damage and histone modifications, as well as *P53* deletion and/or mutation.

Therapy-Related Acute Myeloid Leukemia and Therapy-Related Myelodysplastic Syndrome

Therapy-related AML and MDS are distinct clinical syndromes occurring as late complications following high-dose chemotherapy, radiation therapy, or autologous stem cell transplantation. An abnormal karyotype is detected in 92% of this patient population. From the cytogenetic point of view, two different categories of therapy-related AML and MDS can be identified. The first group includes patients who develop AML/MDS following exposure to alkylating agents approximately 5 years after therapy. These leukemias are associated with the presence of monosomy 5/del(5q) or monosomy 7/del(7q) (see Fig. 57.31, *third row*). Many of these patients initially develop MDS features before transforming into frank AML. Recurrent abnormalities of chromosomes 5, 7, or both account for 70% of all abnormalities observed in therapy-related leukemias. These patients respond poorly to therapy and have a poor OS. A second group of patients develop therapy-related AML without prior MDS and exhibit 11q23 (3%) and 21q22 (3%) balanced rearrangements, which have been attributed to the late effects of topoisomerase II inhibitors combined with alkylating agents and radiation see Fig. 57.39). These forms of AML may develop within a few months to 3 years after topoisomerase II inhibitor therapy. Polysomy (tetrasomy, pentasomy, hexasomy) of chromosome 8 defines a clinical-cytogenetic entity associated with therapy-related myeloid malignancies and poor OS (see Figs. 57.47 and 57.48).

A rare but recurrent chromosomal translocation, t(3;8)(q26.2;q24) in therapy-related AML and/or in disease progression often leads to *MECOM-MYC* fusion product. Since only 30+ patients are reported, the median survival of these patients is estimated to be ~6 months. Similar to patients with t(3;3)/inv(3), patients with myeloid disease and t(3;8) often show small dysplastic megakaryocytes in the BM and monosomy 7 is the most frequent additional abnormality (50%). Unlike patients with t(3;3)/inv(3) who often have either normal platelet count or thrombocytosis, patients with t(3;8) commonly are thrombocytopenic. Since *MYC* is consistently upregulated in these patients investigators currently speculate that there is a cooperation between

MYC and *PVT1* whereby inactivation/disruption of the *PVT1* promoter enhancer leads to an increase in MYC in expression. In other words, the *PVT1* promoter partially insulates downstream enhancer elements from regulating MYC expression. As mentioned earlier, variant t(3;21)/*MECOM/RUNX1* is also common in therapy-related MDS/AML. When the genome of 22 patients with therapy-related AML was sequenced and compared to whole genome sequence data from patients with de novo AML and secondary AML arising from MDS, the mutational burden of therapy-related AML genomes was found to be similar to that of de novo AML indicating that prior chemotherapy does not induce genome-wide DNA damage.

In a study of 509 older (60 to 85 years old) patients with secondary AML (disease evolving, 28% from MDS), 53% had an abnormal karyotype and 48% had t-AML-like gene mutations including *ASXL1, SRSF2, STAG2, BCOR, U2AF1, EZH2, SF3B1, and ZRSR2*. These mutations were associated with a shorter EFS within ELN 2017 intermediate risk group (which exclude mutated cases by definition). However, a distinct subset of mutated genes are present in therapy-related AML/MDS. The whole genome sequence data revealed that *TP53* mutations and mutations in ABC transporter genes (a subset of which have been implicated in chemotherapy resistance) are significantly increased in therapy-related AML/MDS compared with de novo AML/MDS. *TP53* mutations are present in approximately 33% of patients with therapy-related AML/MDS and are associated with poor risk cytogenetics and a poor prognosis. More recent genomic data suggests that cytotoxic therapy does not directly induce *TP53* mutations. Rather, these studies support a model in which rare stem cells carrying age-related *TP53* mutations that are resistant to chemotherapy expand preferentially following treatment.

The Pathway Forward

A novel hierarchical prognostic model of AML solely based on molecular mutations was proposed by a German group in 2012. This model was based on 1000 patients with AML at diagnosis after a median follow-up of 23.7 months. Molecular screening for the recurrent balanced rearrangements (*PML-RARA, RUNX1-RUNX1T1, CBFB-MYH11*) and mutations in *CEBPA*, *NPM1*, *RUNX1, ASXL1*, and *TP53* as well as for *FLT3-IDT* and *MLL-PTD* can be used to create a prognostic classification system in AML that is more effective than any prognostic model based on cytogenetics alone[15] (see earlier section on next generation karyotyping[1]). Five distinct prognostic subgroups have been identified: (1) very favorable: *PML-RARA* rearrangement or *CEPBA* double mutations with OS at 3 years of 82.9%; (2) favorable: *RUNX1-RUNXT1*, *CBFB-MYH11* or *NPM1* mutations without *FLT3*-ITD, OS at 3 years of 62.6%; (3) intermediate: none of the mutations leading to assignment into groups 1, 2, 4, or 5; OS at 3 years 44.2%; (4) unfavorable: *MLL*-PTD and/or *RUNX1* mutation and/or *ASXL1* mutation: OS at 3 years 21.9%; and (5) unfavorable *TP53* mutation: OS at 3 years 0%. However, using whole-genome or exome sequencing from 71 patients with AML treated with standard induction therapy demonstrated that for risk stratification the clearance of somatic mutations after chemotherapy is more important than the identification of specific mutations at the time of diagnosis. In this study, the detection of persistent AML-associated mutations in at least 5% of bone marrow cells in day-30 remission samples was associated with significantly increased risk of relapse and reduced OS (see box on Genetic Testing for Acute Myeloid Leukemia).

GENETIC TESTING FOR ACUTE MYELOID LEUKEMIA

At diagnosis, conventional cytogenetics and I-FISH with AML-specific panel of FISH probes, for detection of PML-RARA, RUNX1-RUNXT1, CBFB, BCR-ABL1 fusions, and rearrangements of KMT2A and TP53 is mandatory. Patients with CBF AML should be tested for KIT exon 17 mutations. For patients who have AML with a normal karyotype, mutation studies for DNMT3, NPM1, FLT3, CEBPA, and TP53 are recommended as well as aCGH+SNP.

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL accounts for at least 85% of acute leukemias in children and 20% of acute leukemias in adults (Chapters 66–68). The susceptibility to ALL varies with age; the first peak is between 2 and 5 years of age after birth, followed by a gradual decrease during adulthood but an increase in incidence again in individuals older than age 70 years, suggesting that different environmental and genetic factors contribute to leukemogenesis at different ages. Most published series of patients with ALL indicate that 70% to 75% have an abnormal clone by conventional cytogenetic studies (Figs. 57.51 and 57.52). Genomic rearrangements detected with intensive interphase FISH screening have been found in up to 91% of cases. The application of contemporary genome-wide molecular analysis continues to reveal many additional genetic rearrangements that are not detectable with chromosome studies.[16] At least one clonal aberration has been detected in 60% to 79% of adults and 57% to 82% of children with ALL. Today, cytogenetic analyses combined with FISH and/or array CGH+SNP are mandatory in most ALL clinical trials, and genetic findings play a pivotal role in proper risk stratification and identifying treatment options. Several of the ALL-specific chromosome abnormalities and their molecular counterparts have been included in the 2016 WHO classification. Biology of B-cell ALL is determined mainly by the first genetic hit, which is usually a change in chromosome numbers (hyperdiploidy or hypodiploidy) or a chromosomal translocation (e.g., t(12;21)/*ETV6-RUNX1*). In pediatric patients, these genetic abnormalities can first occur in utero. Accumulated evidence suggests that additional genetic insults are required for leukemia development and these will be described below.

Pretreatment cytogenetics is an independent prognostic factor in children and adults presenting with ALL and is important in determining risk categories.

As shown in Fig. 57.52 and Table 57.12, the risk categories in children include (a) low risk: high hyperdiploidy (trisomies for chromosomes 4, 10, and 17) and t(12;21)/*TEL-RUNX1*; (b) high risk: t(1;19)/*TCF3-PBX1*; and (c) very high risk: t(9;22)/*BCR-ABL1*, *BCR-ABL1*-like, 11q23/KMT2A rearrangements, and iAMP21. In adults the low-risk category includes high hyperdiploidy and del(9p), whereas the high-risk category includes hypodiploidy/near triploidy, t(9;22)(q34;q11), t(4;11)(q21;q23), t(8;14)(q24;q32), and a complex karyotype (five or more chromosomal abnormalities).

Approximately 20% to 30% of children and 3% of adults with B-cell ALL are *hyperdiploid*. Two groups can be distinguished based on cytogenetics (a) those with 56 to 67 chromosomes whose prognosis is excellent and (b) those with 51 to 55 chromosomes whose prognosis is less favorable. Both groups have a more favorable prognosis than do children with hypodiploidy or near-haploid ALL. In a study of 1880 children with ALL, patients with 45 chromosomes have an outcome similar to that of pseudodiploid or low hyperdiploid patients with ALL (47 to 50 chromosomes). Children and adolescents with ALL and hypodiploidy with fewer than 44 chromosomes have a poor outcome. The distribution of specific chromosome gains is not random, with the most-involved chromosomes being X, 4, 6, 10, 14, 17, 18, and 21 with individual trisomies or tetrasomies being seen in over 75% of cases each of which is gained in more than 50% of hyperdiploid patients with ALL, followed by gains in chromosomes 8, 5, 11, and 12, that occur more often in patients with 57 or more chromosomes. The prognosis of children with high hyperdiploidy is excellent with a 5-year EFS rate of between 71% and 83% and a 5-year OS rate of approximately 90%. Pretreatment cytogenetic analyses of more than 5400 children with ALL unequivocally shows that simultaneous trisomies for chromosomes 4, 10, and 17 are associated with a higher long-term EFS (see Fig. 57.52D). By contrast a hyperdiploid karyotype is not associated with a favorable outcome in adult ALL patients. The reason for this discordance may be that adults often have poor-risk chromosomal translocations, such as the Ph chromosome. Approximately 50% of the high hyperdiploid patients harbor other structural abnormalities, such as gains of 1q, del(6q), which do not appear to influence prognosis, with a possible exception of prognostically adverse isochromosome 17q. Frequently,

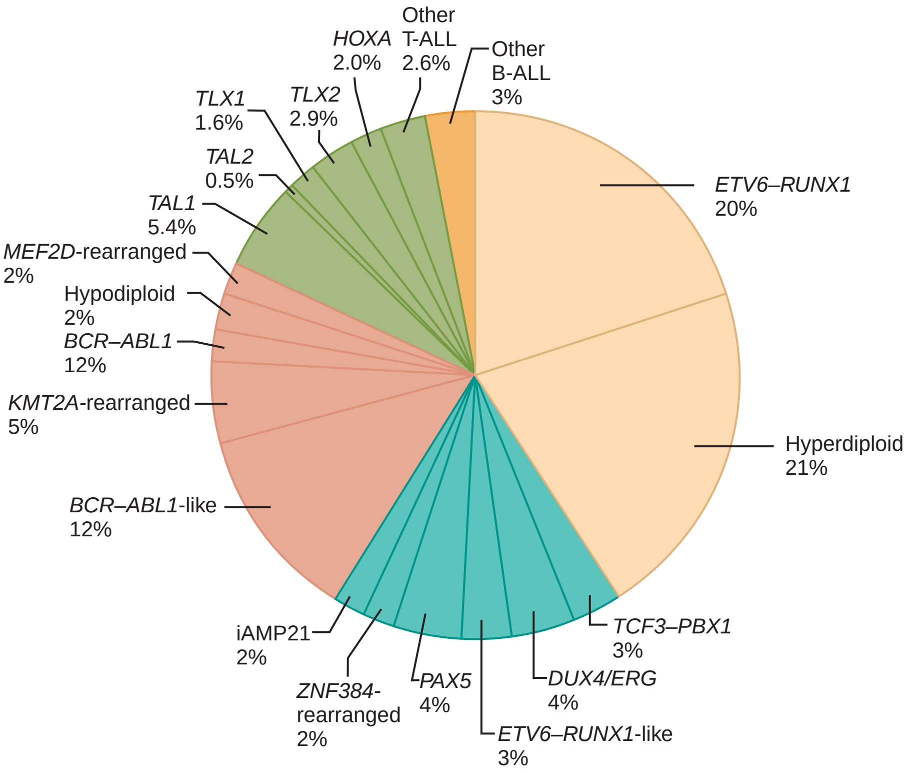

Figure 57.51 ESTIMATED FREQUENCY OF SPECIFIC GENETIC SUBTYPES IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA. The pie chart depicts the estimated frequencies of each subtype of acute lymphoblastic leukemia (ALL) among patients treated in St. Jude Total Therapy Study, with modifications to account for discoveries of novel genetic abnormalities. T cell ALL (T-ALL) subtypes are depicted in blue. Among the B cell precursor ALL (B-ALL) subgroup, low-risk subtypes are in yellow, intermediate-risk subtypes are in green, and high-risk subtypes are in red; however, the prognosis of genetic subtypes depends on treatment efficacy and, hence, might differ between various clinical trials. Moreover, the prognosis of the 3% of patients with B-ALL who cannot be classified into one of these subgroups *(orange segment)* cannot be predicted at present. *DUX4/ERG, DUX4* rearranged and *ERG* deregulated; iAMP21, intrachromosomal amplification of chromosome 21. *(Reproduced with permission from Pui C-H, et al. Somatic and germline genomics in paediatric acute lymphoblastic leukaemia. Nat Rev Clin Oncol. 2019;16(4):227–240.)*

hyperdiploid leukemic cells fail to proliferate in vitro; therefore the use of an ALL FISH panel of probes is strongly recommended. A significant proportion of hyperdiploid ALL patients harbors mutations in *FLT3* (~25%), *NRAS/KRAS* (~15%), or *PTPNI1* (~10%) genes. These mutations are mutually exclusive. Deletions of *ETV6, CDKN2A, PAX5*, and *PAN3* are also frequently deleted loci in these patients. Recurrent somatic hemizygous 13q12.2 microdeletions have been found in 27 of 1418 pediatric patients with B-ALL with high hyperdiploidy and are associated with *FLT3* mutations and deletion of *PAN3*. The size of deletion varies from 39 to 160 kb, with the median size of 129 kb. A novel mechanism leads to simultaneous dysregulation of *FLT3* and *PAN3* deletion in these patients.[17] The interstitial deletions of 13q12.1 are occurring at the 5′ to the *FLT3* promoter and since they are focal deletions, there is a loss of a *PAN3* gene and co-occurring *FLT3* gene overexpression. These two events are changing promoter-enhancer-interactions resulting in an increased expression of the *FLT3* allele encoded on the same chromosome homolog. These observations suggest a novel mechanism of chromatin remodeling whereby enhancer hijacking represents an alternative pathway of *FLT3* activation. High *FLT3* expression has been reported to be a poor prognostic parameter in both AML and ALL.

Modal chromosome numbers of 45 or less occur in 1% to 2% of cases (specifically, the near-haploid numbers of 24 to 36) that confer a poor prognosis. Similarly, ALL in adults presenting with low hyperdiploid/near-triploidy have poor outcomes. Loss of chromosome 7 is frequently a secondary abnormality in adult patients with ALL and the majority of these patients also have t(9;22). Hypodiploid ALL can be further divided into multiple subgroups according to chromosome number. Genomic profiling has shown that near haploid (24 to 31 chromosomes) and low-hypodiploid (32 to 39 chromosomes) childhood ALL are distinct subtypes: near-haploid-ALL is associated with a high frequency of *RAS*-activating mutations including focal deletions of *NF*-1(71%) whereas low-hypodiploid ALL has biallelic alterations of the *TP53* locus, deletions of *CDKN2A/B, IKZF2*, and/or *Rb1(41%). TP53* mutations are also present in non-hematopoietic cells in half of childhood patients with a low-hypodiploid karyotype, indicating that this disease is a manifestation of Li-Fraumeni syndrome (Chapter 30). Diagnosis of low hypodiploid ALL requires *TP53* testing and genetic counseling.

In childhood ALL, *t(12;21)* is difficult to detect with conventional cytogenetics because the translocated portions of 12p13 and 21q22 have virtually identical G-banding patterns. In contrast, the *ETV6-RUNX1* fusion product of t(12;21) is detected using PCR or FISH in 17% to 30% of pediatric patients with ALL (see Fig. 57.52A–C). The *ETV6-RUNX1* fusion, found almost exclusively in children 1 to 15 years old with B-precursor ALL, represents the most frequent molecular rearrangement in childhood cancer. Children with the *ETV6-RUNX1* fusion gene have significantly lower rates of relapse than do *ETV6-RUNX1*-negative patients. *ETV6-RUNX1*-positive B-precursor ALL is characterized by a prolonged duration of first remission and excellent cure rates. Prospective analyses have demonstrated that the survival rate in t(12;21)-positive patients is significantly better when compared with cases lacking this abnormality; however, this abnormality in multivariate analysis was not found to be an independent predictor of outcome. The *ETV6-RUNX1* fusion is rare in adult ALL. t(12;21)(p13;q22) fuses the helix-loop-helix domain of the *ETV6* gene, located on chromosome 12, band p13, to the DNA-binding and transactivation domain of the *RUNX1* gene, located on 21q22. FISH studies allow visualization of the fusion gene on 21q22. Fusion with *ETV6* converts *RUNX1* from an activator to a repressor of transcription. The *ETV6-RUNX1* fusion is accompanied in 55% to 70% of patients by the

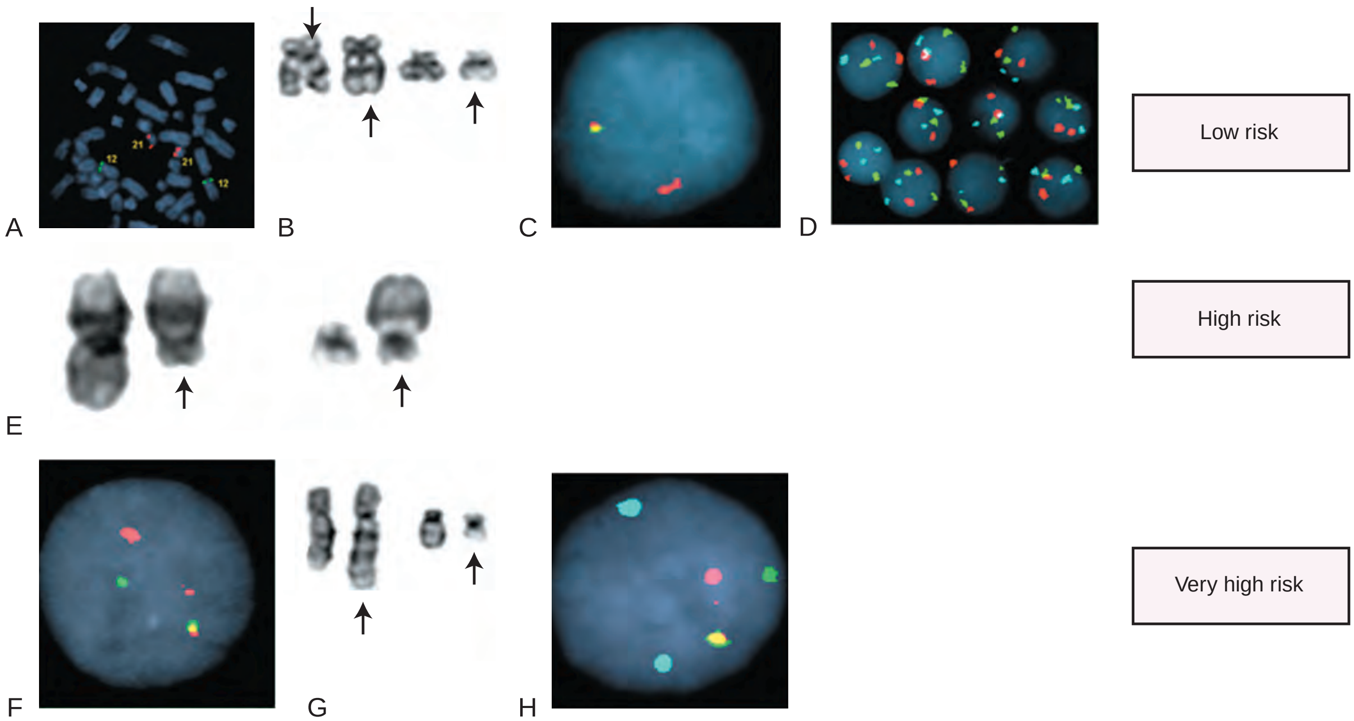

Figure 57.52 PROGNOSTIC CYTOGENETIC CATEGORIES IN ACUTE LYMPHOBLASTIC LEUKEMIA. (A) Localization of *TEL/ETV6* and *AML1* fluorescence probes to chromosomes from a normal bone marrow metaphase cell. *TEL/ETV6* is on 12p13 *(green)* and *AML1* is on 21q *(red)*. (B) Partial karyotype showing t(12;21)(p13;q22) *(arrows)*. The short arrow at 12p indicates a possible *TEL* deletion from normal chromosome 12. (C) FISH study showing loss of *TEL (green)* from normal 12 homologue in interphase nucleus, a frequent subclonal evolution in patients with t(12;21). (D) Hyperdiploidy, specifically trisomies for chromosomes 4 *(green)*, 10 *(red)*, and 17 *(aqua)*, is associated with low-risk cytogenetic category (see text for details) and is present in disomy in interphase cells *(top left)*. (E) Partial G-banded karyotype showing t(1;19)(q23;p13.3), which occurs in approximately 6% of patients with B-cell precursor childhood acute lymphoblastic leukemia. (F) FISH hybridization to bone marrow nucleus showing BCR-ABL fusion *(yellow)*. (G) As a consequence of t(9;22), occurring in 5% of children and 20% to 25% of adults with acute lymphoblastic leukemia. (H) Interphase nucleus after FISH study with tricolor probe. Dual-color/breakapart *MLL* shows separation of the 3′ end and the 5′ end as a result of 11q23 rearrangement. CEP11 *(aqua)* indicates disomy of chromosome 11, used as internal control. *MLL* rearrangements in acute lymphoblastic leukemia are associated with unfavorable prognosis. *FISH*, fluorescence in situ hybridization.

loss of the other *ETV6* allele. This deletion represents subclonal evolution. *ETV6-RUNX1* has been detected in utero, probably in a committed B-cell progenitor, and is present in normal cord blood and peripheral blood samples at frequencies 100-fold greater than the risk for corresponding leukemia. The current view of development of *ETV6-RUNX1*-positive leukemia is that these early events are followed by a long “preleukemic” phase followed by loss of the normal *ETV6* homologue, which appears to be an important event in the multistep pathogenesis of this form of leukemia. Currently, of the 397 children with *ETV6-RUNX1*-positive leukemia reported, approximately 60% harbor additional karyotypic abnormalities that contribute to their pseudodiploid or near-diploid karyotypes. The most common secondary change, which occurs in approximately 50% of cases with additional abnormalities, is trisomy 21.

A rare group of patients with B-precursor ALL lack fusion of *ETV6* and *RUNX1* but have 3 to 15 copies of the q22 band of chromosome 21, including the *RUNX1* locus. Intrachromosomal amplification of the 21q22 band of chromosome 21 is a clonal marker of the leukemic cells that defines a distinct ALL subgroup (Fig. 57.53A). The British Childhood Leukemia Working Party prospectively screened 1630 patients with childhood ALL and identified 28 children with intrachromosomal amplification of chromosome 21 (iAMP21) (see Fig. 57.53D). Approximately 2% of children and less than 0.5% of adults display iAMP21. Children with iAMP21 have a common or pre–B-cell immunophenotype, a median age of 9 years at presentation, and a significantly inferior event-free and OS at 5 years as compared with children exhibiting other cytogenetic subgroups. Even children with Ph-positive ALL have a better 5-year EFS as compared with children with iAMP21. These children have a threefold increased risk for relapse and are twice as likely to die than are their counterparts without iAMP21. The complexity and variability of the iAMP21 includes multiple regions of gains, amplification, inversion, and deletions. In spite of their differences in genomic profiles, the consistent features of patients with ALL and iAMP21 include a common region of highest-level amplification spanning 5.1 Mb from 32.8 to 37 Mb, within which the *RUNX1* gene is located. These observations confirmed that FISH, using probes directed to *RUNX1* locus, to determine the number of copies of the most amplified region, provides a reliable detection method. Thus the finding of three or more extra copies of *RUNX1* on a single abnormal chromosome 21 (a total of five or more *RUNX1* signals per interphase cell) is currently used as the international definition of iAMP21.

Recent genomic, cytogenetic, and transcriptional analyses coupled with novel bioinformatics approaches revealed that individuals born with a rare constitutional Robertsonian translocation, t(15;21)(q10;q10)c, have an approximately 2700-fold increased risk of developing iAMP21ALL compared with the general population. In these patients, amplification is initiated by a chromothripsis event (a process whereby localized genomic regions are shattered and rearranged in one catastrophic event) that affects both sister chromatids of the Robertsonian chromosome. In sporadic iAMP21, breakage-fusion-bridge (BFB) cycles are typically the initiating event, often followed by chromothripsis. In both sporadic and rob(15;21)c-associated iAMP21, the final steps frequently involve duplications of the entire abnormal chromosome. The end-product is a derivative of chromosome 21 or the rob(15;21)c chromosome with gene dosage optimized for leukemic potential, showing constrained copy number levels over multiple linked genes.

TABLE 57.12 Frequency of Cytogenetic Aberrations in Adult and Childhood Acute Lymphoblastic Leukemia and Their Prognostic Relevance

		Adults		Children	
Cytogenetic Abnormality	**Genes Involved**	**Frequency (%)**	**Prognosis**	**Frequency (%)**	**Prognosis**
Normal karyotype	NA	15–34	Good	31–42	Favorable
High hyperdiploidy (>55)	NA	7–8	Good-intermediate	23–30	Good
Low hyperdiploidy (>50)	NA	10–15	Poor	10–11	Intermediate
Near haploidy (<35)	NA	Rare	NA	1–4	Poor
Pseudodiploidy	NA	31–50	Poor	18–26	Intermediate
Hypodiploidy (35–44)	NA	4–9	Poor	6	Poor to intermediate
t(9;22)(q34;q11.2)	*BCR-ABL1*	11–29	Poor	1–3	Intermediate
t(4;11)(q21;q23)	*MLL-AFF1*[a]	4–9	Poor	2	Poor
t(1;19)(q23;p13.3)	*TCF3-PBX1*	1–3	Poor, intermediate favorable	1–6	Intermediate, favorable
t(12;21)(p12;q22)	*ETV6 (TEL)-RUNX1*	0–3	Not known	22–26	Good
t(8;14)(q24;q32)	*MYC-IGH*	5–15	Poor	5	Poor
Abnormal 9p	*CDKN2A*	7–13	Poor	7–11	Adverse
Abnormal 9p13	*PAX5*	2	?Intermediate	2–5	Poor
Abnormal 12p	*ETV6*	0–3	Favorable/unfavorable	3–9	Not prognostic
del(6q)	Not known	3–6	Not prognostic	6–9	Adverse
del(7p)/del(7q)/–7	Not known	6–11	Not prognostic	1	Adverse
del(5q)	Not known	<2	Not prognostic	2	Not known
Trisomy 8	NA	10–12	Poor	3–4 (17%–22% in T-ALL)	Not prognostic
14q11	*TCRα*	5–7 (26% in T-ALL)	Excellent	Rare	Poor
t(10;14)(q24;q11)	*TRD-TLX1*	1–3	Excellent, intermediate		
BCR-ABL1-like	*ABL, JAK, EPOR CRLF2, IKZF del*	17	High risk	15	High risk
iAMP21	*RUNX1*	0.5	Poor	2	Poor, unless treated on intense protocol
Monosomal karyotype	*NA*	9.2	Treated on high-risk protocol	12.8	Treated on high-risk protocol

NA, Not applicable; *T-ALL*, T-cell acute lymphoblastic leukemia.

[a] See Table 57.11 for all other mixed lineage leukemia rearrangements.

Patients with iAMP21 display a unique spectrum of secondary chromosomal abnormalities and they include gain of X chromosome, 10 or 14, or monosomy 7/deletion 7q, deletions of 11q, including *ATM* and *MLL* genes, deletions of *ETV6* and *RB1*.

Both the UK and US Children Oncology groups demonstrated that patients with ALL and iAMP21 when considered a high-risk group and treated on the most intensive treatment arm have a 5-year EFS (from 29% to 78%), a risk of relapse (reduced from 70% vs. 16%), and OS from 67% versus 89%.

The *ETV6* transcription factor gene was first identified as a part of a *TEL*–platelet-derived growth factor receptor β fusion [TEL (ETV6)-PDGFRB] created by t(5;12)(q33;p13) in chronic myelomonocytic leukemia (Chapter 73). It was detected using FISH owing to difficulties in detecting cytogenetic rearrangements at the 12p13 site. As a result of this translocation, the helix-loop-helix domain of *ETV6* is fused in frame to the *PDGFRB* transmembrane and tyrosine kinase domain. Fusion of *ETV6* to a tyrosine kinase also occurs as a result of t(9;12)(q34;p13), leading to the *ABL1-ETV6* fusion that has been observed in patients with ALL, AML, and atypical CML. More than 39 partner genes are known to participate in fusions with *ETV6*, primarily in ALL and less frequently in myeloid malignancies.

Other rearrangements involving 12p include deletions, duplications, and translocations and are observed most often as part of a complex karyotype, frequently associated with chromosome 5 and/or 7 abnormalities. Deletion of 12p13 is much more frequent in children than in adults with ALL and is observed in patients with myeloid disorders, specifically in adults with MDS. Two other genes residing on 12p are also rearranged: *CCND2* is frequently amplified, and *CDKN1B* is often deleted.

Less than 5% of children and 20% to 25% of adults with ALL have a Ph chromosome, making it the most common structural rearrangement in adult ALL (Fig. 57.54). The breakpoint on the Ph chromosome is more centromeric than in CML (see Chronic Myeloid Leukemia, earlier). It includes the 5′ breakpoint on chromosome 22, distal to the first exon (falling between exon e1 and 32) of the *BCR* gene, resulting in the P190$^{\text{BCR-ABL1}}$ variant, providing a diagnostic distinction between the lymphoid blast crisis of CML and de novo ALL. Ph-positive ALL is characterized by a smaller BCR-ABL1 (P190) protein, containing less BCR than the P210 and P230 fusion proteins. Among Ph-positive patients with ALL, approximately 30% to 50% of adults and 85% of children have this breakpoint variant. Up to 19% of Ph-positive patients with ALL may express both the P190 and the P210$^{\text{BCR-ABL1}}$ proteins. ALL has been classified as a stem cell disorder because of the presence of the *BCR-ABL1* transcript in both the myeloid and lymphoid cells.

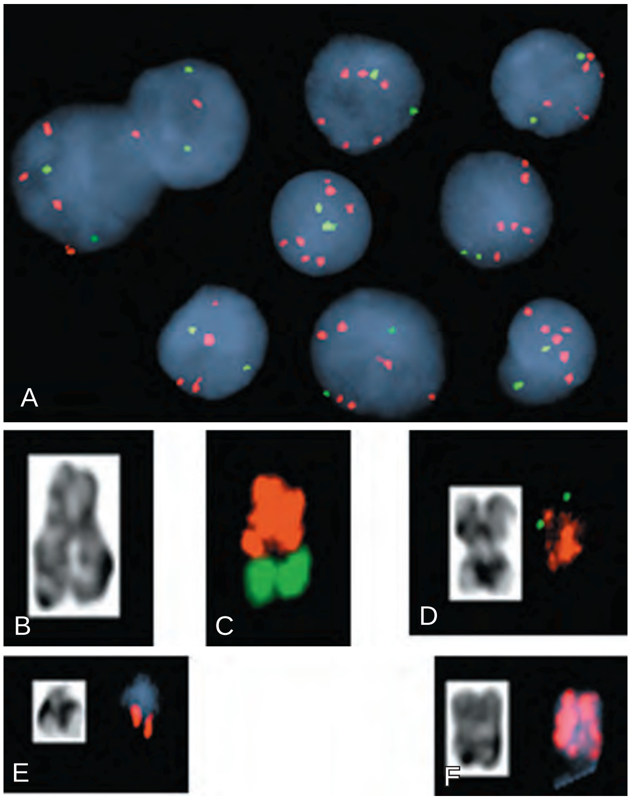

Figure 57.53 DETECTION OF *RUNX1* AND 21q22 AMPLIFICATION. (A) Intrachromosomal amplification of *RUNX1 (red)* (*ETV6 [green]*, present in disomy) in a pediatric patient with pre–B-cell acute lymphoblastic leukemia. This finding is associated with poor prognosis. (B) G-banding of der(18) chromosome and after FISH study (C) with WCP 18 *(green)* and LSI 21q22.13 *(red)*, documenting der(18)t(18;21) and amplification of 21q22 region in a patient with myelodysplastic syndrome/acute myeloid leukemia. (D) Amplification of 21q22 region in myelodysplastic syndrome may be present in another formation: der(21) (G-banding, *left*). FISH study shows amplification of 21q22.13 locus *(red)* and identified der(21) as t(5;21) with 5p15.2 probe *(green)*. (E) Localization of 21q22.13 LSI probe on normal chromosome 21. (F) Homogeneous staining region (hsr)(21), G-banding *(left)*, and after FISH study *(right)* with locus-specific probe for 21q22.13 *(red)* consistent with 21q22.13 band amplification in a patient with myelodysplastic syndrome. *FISH*, fluorescence in situ hybridization; *LSI*, locus-specific indicator; *WCP*, whole chromosome painting probe.

The *BCR-ABL1* fusion variants are easily detectable by FISH using an extra-sensitive probe strategy, and *BCR-ABL1* leukemia can be identified in up to 10% of Ph-negative cases using conventional cytogenetics. Moreover, FISH will identify *ABL* rearrangements in *BCR-ABL1* patients with fusion-negative ALL.

Reactivation of BCR-ABL1 kinase activity is most commonly associated with the emergence of a point mutation in the ABL1 kinase domain implicated in imatinib resistance (see Chronic Myeloid Leukemia, earlier). Recent studies have indicated that kinase domain mutations are present in 70% of imatinib-resistant patients with T315I (37%), E255K (18%), and Y253H (18%) mutations accounting for 75% of these cases. Moreover, 78% of patients resistant to second-generation TKIs were positive for such mutations, and 58% of them had multiple mutations.

More than 60% of adult patients with Ph-positive ALL show ACAs in the Ph-positive clone. Most frequent are gain of Ph chromosome, monosomy 7, +8, +X, del(9p), and high triploidy. The ACAs have no effect on survival of these patients. High hyperdiploidy is detected in approximately 15% of Ph-positive ALL. According to the WHO classification, 1% of all leukemias are mixed phenotype acute leukemias with t(9;22)(q34;q11.2) and leukemic blast cells expressing B-cell and myeloid phenotypic markers. Occasional T-cell phenotype and trilineage *BCR-ABL1* mixed phenotype leukemia have been reported.

B-cell ALL display a differentiation arrest at the pro-B to pre-B stage and is associated with ongoing *IGH* rearrangements. The IL7 receptor (IL7R) is crucially involved in lymphoid development and mutations in IL7R in pediatric B- and T-cell ALL resulting in the constitutive activation of the receptor and cytokine independent growth of progenitor lymphoid cells have recently been reported. Once activated IL7R interacts with JAK/STAT pathway which is often activated in the blast cells of Ph-positive pre–B ALL which may explain the sensitivity of Ph-positive leukemic cells to *JAK2* inhibitors.

“*BCR-ABL1-like*” Acute Lymphoblastic Leukemia

Retrospective studies have demonstrated that GEP can be used effectively to classify ALL into prognostically important subtypes. *BCR-ABL1*-like ALL is a newly described ALL subtype lacking *BCR-ABL1*, but with a similar expression profile to *BCR-ABL1*-positive leukemia (Chapter 68). This new “*BCR-ABL1*-like” (“Ph-chromosome-like”) ALL includes approximately 15% of all precursor B-cell ALL in children and 30% to 40% of adults with ALL and is associated with higher relapse rate and lower EFS (see Fig. 57.51 and Table 57.13). The prevalence of Ph-like ALL increases with age ranging from 10% to 15% of children to 20% to 25% of young adults (21 to 39 years) and adults (>40 years) with ALL. The WHO (2017) endorsed *BCR-ABL1*-like B-ALL as a provisional entity with the gene expression pattern “very similar” to that seen in Ph-positive/*BCR-ABL1* fusion-positive ALL. Both entities commonly harbor genetic alterations targeting B –lymphoid transcription factors, including *IKZF1*. Large-scale genomic profiling and sequencing studies of over 1700 childhood and young adult patients with ALL has revealed rearrangements of *ABL*-class genes, rearrangements of *JAK2*, *EPOR*, and *CRLF2*. *ABL*-class rearrangements result in the expression of fusion genes that activate *ABL1, ABL2, CSFR1*, and *PDGFRB*. In this group of patients *IKZF-1* deletions occur in 40% of pediatric and in 46% of adult patients. *CRLF2* (Xp22.33/p11.3) rearrangements are observed in approximately 50% of patients with *BCR-ABL1*-like ALL with frequent concomitant mutations of *JAK2*, and as mentioned above, are potentially amenable to treatment with *JAK2* inhibitors. Two forms of *CRLF2* rearrangements have been identified which occur either as translocations, *CRLF2-IGH*, or through focal deletion of the *PAR1*, a pseudo-autosomal region of chromosome X/Y resulting in *P2RY8-CRLF2* fusion. The gene encodes for cytokine receptor-like factor 2, also known as thymic-stromal–derived lymphopoietin receptor which in combination with the interleukin-7 receptor forms the receptor for the thymic stromal lymphopoietin. *CRLF2*-rearranged leukemic cells have activated JAK-STAT and PI3K signaling pathways. Detection of rearrangements involving *ABL1, ABL2, CRLF2, EPOR, PDGFRB, and CSF1R* using FISH analysis is very useful to identify *BCR-ABL1*-like ALL.

t(1;19)(q23;p13.3)/E2A-*PBX1* occurs in 5% to 6% of patients with B-cell precursor childhood and adult ALL. However, among patients with a pre-B (cytoplasmic Ig-positive) t(1;19) is found in approximately 25% of cases (see Fig. 57.52D). Cytogenetically, two forms of t(1;19) have been identified: 25% of cases have a balanced reciprocal t(1;19), whereas 75% have a rearrangement of unbalanced der(19)t(1;19)(q23;p13.3). The unbalanced der(19)t(1;19) arises from the initial trisomy of chromosome 1 followed by the t(1;19) translocation, with subsequent loss of the derivative chromosome 1. More than 95% of t(1;19) are associated with the *E2A–PBX1* chimeric gene protein product which arrests cell differentiation. The *E2A* gene (originally identified by the binding of *E2A* proteins to the kE2DNA sequence motif contained in the Ig κ light-chain enhancer) on chromosome 19, band p13.3, is fused to the *PBX1* (homeobox) gene on chromosome 1, band q23. Approximately 1% of pediatric patients with B-cell-ALL have a variant t(17;19)(q21–q22;p13)/*E2A-HLF* translocation resulting with two different genomic rearrangements. The first is the fusion between the *HLF* gene (breakpoint in intron 3) on chromosome 17 and the *E2A* gene (within intron 13) on chromosome 19, associated with disseminated intravascular

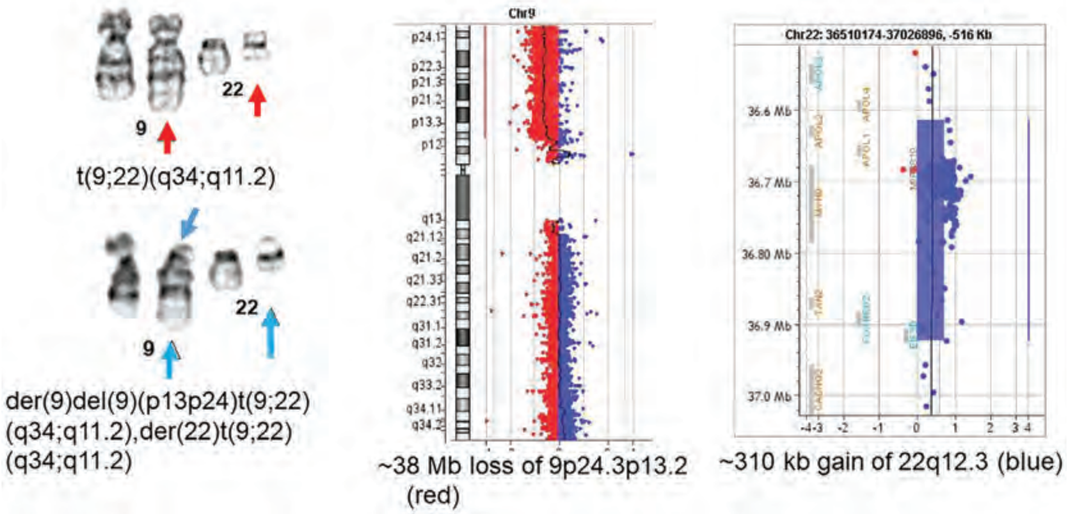

Figure 57.54 THE Ph CHROMOSOME IN ACUTE LYMPHOBLASTIC LEUKEMIA. Partial karyotype of two cells from a 29-year-old patient with B-cell ALL. The t(9;22)(q34;q11.2 *(top)* was detected in 15% of cells at diagnosis *(red arrows)*. The other 85% of cells *(bottom)* had der(9)del(9)(p13p24)t(9;22)(q34;q11.2),der(22)t(9;22)(q34;q11.2) *(blue arrows)*. Note that the 9q+ has loss of almost entire 9p. Using array CGH+SNP it was determined *(right panels)* that loss is ~38 Mb large (as shown in *red*) between 9p24.3 and p13.2. This is a frequent finding in both adult and pediatric patients with ALL. Array results also uncovered a cryptic gain of ~310 kb of chromosome 22 (22q12.3) that was not cytogenetically visible. *ALL*, acute lymphoblastic leukemia; *CGH*, comparative genomic hybridization; *SNP*, single-nucleotide polymorphism.

coagulopathy. The second is the breakpoint in intron 12 of *E2A* and intron 3 of *HLF*, which is associated with hypercalcemia.

Currently, it is thought that an unbalanced der(19) in pediatric ALL is associated with significantly improved outcome as compared with patients with balanced t(1;19). In adults as the sole abnormality, t(1;19)/der(19)t(1;1.9) is associated with an intermediate prognosis; however, within the context of a hyperdiploid karyotype, it is associated with a poor prognosis. Patients with *E2A-PBX1* fusion also display *PAX5* (19p13.2) haploinsufficiency, detectable both by conventional and molecular cytogenetics. A variant t(17;19) rearrangement is associated with a poor prognosis. A recent study of adult patients with ALL has suggested that prognosis of patients with t(1;19) can be substantially improved by the treatment with the hyper-CVAD regimen. Both t(1;19) and t(17;19) are easily identifiable by conventional cytogenetics, FISH, and RT-PCR; the latter two methodologies are particularly useful in post-treatment specimens that are cytogenetically normal. Similar to the *ETV6-RUNX1* fusion, in utero origin of *E2A-PBX1* (see later) was recently documented as well as its presence in approximately 0.6% of healthy newly born and therefore they either convert to overt leukemia or, in most cases, die out later in life. Recent molecular studies underlying leukemogenesis of t(1;19) proposed the following model by which *E2A-PBX1* directly interacts, through a region spanning the *PBX1* homeodomain, with *RUNX1* gene that specifically targets a subset of *RUNX1*-occupied genes and 2 enhancers in the *RUNX1* locus. Gene-expression analysis confirmed that *E2A-PBX1* directly controls *RUNX1* activation in pre-B ALL. Therefore *RUNX1* acts as a master regulator in the establishment of hematopoietic stem cells. It is the physical interaction of *E2A-PBX1* with *RUNX1* but not the DNA binding activity that plays the crucial event in the activation of *RUNX*1-related gene programs both by direct activation of *RUNX1* targets and by reinforcing *RUNX1* transcriptional autoregulatory loop and thereby contributing to ALL pathogenesis.

In ALL, the most frequent *KMT2A* translocations include t(4;11) (1% to 2% incidence in children and two-thirds of *KMT2A*-positive adults) (Fig. 57.55) leading to an *MLL-AFF1* (AF4) fusion and t(11;19)(q23;p13.3) (see Fig. 57.39L) resulting in *KMT2A*/*MLL-MLLT1 (ENL)* fusion. These abnormalities are present in more than 80% of patients with infant leukemia and 10% of childhood and adult *KMT2A*-positive leukemia. *KMT2A*r is associated with a poor outcome in both children and adults. One-third of patients with t(4;11) have secondary abnormalities; the most frequent are +X, i(7q), abnormalities of 9p, including i(9q), and +8. The outcomes of patients with t(11;19) is generally poor, especially in children younger than 1 year of age. The most frequent additional abnormalities in patients with t(11;19) are +X, +8, and del(6q). Other less common *KMT2A*/*MLL* translocations include t(9;11)(p22;q23)/*KMT2A*/*MLL-MLLT3*, t(10;11)(p13–15;q23)/*KMT2A-MLLT10*, and others. A large multi-institutional study has determined that secondary aberrations do not affect the prognosis of children with ALL showing t(4;11), t(11;19) or other *KMT2A* translocations.

Secondary or therapy-related forms of ALL are rarely reported but the majority of them are associated with *MLL* rearrangements, the most frequent being t(4;11). Most of these patients have received topoisomerase II inhibitors which are known to cause double-strand DNA breaks.

t(8;14)(q24;q32) is seen in fewer than 5% of all patients with ALL (children and adults) (Fig. 57.56). Variant translocations t(8;22)(q24;q11) and t(2;8)(p12;q24) are seen in less than 1% of children and adults. These cells express CD10, CD19, CD20, and surface IgM immunophenotype. This form of ALL has an extremely poor prognosis. The same translocation is found in Burkitt lymphoma (BL), and both entities likely represent the same disease with different manifestations. The majority of adult patients with t(8;14) die within 1 year of diagnosis. Approximately 4% of children and 11% of adult pre–B-cell precursor ALL have recurrent *IGH* translocations usually identified by cytogenetics or FISH. The *CRLF2* gene, which maps to the pseudo-autosomal region 1 of the sex chromosomes, is the gene that is most frequently targeted in 20% to 26% of *IGH* translocations in pre–B-cell precursor ALL. *IGH-CRLF2* rearrangements result from the cryptic t(Y;14)(p11;q32) or t(X;14)(p22;q32). The second most frequent *IGH* translocation is t(14;19)(q32;q13) and *IGH-CEBP* chimeric fusion. The third most frequent translocation partner involves *CEBPD* gene (8q11) resulting in t(8;14)(q11;q32) and *IGH-CEBPD* fusion, which is primarily found in children and young adults and is strongly associated with DS (about 30% of cases). This subgroup frequently has a gain of X chromosome, trisomy 21 as an acquired abnormality, and the Ph chromosome/t(9;22)(q34;q11). The t(14;19)(q32;q13)/*IGH-EPOR* appears to be causally related to pre–B-cell precursor ALL because it always appears as the single abnormality. The inv(14) (q11q32)/ins(14;14)(q11;q32) leads to *IGH-TRA/D*, which represent a rearrangement mediated by an

TABLE 57.13 **Clinical and Biological Characteristics of Newly Identified Molecular Subtypes in Childhood Acute Lymphoblastic Leukemia**

Molecular Subtype	Frequency	Characteristics
Ph-like	• 12% in children • 21% in adolescents	• Dysregulation of cytokine receptor and kinase signaling pathways owing to genetic aberrations including *CRLF2* rearrangement (in ~50% of patients) and translocation of non-receptor tyrosine kinases (predominantly ABL class and Janus kinases) • Generally unfavorable
iAMP21	2%	• ≥3 extra copies of *RUNX1* on a single abnormal chromosome 21 (total of ≥5 copies of *RUNX1*per cell) • Requires intensified treatment to reduce risk of relapse
DUNX4-rearranged	4%–5%	• Overexpression of *DUX4* and transcriptional deregulation of *ERG*, resulting in loss of function of the transcriptional regulator ERG • Favorable prognosis
MEF2D-rearranged	2%–3%	• Increased *MEF2D* transcriptional activity, activation of *HDAC9* expression and increased sensitivity to histone deacetylase inhibitor treatment • Low or absent expression of CD10 and high expression of CD38 • Older age at diagnosis (median of 12 years) • Unfavorable prognosis
ZNF384-rearranged	2%–3%	• Enrichment of gene expression for hematopoietic stem cell signatures • Low CD10 expression and aberrant CD13 and/or CD33 expression • intermediate prognosis
ETV6-RUNX1-like	2%–3%	• Gene expression profile similar to that of *ETV6-RUNX1*-postive ALL with coexisting *ETV6* and *IKZF1* aberrations • Expression of CD27, and no or low expression of CD44 • Intermediate of favorable prognosis

Favorable, intermediate, and unfavorable prognosis acute lymphoblastic leukemia (ALL) subtypes are associated with 5-year overall survival of >90%, 70%–90%, and <70%, respectively.
iAMP21, Intrachromosomal amplification of chromosome 21; *Ph*, Philadelphia chromosome.
Modified from Pui C-H, Nichols KE, Yang JJ, et al. Somatic and germline genomics in paediatric acute lymphoblastic leukaemia. *Nat Rev.* 2019;16(4):227.

interlocus site-specific recombination event between *IGH* and the *TRA* and *TRB* genes. The t(14;20)(q32;q13) results in *IGH-CEBPB*. Collectively, patients with *IGH* translocations may be included in a subgroup of pre–B-cell precursor ALL.

Abnormalities of the short arms of chromosome 9 (p21–22) occur at a frequency of 7% to 13%. In adults the presence of del(9p) appears to be associated with a favorable outcome, whereas in children with ALL, del(9p) is associated with poor outcome. The most frequent abnormalities are co-deletions of two genes, *CDKN2A* and *CDKN2B*, as well as the interferon α and β genes found in many cases. Among the structural rearrangements involving the short arms of chromosome 9, t/dic(9;12)(p11–12;p11–13) is a rare recurrent abnormality associated with L1 morphology (FAB classification), a pre–B-cell phenotype, and an excellent prognosis.

The *IKZF1* gene at 7p12.2 codes for *IKAROS*, an essential transcription factor in hematopoiesis primarily involved in lymphoid differentiation and is an essential player in the regulation of both T- and B-cell lineage specification (Chapter 9). The gene is composed of eight exons, spanning a total of 6.2 kb and coding for a 519-amino acid protein. Deletions of *IKZF1* have been reported in 15% of pediatric and 30% to 50% of adult patients with ALL, and in 75% of Ph-positive B-cell ALL. Both focal and nonfocal *IKZF1* deletions have been shown to be associated with an increased risk of relapse and decreased EFS in both pediatric and adult ALL. Most laboratories use SNP array technique to detect *IKZF1* deletion. Recent genomic studies of patients with ALL have confirmed a higher hazard of relapse in adult ALL with focal *IKZF1* deletions.

Other chromosomal abnormalities detected in nonrandom fashion in adult patients with ALL include deletions, both terminal and interstitial, of the long arm of chromosome 6, and isochromosomes of 7q, 9q, 17q, and 21q. Adult patients with ALL harboring t(9;22), t(4;11), t(8;14), -7, +8 chromosomal aberrations have a poorer prognosis and significantly lower probability of long-term CR and survival than do patients with a normal karyotype or patients with other chromosomal rearrangements.

Complex and Monosomal Karyotype

Complex karyotype (≥3 or ≥5 chromosomal abnormalities) as well as patients with near triploidy defined as 60 to 78 chromosomes and high hyperdiploidy, as well as the presence of 51 to 65 chromosomes are adverse prognostic factors in adults with ALL independent of MRD status. In a more recent study 9.2% of adult patients with ALL had a complex karyotype and 12.8% had a MK and neither was associated with a worse prognosis when treated with risk-adapted or subtype-oriented protocols. MK did not have an impact on prognosis in Ph-positive ALL irrespective of imatinib treatment.

The lymphoid leukemias associated with Down syndrome (DS-ALL) are almost exclusively B-precursor ALLs. In a recent large series of DS-ALLs, there were only five cases of T-ALL among 700 patients. Also, in a sharp contrast to the myeloid neoplasms, they almost never occur in infants. Clinically the outcome of DS-ALL is significantly worse than sporadic childhood B-cell precursor ALLs because of intrinsic resistance to therapy and increased treatment-related mortality. Although all known cytogenetic subgroups of childhood B-cell ALLs have been observed, the common abnormalities such as *ETV6/RUNX1* fusion and hyperdiploidy are less frequent.

Up to 60% of DS-ALLs have aberrant expression of the cytokine receptor *CRLF2* that is often associated with additional mutations activating JAK-STAT signaling. The aberrant expression of this receptor is caused by genomic rearrangements consisting either of a translocation into the *IgH* locus control region or a microdeletion upstream to the *CRLF2* gene, located on the pseudoautosomal component of the sex chromosomes. This deletion fuses *CRLF2* with the promoter of an upstream constitutively expressed *P2RY8* gene. Analysis of the breakpoint sequences suggest that this rearrangement is mediated by *RAG1* or *RAG2* in early B-cell precursors.

Application of high-resolution RNA sequencing, FISH, and CGH+SNP array to 117 consecutive pediatric patients with B-ALL demonstrated that all genetic changes necessary for risk stratification were reliably identified. Specifically, array CGH+SNP proved to be more sensitive in detecting cryptic hyperdiploidy. Hyperdiploid leukemic cells frequently fail to proliferate in culture resulting in

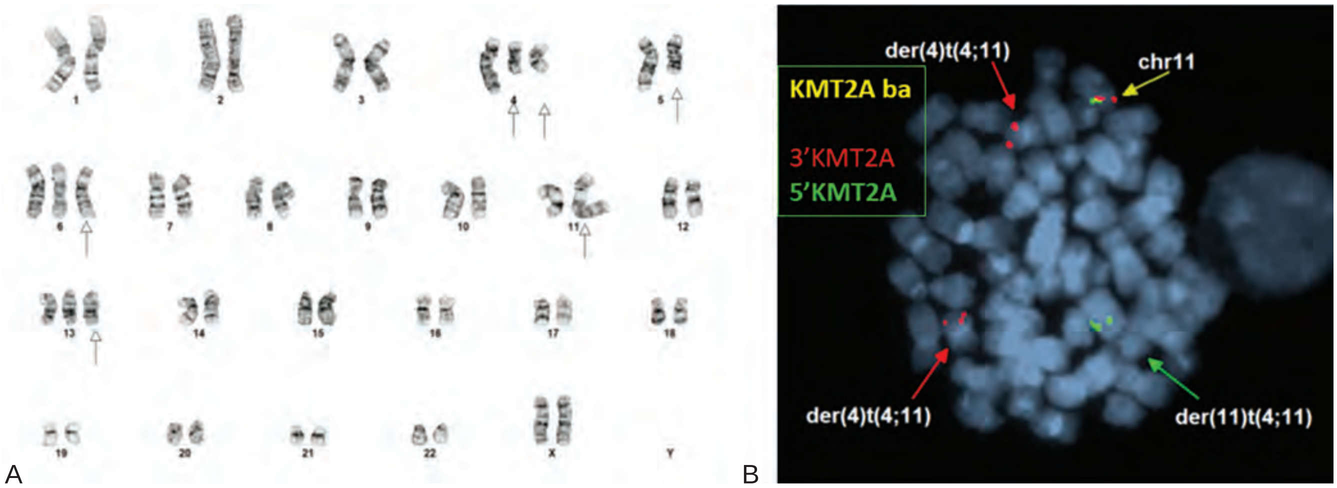

Figure 57.55 A HYPERDIPLOID B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA WITH TWO COPIES OF t(4;11). A diagnostic karyotype, in 100% of examined bone marrow metaphase cells, had 49,XX, +der(4)t(4;11) (q21;q23),t(4;11), del(5)(q15q34),+6,+13 karyogram. These findings are consistent with a hyperdiploid karyotype including trisomies of chromosomes 6 and 13. The patient also had a balanced translocation between the long arms of chromosomes 4 and 11 followed by a replication of the abnormal derivative chromosome 4. (B) A second abnormal chromosome der(4) is shown within the metaphase cell after FISH probing using a KMT2A breakapart FISH probe. *Red arrows* point to a gain of 3′ *KMT2A* localized on two der(4) chromosomes while the green arrow indicates that the 5′ of KMT2a remained on the abnormal 11. In adult ALL, a hyperdiploid karyotype involving t(4;11) is considered a high-risk category. Of note, del(5q) is typically observed in myeloid disorders but it has been reported rarely in lymphoid diseases as well. *ALL*, acute lymphoblastic leukemia; *FISH*, fluorescence in situ hybridization.

an absence of aneuploidy. Moreover, copy-number analysis appears to be a crucial and central diagnostic tool and should be included into a standard workflow for B-ALL patients enrolled in the clinical trials.

Somatic Mutations

The most commonly altered pathways in ALL, involving the transcriptional regulation of lymphoid development, such as *PAX5* (9p13.2), *IKZF1* (7p12.2), and *EBF1* (5q33.3), are frequently mutated (Chapter 66). *PAX5* is required for B-lymphoid lineage commitment and maturation. *PAX5* genetic alterations include deletions, sequence mutations, and chimeric genes with at least 16 different chromosomal partners (http://atlasgeneticsoncology.org/Genes/PAX5ID62.html). *IKZF1* is required for the development of all lymphoid lineages and its genetic lesions are implicated in resistance to chemotherapy and TKIs.

Other commonly mutated pathways in ALL include genes involved in tumor suppression and cell cycle regulation (*TP53*, *Rb1*, and *CDKN2A*), cytokine receptor, RAS-signaling, lymphoid signaling, and epigenetic modification such as *EZH2*. An integrated approach including NGS and array studies has contributed to an increased number of novel molecular entities such as *DUX4/ERG*, *ETV6-RUNX1-like* ALL, and *MEF2D/ZNF384* ALL. Rearrangements of *DUX4*, a homeobox transcription factor (4q35.2) such as overexpression, or transcription binding causing a loss of function of *ERG* (21q22.2) is present in 4% to 7% of B-cell-ALL. Aside from ERG deletion, *DUX4* fusions are frequently accompanied by *IKZF1, PAX5*, and 9p deletions and by activating mutations in *NRAS*, *KRAS*, and *MYC*. Another novel form, *ETV6-RUNX1-like ALL*, is characterized by *ETV6* and *IKZF1* aberrations and approximately 3% to 5% of all childhood B-cell ALL belong to this new biological category. This integrated approach revealed that *MEF2D* (1q1.3) and *ZNF38* (12p13.1) fusions as recurrent events both in adult (~7%) and pediatric (3.6%) ALL and that they should be considered as two distinct expression subgroups. *MEF2D* fusions identify a group of patients with upregulation of *HDAC9* both in children and adults which is associated with a poor outcome. The expression subgroup of patients with *ZNF384* fusions is observed in patients with hyper-expression of JAK-STAT signaling pathways genes, and of *GATA3* and *CEBPA/B*.

Prenatal Origin and Multistep Pathogenesis of Acute Lymphoblastic Leukemia

Epidemiologic, genomic, and twin studies indicate a multistep pathogenesis of B-cell ALL in infants and children, with an initial leukemogenic event(s) occurring in utero and subsequent genomic changes occurring postnatally. Most of the current thinking of the natural history of childhood ALL was based on the exquisite work of Greaves and co-workers who studied the clonal origin of leukemia in monozygotic twins 30 years ago. Greaves found that most common chromosomal translocations and their resultant gene fusions were present on neonatal blood spots or Guthrie cards. If a unique gene fusion sequence is present in at least one cell per 30,000 in the peripheral blood, it can be detected by a sensitive PCR assay. The first observations of an in utero origin of an acute leukemia were demonstrated with *KMT2A* rearrangements in three children with ALL, in monozygotic twins who shared the identical fusion, and in a pair of twins diagnosed at age 3 with B-precursor cell ALL. Subsequently in utero occurrence of *ETV6-RUNX1, BCR-ABL1, E2A-PBX1*, and loss of *IKZ1, PAX5*, biallelic loss of *CDKN2A*, and hyperdiploidy were documented prenatally on Guthrie cards. The concordance rate of twins who share a monochorionic placenta and develop leukemia is nearly 100%, whereas older twins have a discordance rate of 90%, indicating that additional postnatal leukemic events are needed. The frequency of an in utero origin of a B-cell precursor ALL in patients who are not twins as measured by clonal *IGH* rearrangements is reported to be 71%, supporting the notion that in the majority of infants older than 1 year, the development of ALL occurs during fetal development because they share a single placenta resulting in blood cell chimerism. The prenatal mutation occurs commonly, exceeding the actual rate of developing leukemia by some 100-fold, indicating a low rate of evolution. The acquisition of the additional genetic lesions, such as copy number alterations of *ETV6*, *PAX5* and *CDKN2A* (25% to 75% of cases) are recurrent and contribute to leukemogenesis. After testing five pairs of monozygotic twins with concordant *ETV6-RUNX1*-positive

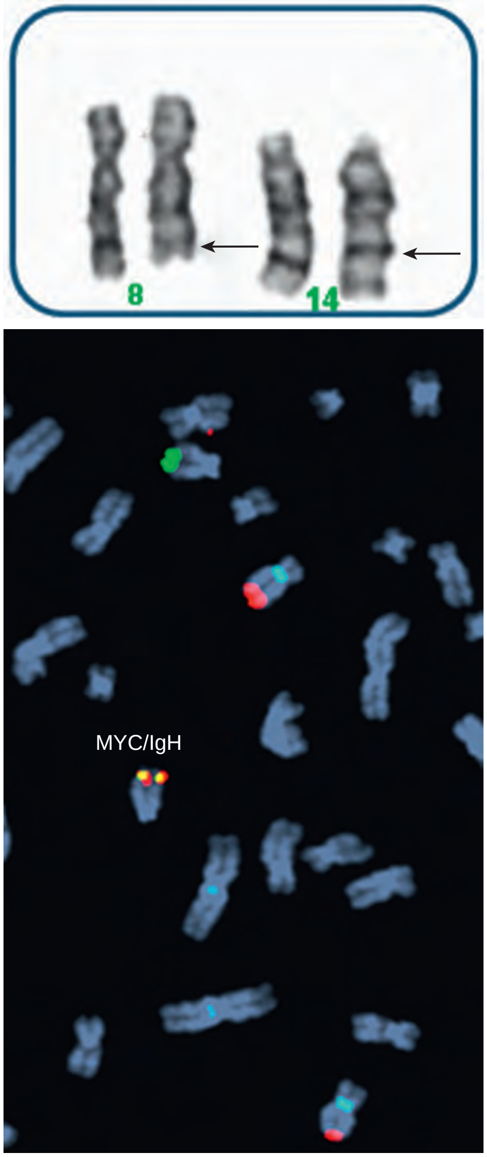

Figure 57.56 t(8;14)(q24;q32) IN ACUTE LYMPHOBLASTIC LEUKEMIA. *Top panel* shows a partial G-banded karyotype of chromosomes 8 and 14 with *arrows* indicating the breakpoints on each chromosome. The *bottom panel* is a partial metaphase (chromosomes are stained blue with DAPI) after FISH testing using three probes: *IGH* signal *(green)* is seen on normal chromosome 14, *aqua* signals for centromere 8 are observed on both chromosomes 8, *MYC (red)* is seen on both chromosomes 8 but note a more bold signal on one chromosome 8 when compared to the other. Because *MYC* is broken as a result of t(8;14), the third copy of *MYC* is on chromosome 14 where it is fused to *IGH* and seen as a *yellow* signal.

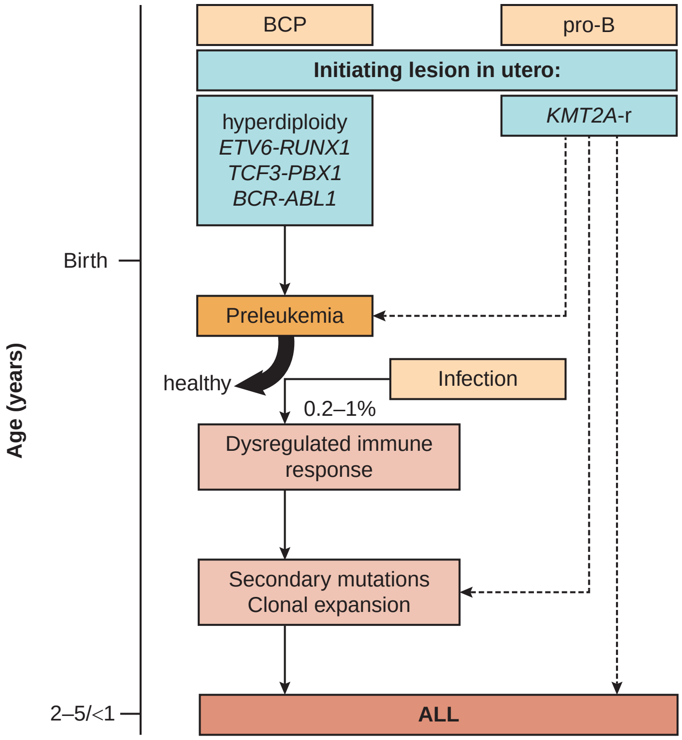

Figure 57.57 TIMELINE OF ALL DEVELOPMENT. The initiating lesions *(green)* occur in utero and lead to a state of preleukemia after birth. Exposure to infection leads to a dysregulated immune response in a small fraction (about 0.2% to 1%) of preleukemic children. Most preleukemic children remain healthy.[6,7] The children develop ALL by acquiring secondary mutations, eventually leading to clonal expansion. In the case of *KMT2A* rearrangements (*KMT2A*-r, right), it is not completely clear whether the *KMT2A*-r are sufficient for ALL development *(right dashed arrow)*. It is also possible that the *KMT2A*-r directly trigger secondary mutations *(central dashed arrow)*. One case of a healthy *KMT2A*-r carrier has been reported leading to the possibility of a preleukemic state for those cases *(left dashed arrow)*. The given median ages of ALL onset are 2–5 years of age for B-cell precursor subtypes (BCP, left) and below 1 year of age for pro-B-cell subtype (pro-B, right). *ALL*, acute lymphoblastic leukemia. *(Reproduced with permission from Hein D, Borkhardt A, Fischer U. Cancer and Metastasis Review, 2020;39:161–171.)*

ALL, Greaves and his colleagues demonstrated that all recurrent driver mutations detected (32 in total) were different within twin pairs, indicating that they are postnatal in origin in both twins and most likely represent secondary mutations. Single cell analyses have revealed considerable complexity within a tree-like or branching structure of genetically distinct subclones, as Greaves and colleagues first suggested. Current molecular data suggest that *KMT2A* fusions may be sufficient to cause leukemia since they are found in aborted fetal tissues (Fig. 57.57).[4] However, formation of *ETV6-RUNX1* fusion in utero is not sufficient to cause leukemia and postnatal mutations are required, such as a loss of a normal *ETV6* from the other homologue. Formation of *ETV6-RUNX1* has been shown, using qRT-PCR and FISH, to be present in ∼1% of newborns. Current evidence suggests the frequency of *ETV6-RUNX1* incidence in a newly born is estimated to be very low, about 10^{-4}. Prenatal origin of *E2A-PBX1*, as mentioned above, was also traced to Guthrie cards and was detected in cord blood of healthy newborns at the frequency of 0.6% (see box on Genetic Testing for Acute Lymphoblastic Leukemia).

GENETIC TESTING FOR ACUTE LYMPHOBLASTIC LEUKEMIA

At diagnosis it is mandatory to perform conventional cytogenetics especially for pediatric patients in whom solely numerical abnormalities occur in 25%, while in adults complex and near triploid karyotype are associated with adverse prognosis. The panel of FISH probes useful at diagnosis of pediatric ALL include ETV6-RUNX1, MLL, BCR-ABL1, E2A-PBX1, and CDKN2A and CDKN2B. Array CGH+SNP is recommended as a reflex test for patients with a normal karyotype.

CHRONIC B-CELL LYMPHOCYTIC LEUKEMIA (CHAPTER 76)

Historically, classic metaphase cytogenetic analyses of CLL were difficult because of the low mitotic rate of neoplastic B cells despite the use of polyclonal B-cell mitogens. FISH analysis of nondividing interphase cells was applied for the first time to hematologic malignancy and was used to create a risk stratification tool for CLL. Introduced in 2000 by Dohner, the FISH hierarchical prognostic model stratifies patients into good [normal cytogenetics, del(13q)], intermediate (trisomy 12), and poor [del(11q) and del(17p)] prognostic groups and remains the most accepted and validated genomic prognostic model. Moreover, current guidelines still recommend FISH analysis before treatment initiation and following relapse or lack of response to therapy.

Cytogenetically CLL is characterized by relatively stable genome harboring a gain or loss of chromosomal regions; balanced translocations are rare in CLL. With improved detection rate of aberrant karyotypes in CLL using cultivation with CD40 ligand (DSP30) and interleukin-2 and the application of FISH, aCGH+SNP, as well as NGS, the detection rate of genomic changes has risen to 80% to 90%. Clinically relevant chromosomal loci, combined with immunophenotyping, mutational analyses of the Ig heavy-chain variable region (IgV_H), and ZAP-70 overexpression, has led to advances in prognostication of CLL patients (Tables 57.14 and 57.15 and Fig. 57.58; see also box on Genetic Testing for B-Cell Chronic Lymphocytic Leukemia). Microarray and high-density SNP array studies are helpful in clarifying the heterogeneous nature of CLL, which is a single disease entity with a common genetic phenotype resembling memory B lymphocytes. Genetic testing is strongly recommended for all patients with CLL, particularly in the context of novel therapeutic trials for. Moreover, a complex conventional karyotype remains an independent prognostic indicator associated with a poor outcome. Chromosome abnormalities in CLL detected by FISH are of prognostic significance (Fig. 57.59). Four genomic aberrations, as well as normal findings, are independent predictors of disease progression and survival. Genomic aberrations of prognostic significance include 17p deletion, 11q deletion, trisomy 12, and 13q deletion. Survival in these groups is 32, 79, 114, and 133 months, respectively, and the treatment-free intervals are 8, 12, 33, and 92 months, respectively. Survival of patients with a normal karyotype is 111 months, and the treatment-free interval is 49 months. In 80% to 90% of the cases, a deletion of 17p tumor suppressor gene (*TP53)* is associated with mutated *TP53* on the remaining copy. *TP53* mutations have been found in 4% to 15% of patients with early-stage CLL and are associated with poorer outcomes. Deletion of 11q and deletion of the *ATM* gene on 11q23.1 are found in 18% of patients with CLL. In about one-third of patients with deleted 11q, a simultaneous mutation of *ATM* has been found.

TABLE 57.14 **Most Frequent Clinically Relevant Chromosomal Abnormalities and Copy Number Alterations in Chronic Lymphocytic Leukemia**

Chromosomal Abnormality	Frequency %	Likely Gene Target	Clinical Associations and Consequence	miRNAs	Prognosis

GENETIC TESTING FOR B-CELL CHRONIC LYMPHOCYTIC LEUKEMIA

At diagnosis, interphase FISH is used in lieu of karyotype studies because FISH detection of abnormalities in CLL correlates with clinical risk groups and prognosis. FISH studies should be performed on blood for detection of trisomy 12, deletions of 11q22.3, 13q14.3, and the *P53* loci, as well as rearrangement of 14q32.3, *IGH* locus. The FISH test can distinguish between patients with B-cell CLL and those with the leukemic phase of certain lymphomas, such as mantle cell lymphoma and follicular lymphoma. If FISH for these loci is negative then somatic mutations for *ATM, BIRC3, NOTCH 1*, and *TP53* should be searched for using NGS. As per *iw*CLL guidelines, it is absolutely critical for the optimal therapy and clinical trials to perform conventional cytogenetics using the standard procedure of stimulating CLL lymphocytes in the presence of DSP30 plus interleukin 2.

FISH-detected anomalies are frequent in B-CLL cases with Rai stages 0 to 1 disease, but are more frequent among patients with progressive disease (88%) than in those with stable disease (66%). Two risk groups have been recognized: (a) low-risk disease includes patients with a normal karyotype or isolated del(13q); (b) high-risk includes patients with del(11q) and del(17p). Patients with +12 are high risk, but in contrast to del(11q) and del(17p), they respond to fludarabine-based therapies. A comparison of quantitative PCR method with FISH for assessment of the four most frequent aneuploidies revealed a tight correlation in 103 of 110 patients examined, with FISH being more sensitive in detecting subclonal genetic evolution (Fig. 57.60).

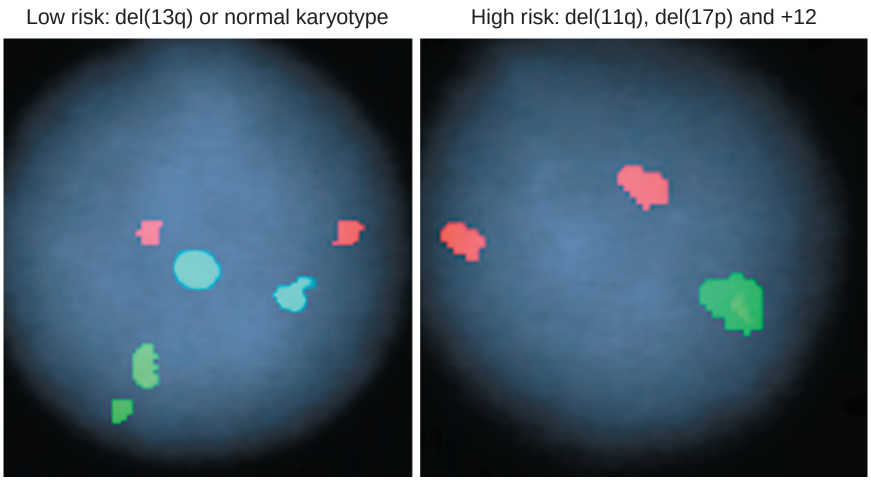
The frequency of chromosome 13 abnormalities in CLL detected by conventional cytogenetics is 10% to 15%. However, with the use of FISH, smaller or larger deletions of band q14.3 are detected in up to 60% of patients over time. When multiple DNA probes are used, D13S319 and D13S25 DNA markers are deleted more frequently than is *RB1*. Molecular analyses have detected deletions of 13q in cells that are cytogenetically normal as well as abnormal. These deletions can either be heterozygous (76%) or homozygous (24%). Heterozygous deletions most frequently occur in the early stages of the disease and homozygous deletions occur in the more advanced stages. In a study examining loss of heterozygosity and subchromosomal copy losses of chromosome 13, two types of deletions were defined: type 1 aberrations occurred in 60% of cases and were associated with loss of *RB1* and breaks close to the *miR16/15a* locus; and type 2 aberrations that included *RB1* occurred in 40% of cases. The 13q14.3-deleted segment contains micro-RNA (miRNA) genes (Chapters 4 and 76). All patients with homozygous 13q deletion have a dramatic downregulation of miRNA15a, whereas patients with hemizygous 13q deletions are indistinguishable from controls, providing the first molecular clues for pathogenesis of CLL. The percentage of CLL cells with del(13q) is predictive of survival. A high percentage (>80%) of del(13q) cells is correlated with a higher lymphocyte count, a tendency to exhibit a diffuse bone marrow infiltration pattern, and splenomegaly. Trisomy 12 or 13q rearrangements are found separately in a substantial proportion of patients with CLL. They co-exist in only 2% to 5% of patients, suggesting that each change may have a distinct pathogenetic route.

Among the first-degree relatives of patients, population studies have demonstrated a sevenfold increased risk for developing CLL and a twofold increased risk for developing other lymphoproliferative disorders (Chapter 76). More than 80 families with CLL affecting multiple family members have been reported. Linkage studies suggest a region of interest in band q22.1 of chromosome 13 (marker D13S156). Fine FISH mapping of six CLL-prone families (63 individuals) reveals deletion of 13q14 in 85% of patients with familial CLL, and four CLL families shared a 3.6-Mb minimal region in 13q21.33–q22.2. This region included 12 candidate genes, but thus far informative candidates have not been identified.

Trisomy 12 was the first recurrent abnormality reported in CLL patients. It is detected by classic cytogenetics in 7% to 15% of all cases. FISH detects +12 in 15% to 20% of patients with CLL. Trisomy 12 may be present as a sole abnormality or in combination with other chromosomal rearrangements. Because only a proportion of cells are trisomic, normal cells or disomic neoplastic cells may also be present. Follow-up analysis over a 4-year period demonstrated clonal expansion of cells with trisomy 12 as the disease progresses. The observation that trisomy 12 is present in B cells and is absent from T lymphocytes and CD34 cells in the majority of CLL patients is consistent with the hypothesis that CLL is of clonal origin and that trisomy 12 arises in a progenitor cell already committed to the B-cell pathway. The exact mechanism by which trisomy 12 contributes to the pathogenesis of CLL remains unknown.

The chronic lymphocytic leukemia upregulated gene-1 (CLLU1) has been shown to be the first highly specific CLL gene. Six transcripts have been identified, two of which contain a putative coding sequence with low similarity to human interleukin-4. Overexpression of the transcript cDNA1 appears to be specific for CLL, and is of prognostic significance and can be used for MRD detection.

Deletions of the long arm of chromosome 11 in CLL as detected by conventional cytogenetics have been reported in 5% to 8% of cases. An interphase FISH study identified deletion of 11q22.3–23.1 in 10% to 20% of cases. FISH characterization of aberrations involved in 11q21–q23 demonstrate a minimal consensus deletion segment of 2 to 3 Mb, containing a number of genes including *ATM* at 11q22.3. Up to 12% of patients have simultaneous deletions of *ATM* and *MLL* at 11q23. Mutations in *ATM* gene are responsible for the ataxia-telangiectasia syndrome. *ATM* functions as a cell-cycle checkpoint regulator. Somatic disruptions of both *ATM* alleles by deletion or point mutation are detected in 25% to 34% of cases. This finding strongly suggests the pathologic role of *ATM* in some patients with



Low risk: del(13q) or normal karyotype
High risk: del(11q), del(17p) and +12

Figure 57.59 PANEL OF CHROMOSOMAL PROBES USED FOR DETECTION OF GENOMIC DEFECTS IN CHRONIC LYMPHOCYTIC LEUKEMIA. They include 13q14.3 *(red)*, 13q34 *(aqua)*, and CEP12 (all present in disomy; *left*) and 11q22.3 (ATM, *green*) and 17p13.1 (P53*; red, right*). Note there is only one copy of the *ATM* gene *(green, right)* consistent with deletion of sequences from the 11q22.3 band region, which is associated with unfavorable prognosis.

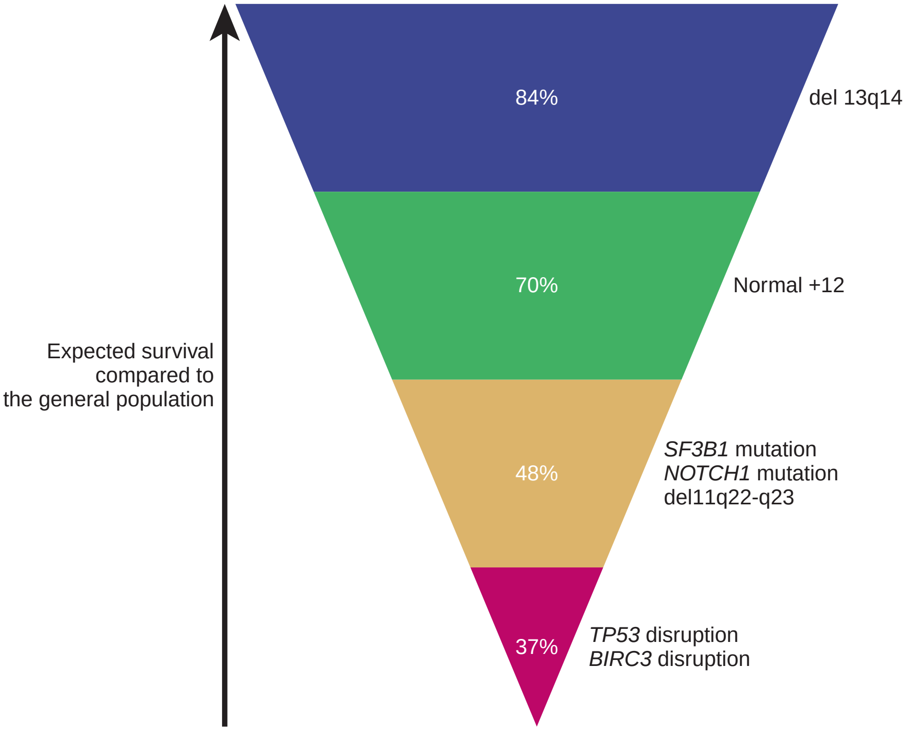


Figure 57.60 SURVIVAL OF PATIENTS WITH SPECIFIC GENOMIC DEFECTS IN CHRONIC LYMPHOCYTIC LEUKEMIA ACCORDING TO GENETIC DEFECTS. Expected survival of patients with chronic lymphocytic leukemia stratified according to the integrated mutational and cytogenetic model and compared to the matched general population. Expected survival is calculated at 10 years. *(Reprinted with permission from Foà R, Del Giudice I, Guarini A, et al. Clinical implications of the molecular genetics of chronic lymphocytic leukemia. Haematologica. 2013;98:675.)*

B-cell-CLL. Moreover, a discontinuous deletion between 11q23.1 and 11q23.3 segments indicates that genes in this region may have pathogenic significance because they constitute independent targets for amplification or deletion in cases of B-CLL. Most of the patients with del(11q) are relatively young. The appearance of this deletion is clinically associated with lymphadenopathy, rapid disease progression, poor response to treatment, and a shorter OS.

Structural abnormalities of chromosome 17 have been observed in 4% of cytogenetically evaluable B-cell CLL cases. This abnormality frequently affects the short arm of chromosome 17, the site of the *TP53* tumor suppressor gene. Monoallelic deletions of *TP53*, detected by FISH, are present in 7% to 20% of patients and represent the strongest predictor of poor survival. The median survival of these patients is only 32 months. *TP53* mutations are associated with aggressive disease and a lack of response to conventional therapy. Deletion of *TP53* and mutations of *TP53* are independent processes and at diagnosis ~about 10% of CLL patients harbor the *TP53* gene mutation. Up to 50% of patients may have *TP53* defects as the disease progresses, or becomes treatment-refractory. Of all patients with *TP53* gene abnormalities, mutations and deletions occur together in the majority of patients with monoallelic *TP53* mutations accounting for another 40% of CLL patients, while monoallelic deletions and also mutations with copy neutral loss of heterozygosity account for a minority of patients. A novel recurrent dic(8;17)(p11;p11) abnormality also results in loss of *TP53*, and low copy repeats in 17p12 and 8p11 may represent the origin of the translocation by nonallelic homologous recombination on a single chromosome 17. B-CLL in patients with deletion of the *TP53* gene is associated with progressive disease, resistance to treatment, and shortened survival. Patients with 17p deletions or *TP53* mutations are frequently resistant to purine analogs.

Deletion 6q is a relatively rare chromosomal change occurring in approximately 6% of CLL cases and is associated with marked lymphocytosis, abnormal morphology, splenomegaly, overexpression of CD38, and unmutated *IGH* heavy chain variable region.

Chromosome 14q32 rearrangements/translocations involving *IGH* was considered a rare abnormality affecting fewer than 4% of CLL patients. With the emergence of novel molecular approaches a higher incidence of *IGH* rearrangements has been reported in recent years (5% to 15%). The genes most frequently rearranged with IGH are *BCL2*/t(14;18)(q32;q21)(~2% of cases) and *BCL3*/t(14;19)(q32q13) or *BCL11*/t(2;14)(p16;q32) (less than 1%). Because the leukemic phase of certain lymphomas can clinically mimic B-CLL, FISH for translocations using an *IGH* probe is important. Fewer than 7% of patients with CLL/prolymphocytic leukemia patients have t(11;14)(q13;q32), and these cases usually evolve into prolymphocytic leukemia. Moreover, *IGH* testing in CLL is important for detecting patients with recurrent del(14)(q24.1) associated with unmutated IgV_H status (66%) and trisomy 12 (47%). Other rare chromosomal aberrations in CLL include trisomy 3q27 (3%), trisomy 8q24 (5%), gains of 15q15-qter, trisomy 18, and trisomy 19. Other recurrent rearrangements involving loss of 8p21-pter and del(9)(q11) have been reported.

Based on the recent CGH results, CLL may be classified into three groups: those with poor outcome (20.6%) exhibit at least one aberration: gain of 2p, 3q, 8q, 17q, and loss of 7q, 8p, 11q, 17p, and 18p; good outcome (32.5%) includes 13q14 loss without any of the other 10 aberrations (gain: 1p, 7p, 12, 18p, 18q, 19, loss: 4p, 5p, 6q, 7p); and the third, intermediate outcome are all other abnormalities. The three groups are significantly separated with respect to time to first treatment and OS ($P < .001$). Gain of 3 and 8q and 17p loss are independent unfavorable prognostic biomarkers.

According to the recently updated *iw*CLL recommendations, genetic risk stratification in CLL requires not only FISH analysis but must be complemented by mutational screening for the *TP53* gene. FISH offers only a partial view (5 loci are tested) of the CLL-genetic landscape whereas classical cytogenetics present a global view of the single cell analysis. Therefore, *iw*CLL guidelines indicate that conventional cytogenetics should be performed and is "desirable" before treatment initiation as well as in the context of clinical trials. Cytogenetic complexity of CLL cells was brought to light when 5082 patients from 17 European institutions on the behalf of European Research Initiative were retrospectively evaluated. This large study defined complex karyotypes in CLL according to the presence of ≥3 numerical and/ or structural abnormalities which was considered to be an unfavorable risk factor.[18] Based on these findings CLL should be considered a heterogeneous group of B-cell malignancies with a clinical course, ranging from remarkably indolent to extremely aggressive. A high-complex karyotype, defined as the presence of at least 5 abnormalities, was associated with a dismal clinical outcome, independently of clinical stage and *TP53* status. In contrast, low-complex and intermediate-complex, defined according to the presence of 3 or 4 aberrations, respectively, appears to be clinically relevant only in the presence of *TP53* abnormalities. At the other end of the spectrum, patients with CLL with complex karyotype and +12, +19 displayed an indolent profile.[19]

Gene Mutations as Diagnostic and Prognostic Biomarkers

Approximately 60% to 65% of patients with CLL have somatic mutations in the *IGHV*. The remaining 35% to 40% lack *IGHV* mutations. *IGHV* gene mutations (M-CLL) are markers for a favorable prognosis, whereas an unmutated *IGHV* gene (U-CLL) in CLL is associated with clinically more aggressive disease. The OS rate for U-CLL is 8 to 9 years whereas that for M-CLL is more than 24 years. The frequency of other somatic mutations is shown in Table 57.16. The somatic mutational landscape of CLL includes more than 50 different genes and the most common mutations are the following genes: *SF3B1, DDX3X, BIRC3, ATM, NOTCH1, EGR2,TP53*, and *XPO1*. As mentioned above, mutations in *ATM* may occur in patients with and without a del(11q) in 10% and 25% of patients, respectively. Thus far the *ATM* mutation remains the most important marker of poor outcome in del(11q) CLL patients. CLL patients carrying *IGHV4-39*, *NOTCH1*, or *TP53* mutations and a complex karyotype are at higher risk of transformation. Patients with Richter syndrome (Chapter 76) (see later) frequently have additional *CDKN2A* deletions and *MYC* translocations or amplifications on top of genomic alterations already present in the original CLL. As mentioned earlier, in addition to del(17p) resulting in deletion of *TP53*, 17p may be targeted by acquired copy neutral loss of heterozygosity (cnLOH) which results from a somatic recombination event that duplicates a single mutated *TP53* allele. Sanger sequencing has identified *TP53* mutations without loss or cnLOH of the other *TP53* allele, and these patients exhibit poor survival. Most CLL patients with *TP53* mutations are refractory to chemotherapy. Most *TP53* somatic mutations are missense and located within the DNA binding domain of *TP53* encoded by exons 5 to 8, and six "hot spots" are mutated in approximately 20% of patients.

In the CLL-IPI scoring system, the presence of either a 17p deletion or a *TP53* mutation confers the same prognostic significance. These two genetic events are usually detected by different methodologies measuring two different abnormalities. Interphase FISH is used to detect deletion of 17p13.1 chromosomal segment on the short arms of chromosome 17, containing the *TP53* locus. The breakpoints, and therefore the size of deletion, may vary between patients. *TP53* mutation usually occurs on one chromosome 17 but only biallelic *TP53* mutations result in the loss of *TP53* function. In practice homozygous 17p13.1 deletion by FISH is very rare and monosomy of 17p or monosomy of entire chromosome 17 may represent an indirect measure of biallelic loss of *TP53* function. Approximately 80% of patients with del 17p also have mutations in the remaining TP53 allele which may explain the strong association between heterozygous 17p deletion with poor prognosis. Recently, mutations of *NOTCH1*, *BRAF*, *SF3B1*, *NFKBIE*, and *EGR2* have been detected in CD34+ cells and CD14+ (myeloid) progenitors in patients with CLL suggesting involvement of early hematopoietic cells in the origins of CLL. These observations may indicate that CLL might develop from preleukemic multipotent hematopoietic progenitors as a result of deregulation of B-cell receptor intracellular signaling and that CLL is preceded by a preleukemic phase.

Genome Complexity in Chronic Lymphocytic Leukemia

Array CGH and NGS studies have effectively clarified the level of genomic complexity in CLL and revealed that the average number of mutations in CLL cells at diagnosis lies between 10 and 20, which is one of the lowest among the adult cancers, confirming previous cytogenetic observations. The recent studies also revealed that no single unifying mutation is responsible for CLL. Array-based genomic profiling has extended previous cytogenetic data demonstrating that a subset of patients with CLL have complex genomic profiles pointing to the interplay between chromosomal abnormalities and somatic mutations that are associated with reduced OS. Moreover, telomere dysfunction in CLL and acute telomere attrition results in fusion events that contribute to genomic complexity such as *chromothripsis*, which is a high level of DNA damage that may occur during a single mitotic division Fig. 57.61. Chromothripsis has been shown to occur in approximately 5% of patients, primarily in patients with unmutated *IGHV* status (74%) and high-risk genomic aberrations (79%). The presence of chromothripsis and kataegis in CLL implies that multiple cancer genes can be disrupted in a single step, providing a "quantum leap" for the malignant potential of the initial CLL clone.

TABLE 57.16 Most Frequent Somatic Mutations in Chronic Lymphocytic Leukemia

Chromosomal Location	Gene	Pathway	Co-Segregation	Frequency
Alterations Associated With M-IGHV				
15q26	*CDH2*	Chromatin modification		5
3p22	*MYD88*	Inflammatory pathway	del(13q)	3–5
Alterations Associated With U-IGHV				
11q22.3	*ATM*	DNA damage response	del(11q)	9–14
11q22	*BIRC3*	Cell cycle control	del(11q)	1–5
7q31.33	*POT1*	Cell cycle control	*SF3B1*	5
17p13.1	*TP53*	Cell cycle control	del(17p)	5–27
2q33.1	*SF3B1*	mRNA processing	del(11q)	10–19

M-IGHV, Mutated immunoglobulin heavy chain variable; *U-IGHV*, unmutated *IGHV* gene.

Richter Syndrome

Approximately 15% of patients with CLL transform eventually to Richter syndrome (RS), a highly aggressive phase of CLL, which morphologically mimics diffuse large B-cell lymphoma (DLBCL) and frequently has a dismal outcome (Chapter 84). RS is characterized by a complex karyotype, *TP53* defects (50% to 60%), *NOTCH1* activation (30%), and *MYC* abnormalities (30%). The majority of RS cases are derived from the original CLL clone with an average of 20 acquired molecular lesions during the evolution to RS (Fig. 57.62). There appears to be considerable heterogeneity regarding the number and type of genomic abnormalities.

Several clinical and biologic risk factors may predict future RS development. Patients with CLL with an unmutated *IGHV* are four times more likely to develop RS as compared to those with mutated *IGHV*. High ZAP70 expression and CD49d have also been associated with an increased risk of RS in some studies.

Recently, two genetic pathways that lead to transformation of RS from CLL have been delineated. Approximately 50% of patients with RS have cell-cycle deregulation via inactivation of *TP53*, loss of *CDKN2A* (9p21.3), gains or translocations of *MYC*, and loss of 13q14.3 region. These patients had a high cell proliferation rate (Ki-67 >70%) and a worse OS than patients with wild-type *TP53* and *CDKN2A*. The loss of *CDKN2A* function appears to be acquired at the time of transformation, as evidenced by its presence in the RS but not CLL cells. The second group of patients with RS (30%) is characterized almost exclusively by trisomy 12 and *NOTCH1* mutations. The remaining 20% represent a heterogeneous group, and do not exhibit either *TP53/CDKN2A* inactivation or trisomy 12 and individual cases are characterized by del(11q), del(14q), *MYC* activation, *IGH* translocations, and *NOTCH1* mutations. Using paired-sample analysis CLL-specific lesions are almost always present in the RS cells along with RS-specific abnormalities. These observations imply that RS develops through a linear model of clonal evolution from the underlying CLL. Genome-wide DNA analysis confirmed that RS DNA profile remains clearly distinct from that of primary DLBCL.

Newly diagnosed RS is an oncologic emergency requiring assessment of a karyotype and at least FISH detection of *TP53, MYC*, and *NOTCH1* mutations.

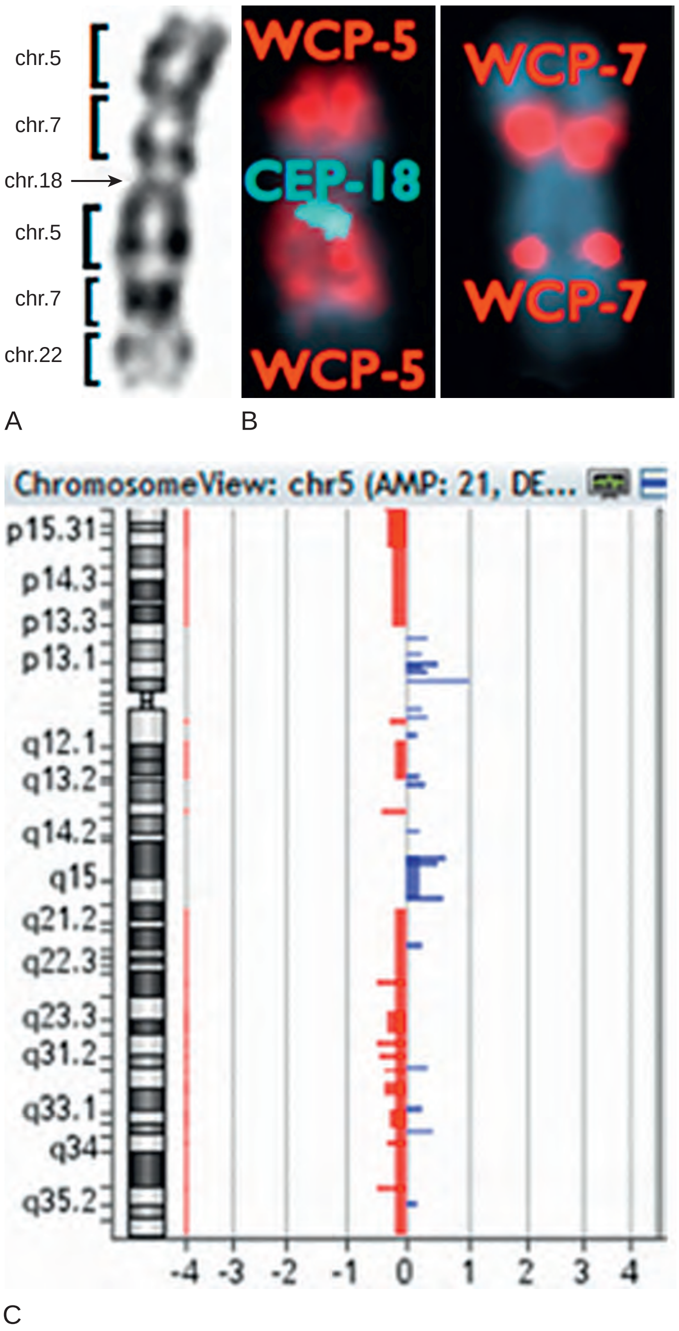

Figure 57.61 CHROMOTHRIPSIS. (A) Conventional G-banded cytogenetic analysis showed a derivative chromosome 18 composed of additional chromosomal segments. (B) Various FISH probes confirmed that the derivative chromosome 18 is composed of segments of chromosome 5, 7, 18, and 22, whereby the fragments of multiple chromosomes are stitched together by paired end joining. (C) Array comparative genomic hybridization (aCGH) of chromosome 5 shows segments within both the p arm and q arm with gains *(blue bars)* and loss *(red bars)* of genomic DNA illustrating that there are frequent copy number changes in a localized region of a chromosome as a result of chromothripsis.

MULTIPLE MYELOMA

MM is a malignancy of terminally differentiated B cells (see Chapters 90 and 91). MM plasma cells, CD138-positive cells, have a very low proliferation rate, which has limited cytogenetic studies. Historically, conventional karyotyping reveals chromosomal abnormalities in 30 to 40% of newly diagnosed patients, especially in cases with an exceptionally high plasma cell proliferative rate. Karyotypes obtained from these cells usually are complex and exhibit more than 20 aberrations in approximately 10% of cases. Currently, many laboratories have adopted a long-term culture, 72 to 120 hours, using a variety of cytokines or growth factors including L2, IL4, DSP30, and others. Despite a low number of chromosomally abnormal cases, cytogenetics is still the only clinically available test that can clearly delineate independent clones and definitively ascertain clonal evolution. Its use has been recommended according to the NCCN 2018 guidelines.

To obtain accurate FISH results with MM cells plasma cells (CD138+) enrichment prior to using FISH for detection of genomic abnormalities is recommended. Magnetic microbeads conjugated with anti-138 antibodies is a quick and rapid way to increase sensitivity of FISH as well as NGS and array CGH-SNP because enrichment of CD138+ cells greatly diminishes the number of non-plasma cells and therefore provides increased test accuracy.

When reassessed by FISH, CGH, and multicolor karyotyping using a large panel of centromere-specific and translocation-specific probes, interphase plasma cell nuclei in MM and other clonal plasma cells including monoclonal gammopathy of unknown significance (MGUS), smoldering myeloma (Chapter 90), and monoclonal immunoglobulin deposition disease (amyloidosis) (Chapter 93) have been shown to be characterized by chromosomal aneuploidy. Array CGH indicates that 100% of patients with newly diagnosed MM have copy number alterations and frequent homozygous deletions of genes including *TRAF3*, *BIRC1/BIRC2*, *RB1*, and *CDKN2C*. Even after achieving CR, after therapy, 12% to 71% of plasma cells may still have a numerical gain or loss of chromosomes 3, 7, 8, 9, 11, 13, 15, 21, and X.

Genomic abnormalities in MM are complex and heterogenous both at diagnosis and even more so with disease progression with several subclones evolving within the same individual. There is no identifiable single genomic abnormality that is MM-specific or that can distinguish MM from other clonal plasma cell entities.

Current recommendation requires that plasma cells are enriched and FISH analysis performed on CD138-positive cells. Table 57.17 lists the most frequent chromosomal rearrangements that occur in patients with MM. Analysis of numerical abnormalities reveals two groups of MM patients: those who are hyperdiploid and those who are not hyperdiploid (hypodiploid, pseudodiploid, or near-tetraploid) and contain immunoglobulin heavy-chain locus (*IGH*) 14q32, translocations (see box on Genetic Testing for Multiple Myeloma.)

GENETIC TESTING FOR MULTIPLE MYELOMA

In practice at the time of this writing (2021) it is recommended that genomic testing be performed on enriched plasma cells (CD138-positive) for FISH and array CGH analysis or NGS. FISH testing of CD138+ purified plasma cells should include, at minimum, t(4;14)(p16;q32), t(14;16)(q32;q23), t(14;20)(q32;q11), gain of 1q, and loss of 17p. In our laboratory we also include testing for the t(11;14) and an IGH breakapart probe because if the t(11;14) as well as other IGH lesions mentioned earlier are not detected, IGH translocations without known partners are associated with adverse prognosis. Testing for gains of 1q 12-q44 is an independent marker associated with disease progression and deletion of TP53 defines a group of patients with ultra-high-risk MM (see Figs. 57.65 and 57.66). If IGH rearrangements are detected using a breakapart IGH locus and CCND-IGH fusion is not identified, refine the translocation partner and use the following set of probes: MAF-IGH for detection of t(14;16) and FGFR3-IGH for detection of t(4;14). Cytogenetics is very useful in determining primary vs secondary chromosomal abnormalities and the clonal evolution.

Hyperdiploid Multiple Myeloma

Approximately 55% to 60% of patients with newly diagnosed MM are characterized by a hyperdiploid karyotype with the number of chromosomes ranging from 48 to 74 and trisomies of odd-numbered

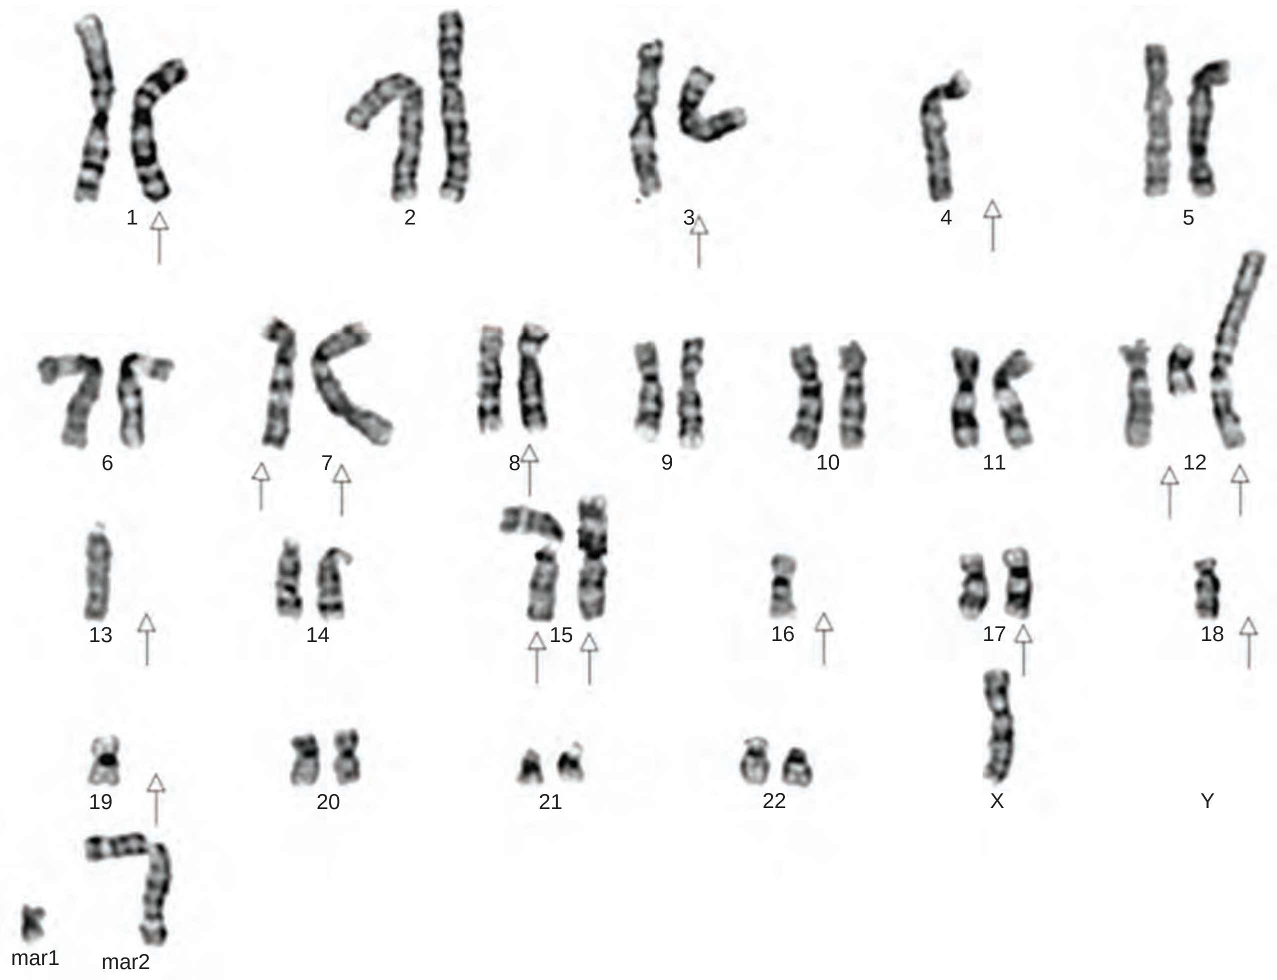

Figure 57.62 COMPLEX KARYOTYPE IN RICHTER SYNDROME. This karyotype is from a patient who progressed from CLL to Richter syndrome. Ninety percent of cells showed a complex modal karyotype 42~46,X,-Y,t(1;7)(p22;q22),del(3)(p21p25),-4,add(7) (q35),+8,der(8)t(8;17)(p11.2;q21.3) x2,+12,der(12)add(12)(p12)add(12)(q12),der(12)t(4;12)(q13;p13),-13,add(15)(p11.2),der(15)t(15;17)(p11.2;q21.3),-16,add(17)(p11.2),-18,-19,-21,add(22)(p11.2),add(22)(p11.2),+mar1,+mar2,+mar3. Abnormalities of 14 chromosomes were identified and the origin of two markers could not be deciphered using conventional cytogenetics. Array CGH+SNP detected additional 31 copy number alterations, including 20 losses and 13 gains. There were 3 to 4 CNAs per 14 abnormal chromosomes including a loss of *TP53* which may explain genomic imbalance of the patient. *CGH*, Comparative genomic hybridization; *SNP*, single-nucleotide polymorphism.

chromosomes including 3, 5, 7, 9, 11, 15, 19, and 21 and few *IGH* translocations (Figs. 57.63 and 57.64). Among these gains, chromosomes 9, 15, 19, and 21 are usually acquired first, and may be followed by trisomy of chromosomes 3, 5, and 7. These chromosomal abnormalities are considered primary genomic changes in the early pre-malignant stage and theoretically involved in disease pathogenesis. Therefore, the prognostic relevance of numerical abnormalities using classic cytogenetics is unknown, although the presence of abnormal metaphases cells is an indicator of poor prognosis. However, hyperdiploid MM detected by FISH tend to have a better prognosis than do those with nonhyperdiploid disease. This effect is lost in cases where hyperdiploidy is associated with other genetic markers of progression such as gain of 1q21 and deletion of 17p13. Many studies have shown a median OS of 60.8 months for hyperdiploid patients with MM with no adverse cytogenetic lesions as compared to 33.7 months for those hyperdiploid patients with MM who had one or more of the adverse cytogenetic abnormalities such as t(4;14), t(14;16), t(14;20), del(17p), and +1q (see Figs. 57.65 and 57.66). The exact origins of hyperdiploidy remain unknown, although four processes are proposed: (1) a near-haploid cell doubles all chromosomes; (2) a tetraploid cell experiences subsequent loss of chromosomes; (3) a diploid cell undergoes sequential gains of chromosomes during clonal evolution; and (4) a diploid cell suffers a single mitotic catastrophe resulting in simultaneous gain of additional chromosomes. The data suggest that a single mitotic catastrophe, such as failed mitotic event, may be the most likely mechanism of acquisition of hyperdiploidy, which may be followed by the secondary gain of extra chromosomes during subclonal evolution. In some patients hyperdiploidy may precede primary translocations affecting *IGH* as revealed by studies using single cell sequencing analysis. In general, hyperdiploidy is associated with more favorable survival than hypodiploidy; however, adverse cytogenetic features, such as +1q, del(17p), and t(4;14) predict worse survival than hyperdiploidy alone.

Nonhyperdiploid Multiple Myeloma

Approximately 45% to 50% of patients with MM have nonhyperdiploid MMs that include patients with hypodiploid, near diploid, pseudodiploid, or near-tetraploid chromosome numbers (fewer than 48 or more than 74 chromosomes), which are characterized by a high frequency of *IGH* translocations (>85%). With the exception of t(11;14)(q13;q32), most of the nonhyperdiploid patients have an aggressive disease course characterized by a short time to relapse and limited survival. Table 57.18 outlines a risk stratification system of

TABLE 57.17 Most Frequent Chromosomal Abnormalities in Multiple Myeloma and Their Frequencies

Genetic Lesion	Frequency (%)	Oncogenes/Fusion Genes
Hyperdiploid	~50	Gain of odd-number chromosomes
Nonhyperdiploid		IGH translocations
Translocations		
t(4;14)(p16.3;q32.3)	15	*FGFR3, MMSET-IGH*
t(11;14)(q13;q32.3)	15–20	*CCND1-IGH*

Modified from Anderson KC, Carrasco RD. Pathogenesis of myeloma. *Ann Rev Pathol.* 2011;6:249.

patients with MM based upon chromosomal abnormalities. These patients are at risk of acquiring genetic events such as deletion of chromosomes 13 and 14, chromosome 17 abnormalities, as well as 1q amplification and 1p deletion.

Both hyperdiploidy and nonhyperdiploidy are also present in patients with MGUS, suggesting that such abnormalities occur early in the course of disease. More detailed analyses using genome-wide CNAs have revealed numerical aberrations in 98% of MM cases and identified amplification of 1q and deletions of 1p, 12p, 14q, 16q, and 20p to be associated with a poor prognosis, whereas gains of chromosomes 5, 9, 11, 15, and 19 are associated with a more favorable outcome.

Hypodiploid karyotype (<44 chromosomes) in MM accounts for one-fifth of all patients with MM and represents an aggressive subtype. In these patients, abnormalities such as monosomy of chromosomes 13, 14, and 22 as well as deletions for 1p, 12p, 16q, and 17p are common. These genotypes are associated with a poor outcome and disease progression. Hypodiploid chromosomal status is an independent risk factor for a poor survival.

Translocations in Multiple Myeloma

Primary translocations appear to occur early during the course of MM, whereas secondary translocations occur later on and are involved in tumor progression. Most primary translocations are simple balanced translocations that juxtapose an oncogene and one of the Ig enhancers. An *IGH* rearrangement on 14q32.3 is found in most patients with MM. This rearrangement consists of complex and heterogeneous translocations with the breakpoint involving either the switch region of IGH or the *V, D*, or *J* gene. The primary translocations are caused by somatic hypermutation or errors in the V(D)J portion of the switch recombination region. The translocations include a promiscuous array of at least 20 nonrandom chromosomal partners.14q32 rearrangements are altered in 45% to 50% of MM patients. The characterization of these translocations has led to the identification of critical dysregulated oncogenes (e.g., *BCL2, cyclin D*). In each translocation, a potent enhancer is juxtaposed to dysregulated oncogenes. The five most frequent *IGH* translocations are t(4;14)(p16.3;q32.3), t(6;14)(p21;q32.3), t(11;14)(q13;q32.3), t(14;16)(q32.3;q23), and t(14;20)(q32.3;q12) (see Table 57.17).

A recurrent *CCND1-IGH* rearrangement is characterized by overexpression of cyclin D1. In contrast to mantle cell lymphoma (MCL), breakpoints on 11q13 with MM are not clustered but are scattered over a relatively large genomic region. Virtually all MM and MGUS cells have cyclin D dysregulation, suggesting that this abnormality is an early and unifying pathogenetic event. In contrast to other abnormalities involving the *IGH* locus, t(11;14) MM cells tend to be diploid. There appears to be an association of t(11;14) with an oligosecretory or light chain form of MM with CD20 expression, and a lymphoplasmacytic cell morphology. This chromosomal rearrangement is the most common genetic lesion in MM (15% to 20%) but it has also been observed in MGUS, primary plasma cell leukemia, and light chain amyloidosis. Two groups of patients with t(11;14) are recognized: one with a rather indolent course and the other associated with a more aggressive course.

Approximately 15% of patients have a recurrent t(4;14)(p16.3;q32.3) abnormality associated with aggressive disease. This cytogenetic abnormality is associated with IgAλ form of MM with immature cell morphology, and a poor response to therapy. This abnormality is cytogenetically cryptic and is detected by FISH. Two genes on chromosome 4p16.3 and the *IGH* switch region on 14q32.3 are involved. The fibroblast growth factor receptor 3 gene (*FGFR3*) is detected on der(14), where it is overexpressed along with a fusion of the MM set domain *NSD2* (*MMSET*) gene, which is located on 4p16.3. This is the first example of a translocation that simultaneously deregulates two genes with oncogenic potential: the *FGFR3* gene detected on der(14) and the NSD2 gene detected on der(4). *FGFR3* is 50 to 100 kb telomeric to NSD2. Loss of *FGFR3* on der(4) is detected in approximately 20% of cases. A significant number of these patients have del(1p32) and del(13q) within the same clone and are hypodiploid.

Translocation (14;16)(q32.3;q23) can only be detected with FISH studies. The incidence of t(14;16) has been estimated to be approximately 5% of cases. This translocation results in the relocation of the *MAF* proto-oncogene from its position on 16q23 to chromosome 14, band q32.3, and it is overexpressed. Survival of patients with t(14;16) is significantly shorter as compared with patients without t(14;16).

t(6;14)(p21;q32) is a rare translocation and present in approximately 1% to 2% of patients with MM. This rearrangement results in juxtaposition of *CCND3* to the *IGH* enhancer and causes direct upregulation of *CCND3* expression. The breakpoints are all located in the 3′ end of *CCND3*. The prognostic implication is neutral. Of the five recurrent translocations in MM the rarest translocation is t(14;20)(q32.3;q12)/*IGH-MAFB*, present in approximately 1%, and also results in the upregulation of *MAFB* gene. *MAFB* is also mutated in about 25% of patients harboring t(14;20). These MM patients have a poor prognosis, however, when t(14;20)(q32.3;q12)/*IGH-MAFB* is detected in the MGUS or in smoldering MM stage of disease, it is associated with long-term stable disease.

A large number of *secondary chromosomal aberrations* are found during disease progression. Disease progression is accompanied by four main abnormalities including translocations of *MYC*, the loss or deletion of chromosome 13, deletions of short arms and amplification of long arms of chromosome 1, as well as the deletion of short arms of

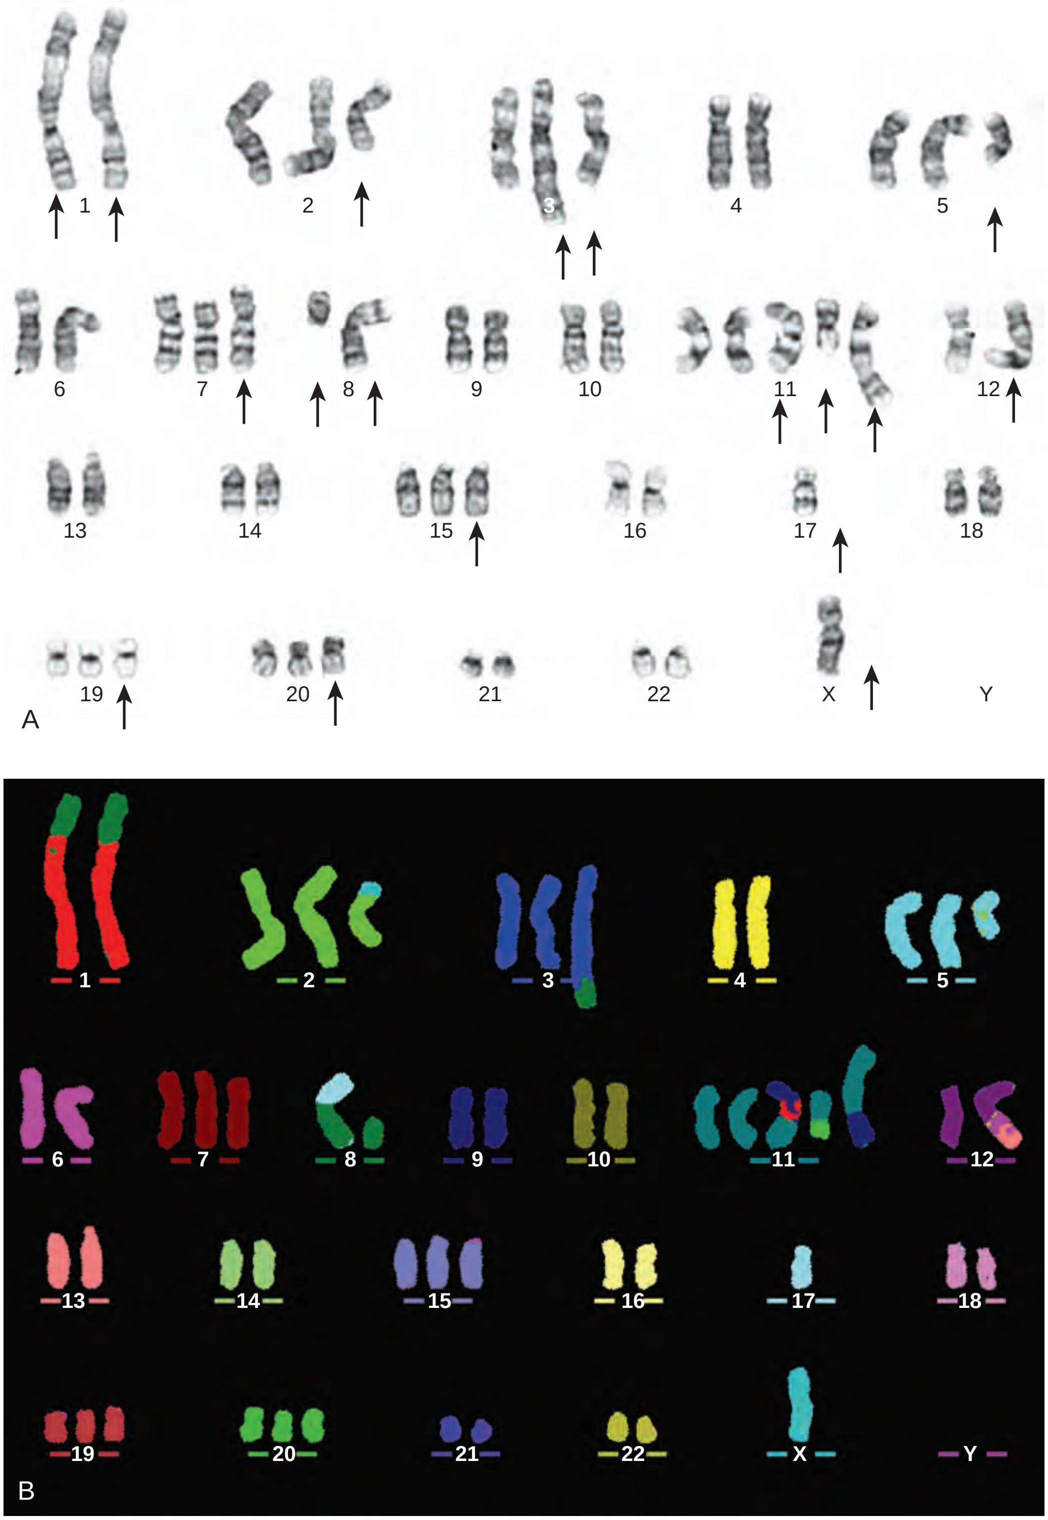

Figure 57.63 A complex hyperdiploid karyotype from a patient with multiple myeloma (A) and after multicolor FISH (B), which was used to resolve a number of complex derivative chromosomes: 54, X,−X, der(1)t(1;8)(q34;q21q24)x2, der(2) del(2)(p13p25)t(X;2)(p21p22.3;p13), t(3;8)(q27;q22q24), +i(5)(p13p15), +7, der(8;17)(p23;q11.2q25), +der(11)t(1;9;11(?p36;q21q31;p15), t(11;20)(q13;q11.2, der(11)t(9;11)(q13q34;q25), t(12;13)9(p13;q14q34), +15, +19, +20.

chromosome 17. Translocations and/or amplification of *MYC* (8q24) may involve up to 45% of patients with an advanced MM, and then cytogenetic studies frequently involve very complex nonreciprocal rearrangements, duplications, and amplifications. More recent data based on SNP-array technologies has revealed homozygous deletions such as *BIRC2/3* on chromosome 11, deletions of *TRAF3* on chromosome 14, and deletions of *CYLD* on chromosome 16. Another recurrent double deletion that has been observed in a limited number of the patients occurs on chromosome 1, targeting the tumor suppressor *CDKN2C* gene at 1q21 chromosomal site.

Deletion of chromosome 13 is detected in 10% to 20% of patients using conventional cytogenetics and in 50% using interphase FISH. The minimally deleted region on chromosome 13, between bands q14.11 to q14.3 contains over 68 genes including *RB1*, DNA marker

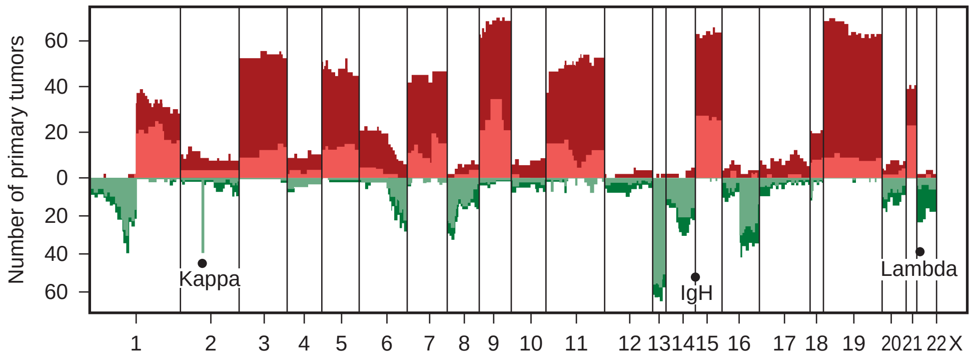

Figure 57.64 CYTOGENOMIC PROFILES IN MULTIPLE MYELOMA. Summary of genomic profiles and recurrence of chromosomal alterations in primary tumors demonstrated by array comparative genomic hybridization. The recurrence plot mirrors the frequencies of previously reported chromosomal gains and losses, including the deletions of 1p and amplifications of 1q. Integer-value recurrence of copy number aberrations across the samples in segmented data is plotted on the y-axis. The x-axis is in chromosomal order. *Dark red* or *green* bands denote the number of samples with gain or loss of chromosome material, and *bright red* or *green* bars represent the number of samples showing amplification or deletion. *Black dots* show focal deletions of the kappa (2p12), IgH (14q32), and lambda (22q11) loci physiologic in B-cell postgerminal center neoplasms. *(Reprinted with permission from Carasco DR, Tonon G, Huang Y, et al. High-resolution genomic profiles define distinct clinico-pathogenetic subgroups of multiple myeloma patients. Cancer Cell. 2006;4:313.)*

D13S319, and micro RNAs *mir16. -1* and *mir15*). Loss of the entire chromosome 13 (82%) is more frequent than is deletion of the long arms of chromosome 13. The median percentage of plasma cells carrying del(13q), as identified by FISH, ranges from 75% to 90%. Deletion of 13q is associated with specific clinical-pathologic features, including a higher frequency of λ-type MM, high plasma cell-labeling index, female predominance, and inferior survival after standard chemotherapy. t del(13q), however, no longer has adverse prognostic significance in patients treated with bortezomib. Molecular cytogenetics analyses have revealed that del(13q) is present in 90% of patients with t(4;14) or t(14;16); therefore the apparent adverse impact of del(13q) may be related to translocation events.

Deletion of *TP53* at 17p13.1, which occurs in 15% of patients with MM, is a powerful independent predictor of shortened survival and is associated with clonal evolution, drug resistance, and genetic instability This deletion is not found in patients with other high-risk abnormalities such as t(4;14) or t(14;16), and it appears to be mutually exclusive. Patients with *TP53* gene deletion have a significantly shorter OS regardless of therapy. The 17p deletion, identified by FISH, is considered the most important molecular cytogenetic factor when determining prognosis. In newly diagnosed MM patients del(17p) is observed in 8% of patients. Biallelic alteration of *TP53* (deletion and mutation, a.k.a. "double hit") is present in 3.7% of newly diagnosed MM and is associated with very poor outcome. Biallelic inactivation of *TP53* has been reported to occur more frequently at relapse, having been reported at 21% to 26% of patients. Another study provides the most compelling evidence that del(17p) is an important prognostic factor even in the absence of *TP53* mutation and should remain a high-risk feature in MM patients.

The gain of 1q21 locus has been identified in 45% of cases of MGUS, about a third of newly diagnosed MM, and 72% of relapsed MM, and represents one of the most frequent recurrent chromosomal abnormalities in MM (see Fig. 57.65). Chromosome 1 abnormalities include both short and long arms of chromosome 1, gains, deletions or jumping translocations. Gain of 1q is observed cytogenetically as an isochromosome, duplications, or jumping translocations and is detected with a 1q21-specific FISH probe. Among 479 patients with newly diagnosed MM, 43% with amp lq21 with either a hypodiploid and hyperdiploid karyotype and del(13q) was associated with poor prognosis as compared with patients lacking amp1q21 (see Fig. 57.65). In a study of 92 patients treated with lenalidomide and dexamethasone, del(17p) and gain of 1q21 was associated with a dismal OS. In the recent retrospective study of 3578 patients with MM 24% had documented chromosome 1 abnormalities or high-risk chromosomal abnormalities within 90 days of diagnosis. Median OS was lower for patients with chromosome 1 abnormalities and these abnormalities were independently associated with an inferior OS, and were older and had high-risk cytogenetic abnormalities despite the use of state-of-the-art therapies. Similar observations were obtained when 1376 patients were examined at diagnosis for the presence of gains of 1q only; FISH analysis confirmed that 28% of patients with +1q, along with other high-risk chromosome abnormalities as well as chromosome 13 abnormalities had decreased OS.[20]

In the most comprehensive expression profiling survey of patients with MM, reported by the Arkansas Multiple Myeloma Group using GEP70 (gene expression profiling of 70 genes), 30% of these genes were located on chromosome 1, with most of the downregulated genes located on the short arms of chromosome 1 and most of the upregulated genes on 1q. The mechanism for the amplification of 1q is believed to involve 1q12 pericentromeric instability, which most commonly increases the copy number of 1q by a direct and/or inverted duplication. Further instability can result in adding a whole-arm segment of 1q to nonhomologous chromosomes by jumping translocations of 1q. The 1q12–q23 amplicon has been reported to contain the 1q12 pericentromeric heterochromatin and the adjacent bands of 1q, resulting in an inverted repeat pattern of amplification of the 1q12–q23 region. Copies of the 1q12–q23 amplicon can become integrated into complex multichromosome translocations during tumor progression. In vitro studies have shown that treatment with hypomethylating agents apparently amplify any 1q region juxtaposed to 1q12 chromosome band producing copy number aberrations in the bone marrow of these patients. Frequent additional deletions detected by conventional cytogenetics include regions within 6q, 8p, 12p, 14q, 16q, or 20p.

The median number of mutations per MM genome is about 55 to 60, with a very large range (21 to 488). Moreover, in contrast to leukemia, "good-risk" cytogenomic abnormalities have not been described. The current data indicate that genetic abnormalities have a major role in determining a patient's prognosis. The current thinking is that development of subclones is a very early event in MM, probably occurring soon after the cell undergoes transformation.

Frequent mutations in MM include *KRAS* (particularly in previously treated patients), *NRAS*, *BRAF*, *FAM46C* (hyperdiploid subgroup), *TP53*, and *DIS3* (in nonhyperdiploid MM with *IGH* rearrangement, *TRAF3*, *CYLD*, *RB1*, and *PRDM1*. Subclonal *KRAS*, *NRAS*, and *BRAF* mutations are observed in about one-third of patients with MM. The most recent exome sequencing study identified germline variant in *DIS3* gene in 4 unrelated families with familial MM. The *DIS3* gene, located on chromosome 13, band q22.1, and as mentioned above, chromosome 13 is recurrently deleted and somatically mutated in MM. This is the first description of germline variant with potential involvement in MM etiology and extend

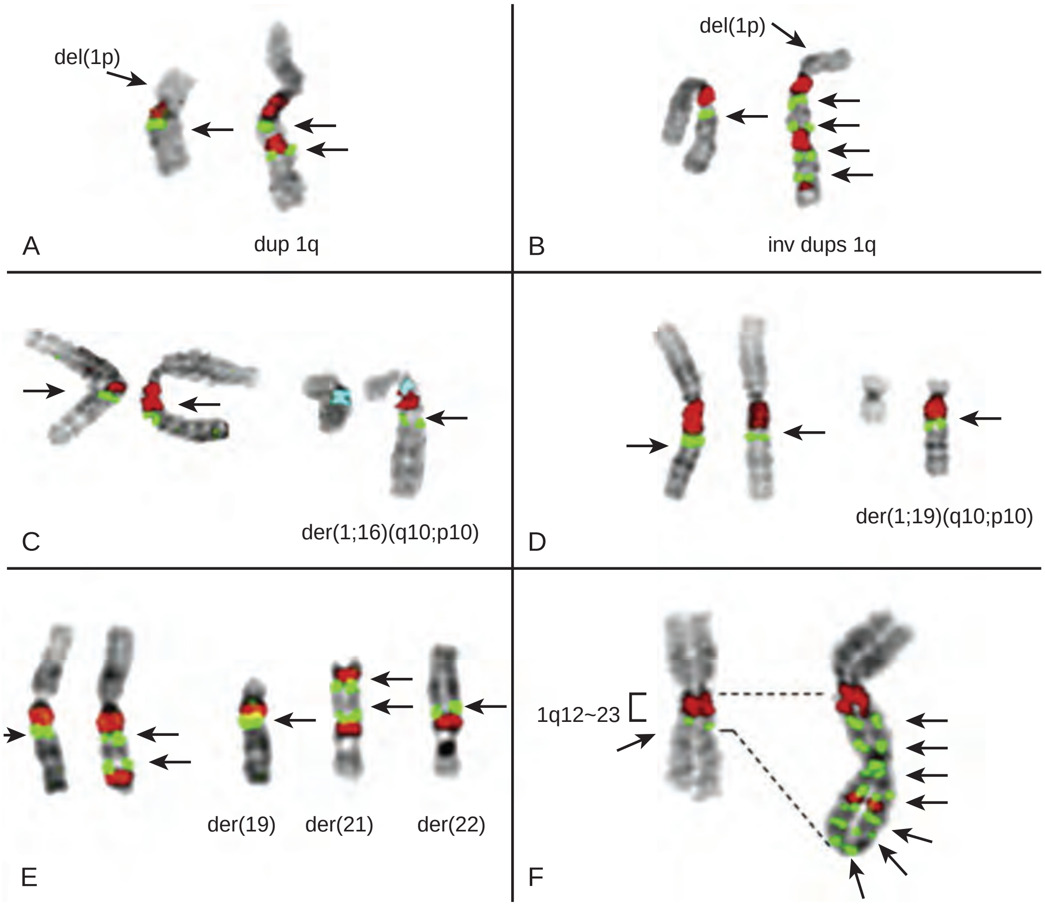

Figure 57.65 REPRESENTATIVE PARTIAL KARYOTYPES OF METAPHASE CHROMOSOMES DEMONSTRATING THE DIFFERENT TYPES AND DEGREE OF AMPLIFICATION OF CHROMOSOME 1. FISH probes for 1q12 *(red)*, 1q21 *(green)*, and 16q11 *(aqua)* are shown on inverted DAPI images of chromosomes. (A) Interstitial deletion of 1p *(arrow)* in the homolog on the left and a direct dup1q12–q23 on chromosome on the right. (B) Normal homolog 1 on the left and the abnormal homolog on the right, demonstrating both an interstitial deletion of 1p and the amplification of 1q in the same chromosome. Note four copies of 1q21 *(arrows)* in an inverted duplication pattern. (C) Examples of an unbalanced whole-arm translocation of 1q to chromosome 16q. Chromosomes 1 are on the left, and chromosomes 16 are on the right. Aqua probe denotes 16q11 heterochromatin. Note the loss of 16q distal to the aqua probe on the der(1;16)(q10;p10). The entire long arm 1q is translocated to the pericentromeric region of 16q, and a total of three copies of 1q21 *(arrows)* are present. (D) Examples of an unbalanced whole-arm translocation of 1q to 19q. Note that the result of this translocation is the der(1;19)(q10;p10) chromosome, which shows an extra copy of 1q21 *(arrows)* and loss of the entire 19q. (E) Examples of jumping 1q, in which all or a part of 1q is translocated to three copies of 1q *(arrows)* on the three different nonhomologous chromosomes. The whole-arm der(19)(q10;p10) in this case is the same type seen in patient in (D). The der(21) results from the segmental translocation of the inverted dup of 1q to the short arm of 21. The der(22) results from the whole-arm 1q translocated to the short arm of 22. (F) Homologous of chromosome 1 demonstrating amplification of 1q12–q23 by breakage-fusion-bridge cycles. Note multiple copies of 1q21 *(arrows)* on the abnormal homologue on the right. The copies of the 1q12–q23 amplicon occur in an inverted repeated pattern, with a deletion of the 1q distal to the amplified region. Dotted lines between normal homologue 1 *(left)* and abnormal homologue denote the size of expansion of the 1q12–q23 region by break-fusion-bridge cycles. *FISH*, fluorescence in situ hybridization. *(Reprinted from Sawyer JR. The prognostic significance of cytogenetics and molecular profiling in multiple myeloma. Cancer Genet. 2011;204:3, with permission.)*

beyond somatic alterations to germline susceptibility. The frequency reported is about 2.6% among four families with multiple cases of MM and MGUS.

Finally it's important to mention that until recently, classification of MM patients and risk stratification has relied on either biochemical parameters, cytogenetic markers, or gene expression analysis. Novel MM-PSN, the first Patient Similarity Network (PSN) of newly diagnosed patients has enabled the identification of 3 broad patient groups and 12 distinct sub-groups defined by 5 data types generated from genomic and transcriptomic patient profiling of 655 patients.[21] PSNs have been proposed as a potential powerful integrative approach to combine different omics data, to create a comprehensive view of a given disease and identify disease subtypes. The MM-PSN classification uncovered novel associations between distinct MM hallmarks with significant prognostic implications and allowed further refinement of risk stratification. Most important, MM-PSN confirmed that gain of 1q is the most important single lesion conferring high risk of relapse, and its association with an MMSET translocation as the most significant determinant of poor outcome. These findings suggest, as previously demonstrated in many studies, that gain of 1q should be incorporated in routine staging systems and risk assessment tools.

Combining novel single cell methodologies, such as sc RNA seq and sci CNV, a tool for inferring CNV from sc RNAseq allows dual profiling of DNA and RNA in a single cell. When MM cells with +1q were evaluated, using this dual profiling, it was recently uncovered that +1q cells in MM cause multiple effects on MM cells including a reduction in the unfolded protein response, enhanced oncogenic growth, oxidative phosphorylation, and *MCL* gene increased expression (anti-apoptotic gene located at 1q21.2). In contrast, there was no increase in *CKS1B* gene expression (located at 1q21.3) indicating that an alternative mechanism likely drives cell cycling in MM cells with a gain of 1q. Another gene, inflammation-responsive RNA editase gene adenosine deaminase acting on RNA1(*ADAR1*), also located at 1q21, has been recently implicated in the possible mechanism underlying 1q21 formation. ADAR1 is an RNA-editing enzyme

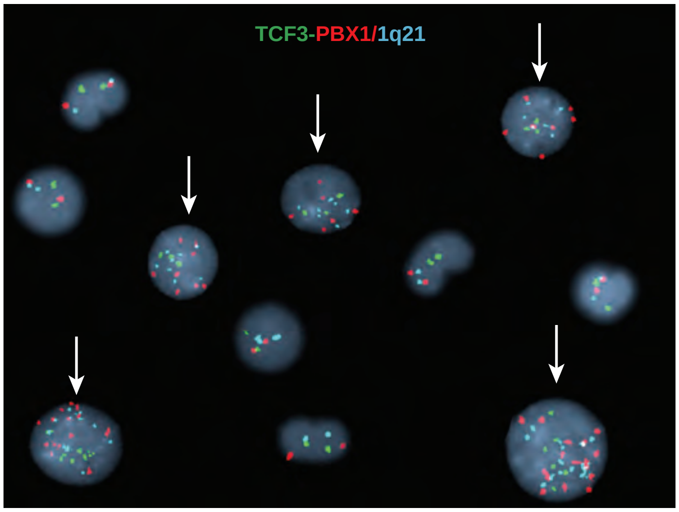

Figure 57.66 Bone marrow nuclei from a patient with multiple myeloma after hybridization using three probes: 1q21 *(aqua)*, PBX1 *(red)* localized on 1q25, and TCF3 *(green)* localized on 19q13. Note amplification (up to 17 copies) of 1q21 an2 1q25 *(white arrows)*, as well as multiple copies of 19q loci. Amplification of 1q21–q25 is associated with disease progression and very poor prognosis in multiple myeloma despite novel therapies.

that edits adenosine-to-inosine (A-to-I) nucleotides within double stranded RNA loops formed by primate-specific *Alu* repeats. ADAR1 has emerged as a vital contributor to transcriptomic diversity and is abundantly expressed in MM suggesting that MM cells with +1q transcriptome are in hyperediting state. In vitro and other functional studies suggests that *ADAR1* can enhance the growth and proliferation of MM cells in an editing-dependent manner and sometimes independently of 1q amplification status implying that a disturbed transcriptome mediated by *ADAR1* overexpression is both clinically and functionally crucial in myeloma. The interplay between the gain of 1q, IL6R (localized also on 1q21.3), and *ADAR1* provides yet another possible mechanism for the adverse outcome of patients with MM and 1q abnormalities.

LYMPHOMA

Non-Hodgkin lymphoma (NHL) is a heterogeneous group of disorders characterized by a localized proliferation of lymphocytes (see Chapters 78, 79, and 81). Analogous to other hematopoietic neoplasms, the pathogenesis of NHL is attributable to a multistep process involving progressive and clonal accumulation of genetic lesions (Chapter 81). The majority of NHLs are of B-cell origin and involve translocations of Ig loci (Table 57.19 and Fig. 57.67). *IGH* translocations usually are detected by cytogenetics, often in conjunction with FISH probes that span the *IGH* loci and/or PCR-based technologies. These molecular abnormalities exhibit multiple and complex translocations, deletions, and amplifications within one clone. Genetic anomalies represent one of the most reliable criteria for classification of malignant lymphomas. The most common associations between chromosome anomalies and specific lymphomas include t(14;18)(q32;q21) and FL (Chapter 82); t(8;14)(q24;q32) and BL (Chapter 85); t(11;14)(q13;q32) and MCL; and t(11;18)(q21;q21) and mucosa-associated lymphoid tissue (MALT) lymphoma (Chapter 83) (see box on Genetic Testing for Non-Hodgkin Lymphoma and Fig. 57.66). However, identification of a specific translocation is not diagnostic of a specific lymphoma subtype. Chromosomal studies are difficult and expensive for the study of lymphomas. Thus many investigators use FISH and/or molecular genetic methods to study touch-cell preparations or paraffin-embedded biopsy material to detect genetic anomalies.

GENETIC TESTING FOR NON-HODGKIN LYMPHOMA

FISH testing can be performed on touch preps from surgically excised nodes, paraffin-embedded tissue, or bone marrow cells if involved by the disease. Peripheral blood cells are not appropriate for genetic testing of NHL. Bone marrow cytogenetics at diagnosis is not mandatory but is important for staging in some cases. Fig. 57.67 lists the most useful FISH probes for detection of genomic defects in NHL. They include CCND1-IGH, IGH-BCL2, MYC-IGH, BCL6, MYC for detection of Burkitt variant not associated with t(8;14), and MALT1 for detection of t(11;18). For patients with suspected anaplastic large cell lymphoma, ALK probe should be informative.

Approximately 85% to 90% of patients with FL and some patients with DLBCL exhibit t(14;18)(q32.3;q21.3), resulting in fusion of *BCL2* on 18q21 and *IGH* on 14q32. This translocation is one of the most common chromosomal abnormalities in NHL (see Fig. 57.67D). This somatic rearrangement places *BCL2* gene under the influence of transcriptional enhancers associated with *IGH*, resulting in overexpression of the antiapoptotic BCL2 protein. Translocation 14;18 appears to originate from an erroneous *IGH* rearrangement, during B lymphopoiesis in the bone marrow (pre-B cells) and therefore represents a very early genomic event. About 75% of the *BCL2* breakpoints occur within a remarkably narrow region of 15 to 20 bp at the 3′ end of the *BCL2* gene, whereas the breakpoints in *IGH* fall within D_H and J_H regions. With routine FISH methods using *BCL2* breakpoint flanking probes, individual 5′ and 3′ breakpoints can be detected. With disease progression, 100% of patients have BCL2 protein overexpression. Variant translocations, such as t(2;18)(p12;q21) and t(18;22)(q21;q11) involving the *IGK* or *IGL* gene, respectively, rather than *IGH*, are also associated with overexpression of *BCL2*.

Although t(14;18) is most likely an early genetic event in the pathogenesis of FL, it is not sufficient for malignant transformation. Approximately 50% of healthy individuals harbor low levels of circulating t(14;18) cells but do not develop FL, indicating that ectopic *BCL2* expression is necessary but not sufficient for lymphomagenesis. Recent studies of 520,000 healthy participants enrolled in the European Prospective Investigation into Cancer and Nutrition study determined that approximately 20% of healthy individuals with t(14;18) will subsequently develop FL up to 20 years later. Progression to FL was significantly associated with elevated t(14;18) burdens in peripheral blood as measured by Q-PCR. They determined that individuals with t(14;18) frequency reaching one in every 10,000 blood cells had a 23-fold greater incidence of progression to FL.

Numerous secondary chromosomal abnormalities have been identified, and at least five recurrent anomalies, each occurring in at least 20% of FL, can be used to distinguish two subgroups of patients with

FL. Patients with t(14;18) and additional trisomy for chromosome 2, 7, or 8 are associated with a more favorable clinical course as compared with patients with del(1p), del(1q), del(6q), der(18), del(22q), or gain of chromosome 12 and X. Interstitial del(6)(q25–q27) is the strongest predictor of a poor prognosis and a shorter survival time. Rearrangements of chromosome 1, such as del(1)(p32–36), + 1(p11–q44), and unbalanced translocations of der(1)(1;1)(p36;q11–23) are among the most frequent secondary chromosomal abnormalities in FL. Progression of FL to DLBCL is accompanied by the accumulation of secondary abnormalities, including homozygous del(9p).

Mutations in the *BCL2* gene are found in 12% of patients with FL at diagnosis and in 53% at the time of progression/transformation. The presence of *BCL2* mutations at the time of diagnosis correlates with increased risk of transformation and an increased risk of death due to lymphoma (the median survival of patients with *BCL2* mutations is 9.5 years vs. 20.4 years without).

As mentioned earlier, the *IGH-BCL2* fusion represents a very early event in the pathogenesis of FL. FL-like cells (FLLC) reside in the germinal center of normal lymph nodes. In a study of 85 reactive lymph nodes in healthy individuals 14% were found to contain high levels of t(14;18) as detected by Q-PCR. These studies provide evidence that FLLCs consistently accumulate within the germinal center, as non-proliferating cells that have not acquired sufficient genetic events to result in transformation to FL.

GEP has identified a distinct pattern associated with an indolent form of FL (median survival 11.1 years) and a more aggressive form (median survival 3.9 years). Detailed genetic analyses have confirmed that a single mechanism driving the transformation of FL to DLBCL does not exist, rather several discrete events are operational, including alterations of cell-cycle control (mutations and deletions of cyclin-dependent kinase, *CDKN2A/B*), *MYC* rearrangements, and impairment of the DNA damage response (loss of *TP53* and/or *CDKN2A/B*). NGS has shown that each is associated typically with between 20 and 200 small somatic mutations. At least 21 different tumor suppressor genes are altered in FL at frequencies between 2% and 86%, suggesting that FL requires multiple collaborative genomic events acquired over many years. Mutations of chromatin modifying genes (*KMT2D*, *CREBBP*, and *EZH2*) are common features of FL. Normal T-cell function within the malignant microenvironment plays a role in the pathology of the disease and includes altered expression and upregulation of *PMCH*, *ETV1*, and *TNFRSF9* genes.

BL is associated with three translocations, all affecting the *MYC* gene at 8q24 (Chapter 85). In 80% of patients a reciprocal translocation t(8;14)(q24; q32) is observed between the *MYC* gene and the *IGH* locus (Figs. 57.68 and 57.69). In the remainder of patients, the reciprocal translocations t(8;22)(q24;q11) and t(2;8)(p12;q24) occur juxtaposing MYC to one of the light-chain loci (κ on 2p12 and λ on 22q11). The t(8;14) translocation was originally described in Epstein-Barr virus (EBV) tumor cells obtained from BL patients in Africa (see Fig. 57.67B–C). Variant translocations involving *MYC* with a variety of other non-*IG* loci subsequently have been reported. In most patients with sporadic BL, the breakpoints on 8q24.1 are located on 5′ end of the coding region of *MYC* gene. By contrast, in most cases of endemic BL and in cases with non-IG translocations, the *MYC* breakpoints are at the 3′ end. Due to the translocation, control of *MYC* is lost, and the intact protein is constitutively expressed throughout the cell cycle.

Although *MYC-IGH* translocations are the *sine qua non* of BL, they are not restricted to BL since they can also appear in DLBCL, plasma cell myeloma, ALL, MCL, and CLL.

MYC regulates almost 15% of human genes. The *MYC* gene can function as both a transcriptional activator and a transcriptional repressor. MYC forms a heterodimer with MYC associated factor X (MAX). MYC-MAX heterodimer binds to the E-box consensus sequence (CACATG) and serves as a platform for other proteins involved in chromatin remodeling and transcriptional regulation. *MYC* represses genes when it is not bound directly to DNA, but instead is recruited by the *MIZ1* transcription factor, which in turn recruits DNA methyltransferase (*DNMT3*) and histone deacetylase 3 (*HDAC3*) which alter chromatin making it less accessible.

An increased level of constitutive *MYC* synthesis is found not only due to a translocation but also as a result of mutations and amplification of *MYC* (see Fig. 57.68). Approximately 65% of BL are associated with *MYC* point mutations. *MYC* both directly and indirectly

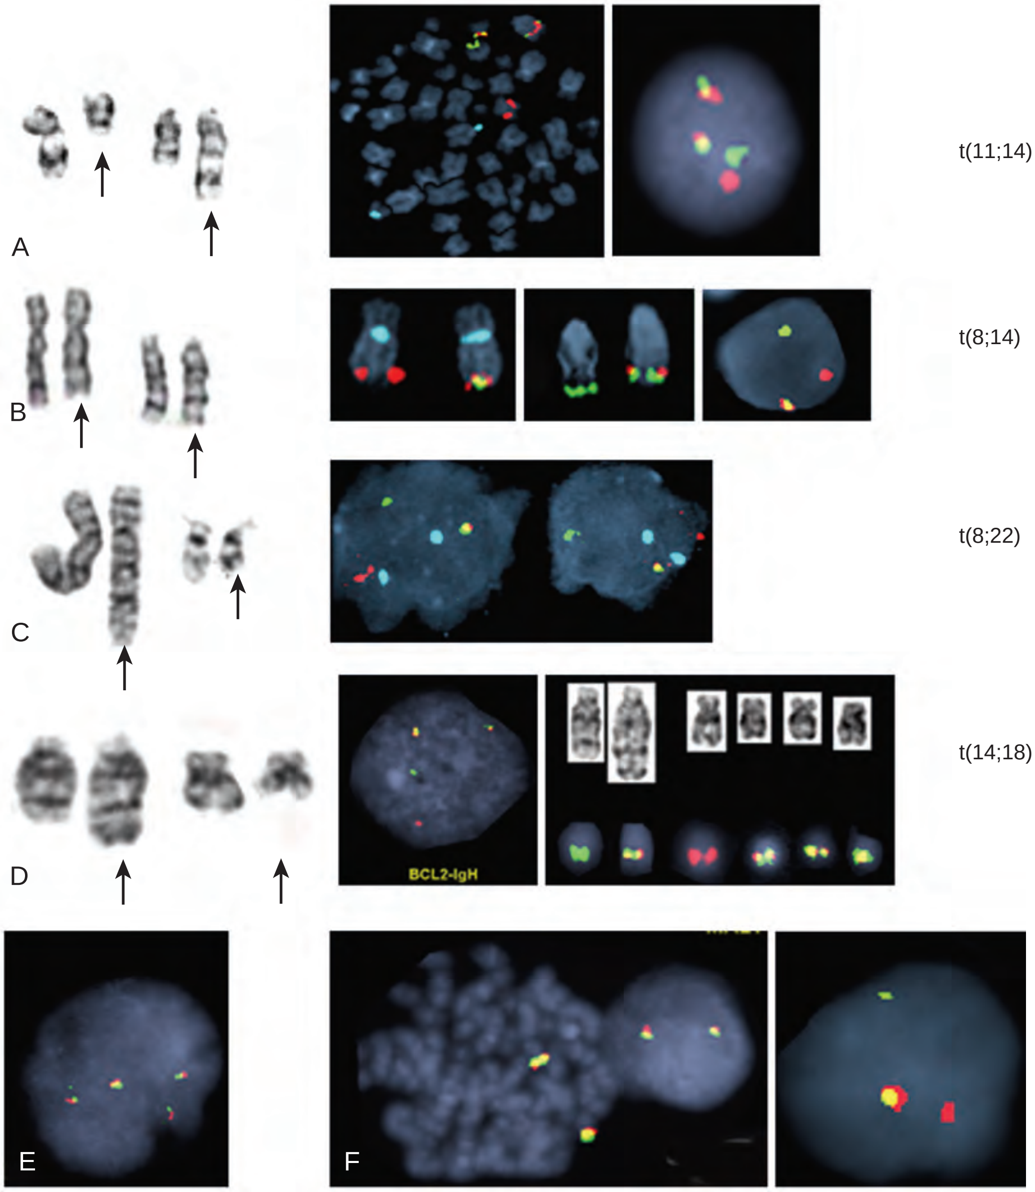

Figure 57.67 MOST FREQUENT CHROMOSOMAL ABNORMALITIES IN NON-HODGKIN LYMPHOMA. (A) Partial G-banded karyotype of t(11;14)(q13;q32.3) *(left)*, resulting in CCND1-IGH fusion *(yellow)* on metaphase *(middle)* and in interphase cell *(right)* present in the majority of patients with mantle cell lymphoma. (B) Partial G-banded karyotype of t(8;14)(q24;q32.3) *(left)*, resulting in *MYC-IGH* fusion [*yellow* on der(8) on isolated chromosomes]. Application of *MYC* breakapart probe shows separation of red and green signals consistent with *MYC* rearrangement. Approximately 80% of Burkitt lymphomas are characterized by t(8;14). (C) Partial G-banded karyotype of t(8;22)(q24;q11), a variant of Burkitt lymphoma *(left)*. Two interphase lymph node cells after hybridization with *MYC* breakapart probe and CEP8 *(aqua)*. Separation of green and red signals is consistent with *MYC* relocation from 8q24 to 22q11. (D) Partial G-banded karyotype of t(14;18)(q32.3;q21.3) *(left)*, resulting in IGH-BCL fusion (two yellow signals, *middle*). A composite image on the *right* shows both a partial karyotype and FISH study of triplicated der(18)t(14;18) and three copies of *IGH-BCL2* fusion *(yellow)*, as well as normal chromosome 14 and 18. Multiple copies of abnormal der(18) chromosome are associated with progressive disease similar to a duplication of the Philadelphia chromosome in the blast crisis of chronic myelogenous leukemia. (E) Lymph node cell from a patient with diffuse large B-cell lymphoma, showing four copies of *BCL6* (breakapart probe). *BCL6* is localized at 3q27 and is numerically or structurally rearranged in 35% of diffuse large B-cell lymphoma. (F) Bone marrow metaphase and interphase cell hybridized with breakapart *MALT1* gene at 18q21 *(left)* indicating two fusion *(yellow)* signals when *MALT1* gene is intact. In contrast, rearrangement of the *MALT1* gene in MALT lymphoma usually is the consequence of t(11;18)(q21;q21.1), as shown in the cell *(right)* with clear separation of the 3′ end *(green)* and the 5′ end *(red)*.

activates *CCND2* and cyclin-dependent kinases and downregulates cell cycle inhibitors, promoting the transition from G0 to S phase. MYC plays a role in the formation and maintenance of germinal centers.

The most common secondary change associated with t(8;14) in BL is duplication of the long arms of chromosome 1, which includes the *MDM4* locus, which is associated with disease progression. A common duplicated region of 93 kb at 1q21.2 has been observed using FISH. A rare complex BL karyotype is shown in Fig. 57.68. Based on the incidence of the *TP53* mutations (40%) and frequent gain of 1q in BL one of the mechanisms involved may include a widespread suppression of *TP53* activity to overcome p53-mediated cell cycle arrest and apoptosis caused by *MYC* overexpression. Rearrangements of *MYC* can now be detected in nondividing cells as well as in paraffin-embedded lymph node biopsies using a very sensitive interphase FISH assay for t(8;14).

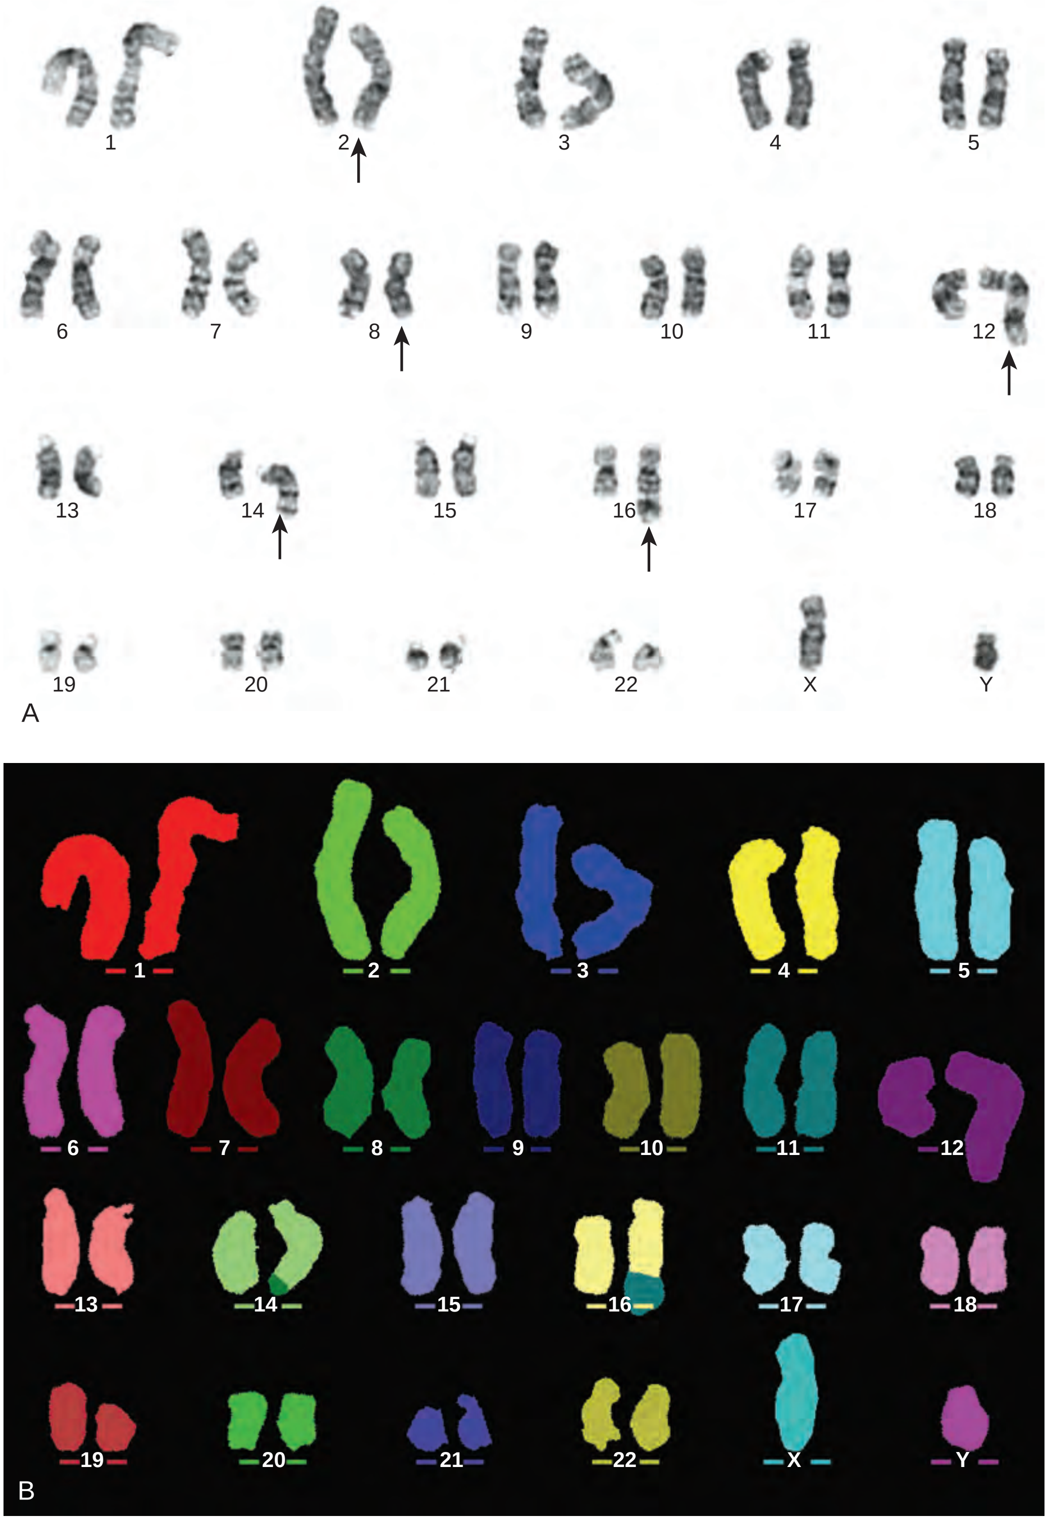

Figure 57.68 COMPLEX KARYOTYPE OF BURKITT LYMPHOMA. Bone marrow karyotype of a patient diagnosed in an advanced stage of Burkitt lymphoma (A) and after application of the multicolor FISH (B) to resolve complex derivative chromosomes, showing 46, XY, del(2)(p21p23), t(8;14)(q24;q32), dup(12)(q13q24.3), der(16)(t(11;16)(p11.2;q24) karyotype. *Arrows* indicate abnormal chromosomes. In addition to the classic t(8;14), both duplications of 11q and 12q were identified with multicolor FISH technology. *FISH*, fluorescence in situ hybridization.

According to the WHO classification, three BL variants are recognized: endemic, sporadic (1% to 2% of all lymphomas and 30% to 50% of childhood lymphoma in the USA), and BL with immunodeficiency disorders such as HIV infections (Chapter 152). In contrast, many cases of Burkitt-like lymphoma (a separate WHO entity) lack BL translocations but exhibit increased MYC expression.

Through an integrated analysis of whole genome and novel transcriptome data EBV-positive tumors have a striking genome-wide increase in aberrant somatic hypermutation supporting a link between the EBV and activation-induced cytidine deaminase (AICDA) activity.[22] High-throughput RNA sequencing has revealed acquired somatic mutations in the *CCND3* gene in 38% of sporadic BL cases.

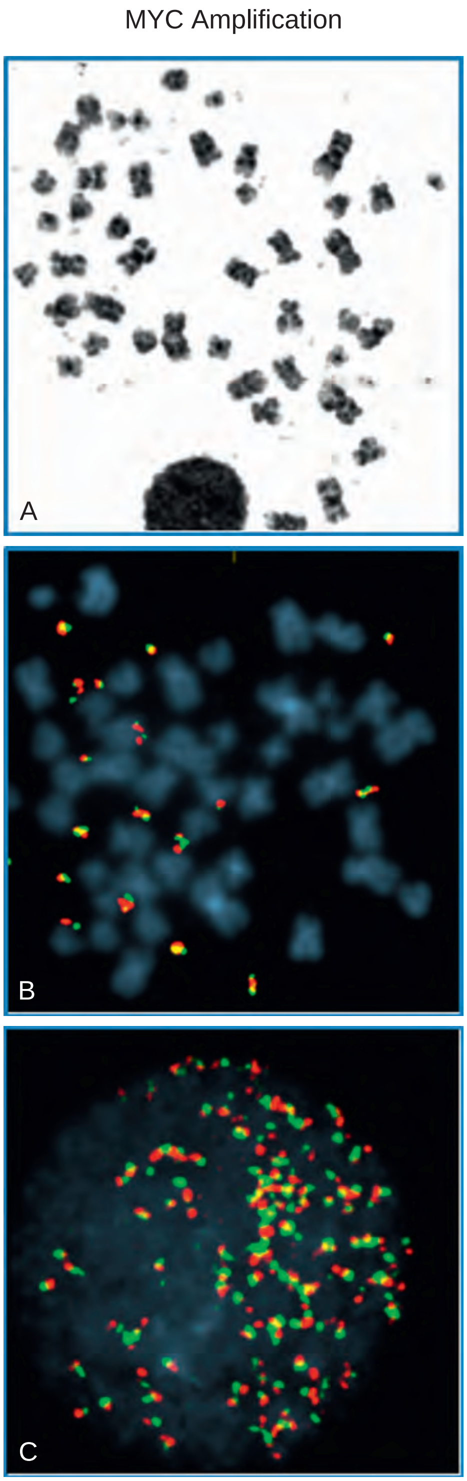

Figure 57.69 MYC AMPLIFICATION. (A) A conventional G-banded bone marrow metaphase from a patient with non-Hodgkin lymphoma. Note very pale doublets of chromatin material all over metaphase cells. They are termed double minutes. (B) All double minutes after hybridization with *MYC* breakapart probe were hybridized to *MYC* consistent with *MYC* amplification. (C) Interphase, nondividing bone marrow cell showing a very high number of *MYC* amplicon. Note that *MYC* gene is not rearranged, only amplified.

This is an important gene in cell cycle progression and 70% of these patients acquire mutations affecting the transcription factor *TCF3* or its negative regulator *ID3*. Mutations in the *ID3* gene have been detected in 50% of all *IGH-MYC* translocation-positive sporadic BL and these mutations were rare in other *IG-MYC*-positive lymphomas. These findings suggest that disruption of *ID3* function may be a key mechanism in the pathogenesis of BL. Moreover, recurrent mutations in *TP53*, *SMARCCA4* (chromatin modulating complex gene), and *DDX3X* (chromatin modulating complex gene) may contribute to BL evolution.

Approximately 35% of patients with DLBCL and approximately 5% to 10% of patients with FL have rearrangements in the *BCL6* gene which resides at 3q27. Translocation and dysregulation of *BCL6* gene represents a key mechanism of the development of DLBCL. Chromosomal rearrangements of the *BCL6* locus occur in about 35% of patients with DLBCL, and at least 33 different partners have been described (http://atlasgeneticsoncology.org/) (see Fig. 57.67). The most frequent chromosomal band partners are 2p13, 4p13, 6p22, 7p12, 8q24, 13q14, 14q32, 18p11.2, and 22q11. These translocations juxtapose the coding domain of *BCL6* downstream to heterologous promoters derived from different chromosomal partners, leading to dysregulated expression of an intact protein by preventing its downregulation during postgerminal center differentiation. The *BCL6* 5′ sequences are targeted by multiple point mutations in over 70% of cases. Most of the breakpoints at 3q27 occur within a 10-kb region. The fact that the 3q27 region is affected in different lymphomas, irrespective of the translocation partner chromosomes, strongly suggests that alterations of *BCL6*, and not the reciprocal loci, are important in lymphomagenesis. The alterations in 3q27 are small so most can be detected with PCR-based assays, or FISH. *BCL6* functions as a transcriptional repressor of genes containing its binding sites; therefore the mechanism responsible for the malignant phenotype is transcriptional deregulation.

The 2016 WHO classification for lymphoma included a new category termed “high-grade B-cell lymphoma” (HGBL) with translocations involving *MYC* and *BCL2* or *BCL6* comprising ~10% of cases of high-grade DLBC. However, a number of reports have appeared describing patients with DLBCL demonstrating, with FISH technology, to have a gain of copy numbers of *MYC*, *BCL2*, and *BCL6* with or without translocations of these genes. Overall, extra copies of these three genes were not associated with a poor outcome, however, there are reports indicating that extra copies of *MYC*, three or more copies, were significantly associated with an inferior prognosis. Moreover, co-occurrence of *MYC* dysregulation and *TP53* mutation indicates ultra-high risk and has an unfavorable impact on survival.

t(14;15)(q32;q11–13) occur in 3% to 4% of DLBCL, which results in fusion of the *BCL8* gene on chromosome 15 to the V_H segment of the *IGH* locus. The most common secondary abnormalities are trisomies of chromosomes 3, 5, 7q, 11, 12p, 18q, and Xq, which are observed in greater than 10% of cases. Amplification of *REL*, *MYC*, *BCL2*, *GLI*, *CDK4*, and *MDM2* genes are most frequently associated with advanced disease. The most frequent monosomies include chromosomes 13, 14, and 15. A complex karyotype may have an adverse impact on prognosis.

The use of modern molecular studies identified two major subgroups in DLBCL: activated B cell–like DLBCL (ABC-DLBCL) and germinal center B (GCB)–like DLBCL (Chapter 79 and 81). According to the WHO 2016 classification, these two subgroups of DLBCL, the GCB and ABC subgroups, differ in their chromosomal alterations, activation of signaling pathways, and clinical outcomes. Patients with ABC-DLBCL frequently exhibit trisomy of 3/+3q and 18q21–23, and loss of the 6q21–23 region. Patients with GCB-DLBCL have frequent gains of the 12q12 chromosomal region. Patients with primary mediastinal lymphoma have gains of 2p14–p16 and 9p21-pter. Apparently, gains in several regions of chromosome 3 are associated with inferior survival. Moreover, genomic gains involving the 3p11–p12 region have an independent impact on prognosis based on previously defined optimal gene expression–based models. Somatic point mutations of the polycomb-group oncogene *EZH2* have been reported in 22% of patients with GCB-DLBCL. The differentiation of GCB B cells into plasma cells requires *PRDM1*, a sequence-specific transcriptional repressor that is upregulated; 25% of ABC-DLBCL have deletions of *PRDM1* as a result of truncated mutations, or genomic deletions, while an additional fraction of patients lack the PRDM1 protein due to transcriptional repression by a constitutively active translocated *BCL6* gene.[23]

Patients with non-BL may have *MYC* translocations without additional mutations in *BCL2* or *BCL6* and they are described as having single hit lymphomas. Although the most recent studies suggested that patients with *MYC*+, but *BCL2*− and *BCL6*− *DLBVL* do not have an inferior outcome when compared to those who are *MYC* negative, the clinical relevance of *MYC* rearrangements as a sole abnormality in DLBCL remains controversial with some studies indicating an adverse prognosis.

Double hit lymphoma (DHL) refers to B-cell lymphoma with multiple activating oncogenes, one of them being *MYC*. Among DHL, those with alterations in *MYC* and *BCL2* are the most common by far, occurring in 87% of patients, followed by *MYC* and *BCL6* rearrangements, found in 5% of patients. Triple hit lymphoma (THL) involves rearrangements of *MYC*, *BCL6*, and *BCL2* in a single cell and is observed in about 8% of patients with DLBCL (Fig. 57.70).

DHL can be detected cytogenetically but cryptic gene rearrangements may be missed. FISH therefore should be used for the detection of DHL and THL. FISH studies can be successfully performed using formalin-fixed paraffin embedded tissue sections as well as fresh smears or touch-cell imprints of an involved tissue.

Because one of the translocations may be cryptic, a combination of three FISH probes, labeled with three colors, is especially useful in identifying these very complex translocations (see Fig. 57.70). Non-*IG* genes also act as *MYC* translocation partners in 35% to 53% of *MYC* rearranged DLBCL. The t(8;9)(q24;p13), which results in the juxtaposition of *MYC* to *PAX5*, has been frequently reported, accounting for 20% of non-*IG*/*MYC* rearrangement. Both the DHL and THL have complex karyotypes. Complex karyotypes are not seen in BL, which by definition always has a single abnormality.

The detection of increased number of cells expressing *MYC* correlates well with the presence of gene rearrangements, but the relationship varies. Tumors with more than 70% of *MYC*-positive cells usually are associated with gene rearrangements, but *MYC* translocations can be present in up to 17% of cases with less than 30% *MYC*-positive cells. The current recommendation is that all patients with DLBCL have FISH for *MYC* rearrangements because combined alterations in *MYC*, *BCL2*, and *BCL6* confers a more aggressive disease phenotype. Targeted sequencing of 928 patients with DLBCL, using a 293-gene panel, by Haematological Malignancy Research Network, reported in 2020 five molecular subtypes: *MYD 88*, *BCL2*, *SOCKS1/2*, *TET2/SGK1*, and *NOTCH2* along with an unclassifiable group. The subtypes characterized by genetic alterations of *BCL2*, *NOTCH2*, and *MYD88* indicated a good, intermediate, and poor prognosis, respectively. The *SOCK1/SGK1* subtype showed biological overlap with primary mediastinal B-cell lymphoma. Although not identified as a distinct cluster, a mutation *of NOTCH2* was associated

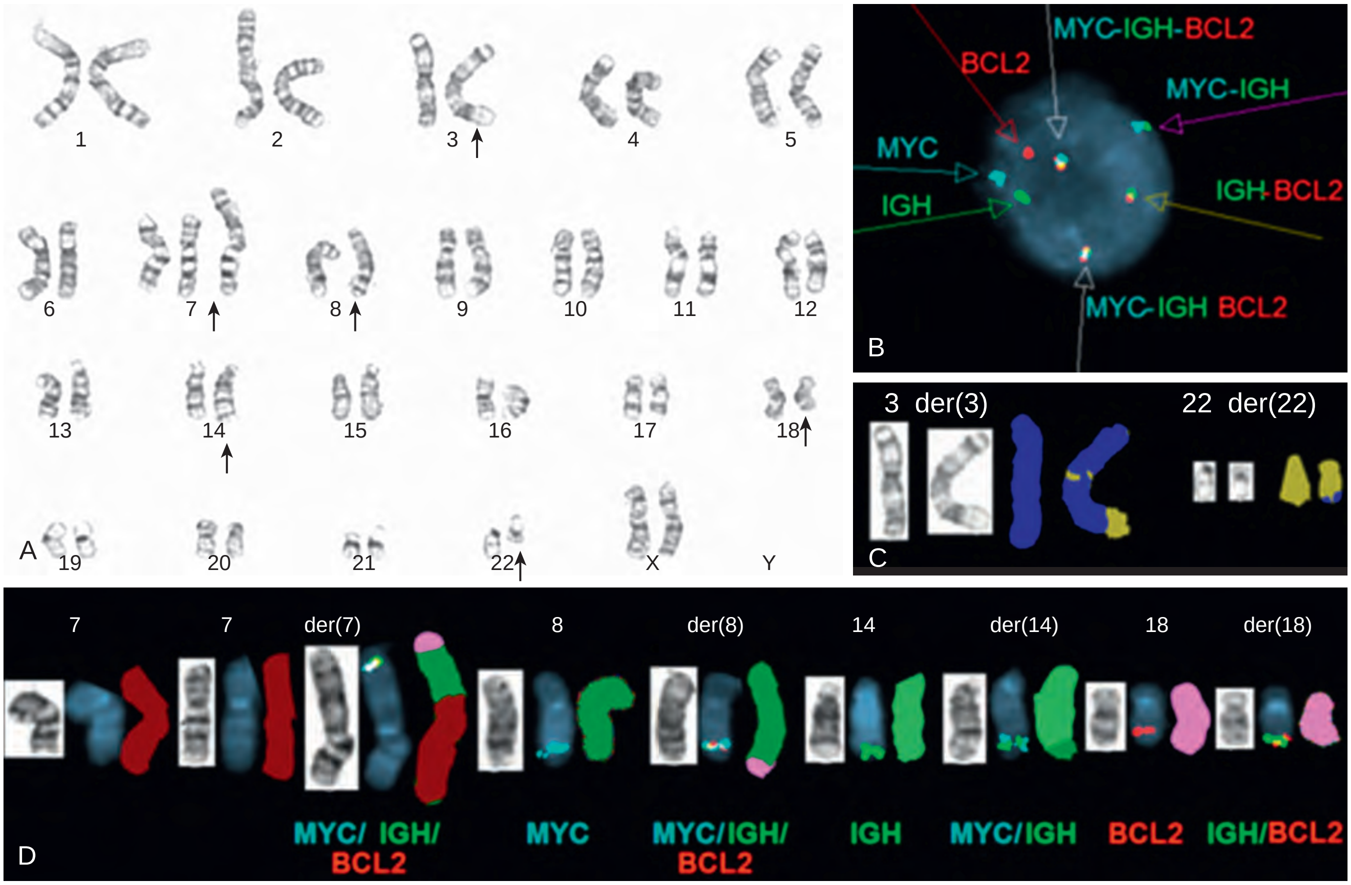

Figure 57.70 TRIPLE HIT LYMPHOMA. (A) A karyotype of patient with triple hit lymphoma with *arrows* pointing to the abnormal chromosomes. Note a gain of der(7;8) resulting in three copies of 7q and three copies of rearranged 8q, and the three-way translocation between chromosomes 8, 14, and 18 as well as a translocation (3;22). (B) A bone marrow nucleus showing normal *MYC (aqua)*, *IGH (green)*, and *BCL2 (red)* as well as two copies of *MYC-IGH-BCL2* fusion, *MYC-IGH*, and *IGH-BCL2* fusion. (C) A partial karyotype after multicolor metaphase FISH study, using chromosome paining probes, showing a t(3;22) resulting in *BCL6* rearrangement. (D) A partial karyotype of chromosomes 7, 8, 14, and 18. G-banded chromosomes are on the left, DAPI-stained chromosomes with *MYC (aqua)*, *IGH (green)*, and *BCL2* are in the middle, and multicolor stained chromosomes are on the right. Note der(7) is composed of 7q *(brown)*, gain of 8q *(dark green)*, and the third copy of *MYC-IGH-BCL2* fusion is on the tip of the 8q. The patients had three copies of *IGH2-BCL2* although cytogenetically this was manifested as a gain of 8q. *FISH*, Fluorescence in situ hybridization. *(Reprinted with permission from McFarland DC, Brody J, Tripodi J, et al. Two cases of triple hit lymphoma: a call for imperative MYC, BCL2 and BCL6 testing by FISH in aggressive lymphomas. Personal Med Oncol. 2015; 4:16–22. Copyright 2015. Green Hill Healthcare, LLC.)*

with a poor prognosis. The impact of *TP53* mutations varied with genomic subtypes conferring no effect on prognosis in the NOTCH2 subgroup and an inferior prognosis in the MYD88 subtype.

All patients with MCL exhibit t(11;14)(q13;q32) abnormality as detected by FISH (see Fig. 57.67, *top panel*) (Chapter 86). t(11;14)(q13;q32) is also found in a variety of other B-cell malignancies, including MM, splenic lymphoma with villous lymphocytes, and B-cell prolymphocytic leukemia. The WHO recognizes two molecular subtypes that differ in their clinical and biological features. The most common MCL is derived from naïve-like mature B cell, expresses the oncogenic transcription factor *SOX11*, and accumulates large numbers of genomic alterations. In contrast, the other subtype, leukemic, non-nodal MCL originates from memory-like B cells, is *SOX11*-negative, and is genetically stable.

Cyclin D1 overexpression is the hallmark of MCL and it is associated with t(11;14). Most breakpoints on chromosome 11, band q13, occur over a region of approximately 130 kb centromeric to the *cyclin D1* (*CCND1*) gene. At the molecular level, the *BCL1* locus (*CCND1*) on chromosome 11q13 is juxtaposed to an enhancer sequence within the *IGH* gene on 14q32, leading to overexpression of the *cyclin D* gene (involved in cell cycle control), which is not expressed in normal B and T cells or in other malignant lymphomas.

Cyclin D1 activates cyclin-dependent kinases 4 and 6 which in turn phosphorylate and inactivate *RB1* and promote the transition from the G1 to the S phase, resulting in rapid cell proliferation. *SOX11* overexpression is observed in many patients with MCL which leads to many events, including blocking B-cell maturation to plasma cells.

Because the breakpoints within 11q13 are scattered along a 130-kb distance, dual-color FISH has proved to be the most sensitive assay for detection of *IGH-CCND1* fusion in MCL. Furthermore, the *CCND1* fusion rearrangement can also be detected in formalin-fixed, paraffin-embedded samples, making this a rapid and reliable method (see Fig. 57.67).

The secondary chromosomal alterations include gains of 3q, 8q, and 15q and losses of 1p, 8p23-pter, 9p21-pter, 11q21–23, and 13q. Some of the genes residing in these chromosomal regions are dysregulated and are involved in cell proliferation, DNA repair, cellular homeostasis, and apoptosis. In MCL, DNA amplification of several chromosomal regions appears to be associated with a blastoid variant. Loss of 9p21-pter, inactivation of *TP53*, gain of 3q, and high cyclin D expression are biomarkers of shorter survival and a more aggressive clinical phenotype. Common MCL is enriched for *ATM* mutations while non nodal MCL is slightly enriched for *TP53* and *TERT* alterations. *ATM* mutations are present in 64% of cases with the common subtype of MCL and represents an early event in pathogenesis with some suggestions that it may even occur in the germline of some patients. Although a number of other somatic mutations were described in both groups of MCL, such as *CDKN1B*, *SAMDHD1*, *BCOR*, *SYNE1*, *SMARCB1*, *CCND1* only *TP53*, and *MYC* alterations, provide MCL cells a higher proliferative capacity and have independent prognostic value.

Two types of aggressive histology of MCL, according to the WHO, can be differentiated as variants of MCL, blastoid and pleomorphic. They may arise de novo or transform from a prior classic MCL. The first and the largest genomic profile of these two variants of MCL included 183 patients with aggressive histology and in general, they had inferior outcomes when compared to patients with classic MCL, and the pleomorphic subtype had a trend for a worse OS compared to patients with blastoid subtype.[24] WES analysis demonstrated that a *CCND1* gene mutation was enriched in both aggressive subtypes and there were predominance of *NOTHC1/2*, *NSD2*, and *KMT2A* gene mutations most likely related to the previous therapy these patients had received before disease transformation.

Extranodal marginal zone lymphoma and MALT lymphoma (Chapter 83) are considered the third most frequent subtypes of NHL. An etiologic link between low-grade gastric MALT lymphoma and a lymphoid reaction associated with *Helicobacter pylori* infection has been well established. Growing evidence suggests that chronic antigenic stimulation caused by autoimmune diseases, such as Hashimoto thyroiditis, also contributes to an increased risk for developing MALT lymphomas.

The most frequent and specific aberration occurring in MALT lymphomas is t(11;18)(q21;q21.1) (see Fig. 57.67F). Although this abnormality has been described in other B-cell lymphomas, t(11;18) in MALT lymphoma it is usually the sole lesion. It is the only recurrent translocation that does not involve *IG* genes, even though it presents in a B-cell lymphoma. As a consequence of t(11;18), *API2* gene on chromosome 11, band q21, which encodes an inhibitor of apoptosis, and a novel gene *MALT1* on chromosome 18, band q21, characterized by several Ig-like C2-type domains, are often rearranged. The resultant chimeric transcript consists of *5′-API2 and 3′-MALT* located on der(18). More than 90% of breakpoints in the *API2* locus occur in intron 7, whereas the breakpoints within *MALT1* are variable and occur in four different introns. The *API2-MALT1* fusion can be identified using a dual-color *API2-MALT1* FISH probe or the breakapart dual-color *MALT1* probe on lymph node biopsy specimens (see Fig. 57.67F). However, detection of deletions and duplications occurring at high frequencies in both the *API2* and *MALT1* genomic sequences require more precise molecular cytogenetic methods.

t(1;14)(p22;q32) and its variant t(1;2)(p22;q12) occur in less than 5% of MALT lymphomas, and are associated with an advanced disease. This translocation relocates the entire *BCL10* gene from 1p22 to chromosome 14, bringing it under the control of an *IGH* enhancer. Currently, a specific probe for detecting *BCL10-IGH* fusion is not commercially available, but an *IGH* dual-color breakapart FISH probe may determine *IGH* rearrangements without identifying the partner chromosome. The recurrent t(3;14)(p13;q32) abnormality, which results in fusion of the *FOXP1F* gene on chromosome 3 to *IGH*, is a rare rearrangement that causes *FOXP1F* overexpression. Its significance in lymphoma remains unknown. The t(14;18)(q32;q21), which occurs in 2% to 18% of all MALT lymphomas, results in fusion of *IGH-MALT*. The 18q21 breakpoint involving the *MALT1* gene is 5 Mb centromeric from the *BCL2* breakpoint on chromosome 18, which is associated with FL. In contrast to *API2-MALT1* cases, patients with an *IGH-MALT1* fusion gene have disease outside the gastrointestinal tract, usually presenting with ocular, skin, liver, or salivary gland tumors. Trisomy of chromosomes 3, 7, 12, and 18 are recurrent numerical changes associated with MALT lymphomas. FISH studies are useful for detecting the *IGH-MALT* fusion in paraffin-embedded lymph node biopsies. Compelling evidence links these translocations to constitutive activation of the NF-κB pathway. In those MALT lymphomas lacking the aforementioned aberrations, inactivating mutations of *TNFAIP3* (tumor necrosis factor alpha-induced protein 3) are frequent. Remarkably, the majority of mutagenic events in MALT lymphomas, at least two of the three trisomies, three of the translocations and *TNFAIP3* inactivation, all result in activation of the NF-κB pathway.

Splenic marginal zone lymphoma (SMZL) (Chapter 83) lacks recurrent chromosome translocations although approximately 30% of patients have heterozygous 7q deletions. Studies utilizing whole-exome sequencing have identified novel and recurrent inactivating mutations in Kruppel-like factor 2 (*KLF2*) in 42% of patients. These mutations are rarely observed in other B-cell lymphomas. Different *KLF2* mutations compromise the ability of *KLF2* gene to suppress *NF-κB* activation, leading to an altered gene expression pattern favoring B-cell homing to the marginal zone. *KLF2* inactivation alone is insufficient for malignant transformation and requires cooperating genetic events. Other common mutations found in SMZL include *NOTCH2*, *TRAF3*, *TNFAIP3*, and *CARD11*. These mutations with and without *KLF2* mutations indicate that *KLF2* mutation identifies a subset of patients with SMZL with distinct genotype. NGS has demonstrated that 40% of patients with SMZL have mutations in fours genes: *TP53*, *KLF2*, *NOTCH2*, and *TRAF3*, of which *TP53* mutations were associated with a shorter survival whereas mutations in *MYB* gene were predictors of a longer OS.

Lymphoplasmacytoid lymphoma (LPL) (Chapter 92) is a small lymphocytic lymphoma with plasmacytoid differentiation (CD5− CD10−) characterized by t(9;14)(p13;q32) in approximately 50% of cases. As a result of this translocation, the paired homeobox 5 (*PAX5*) gene on 9p13 moves to the *IGH* locus on der(14), causing dysregulation of *PAX5*. Molecular characterization of t(9;14) has revealed that the coding region of the *PAX5* gene remains intact in some patients. t(9;14) should be considered a regulatory alteration in which the *PAX5* gene is brought under the control of the *IGH* locus. In other cases, molecular studies of t(9;14) have revealed that the breakpoint occurs upstream of the *PAX5* promoter, leading to insertion of the *IGH* enhancer upstream of the *PAX5* gene. Recurrent mutations in *MYD88*, specifically L265P mutation, have been identified in over 96% of patients with LPL whereas mutations in chemokine receptor, *CXCR4*, have been observed in about 36% of cases. These mutations identify a subgroup of LPL with aggressive disease.

Waldenström macroglobulinemia (WM) (see Chapter 92) is characterized by a lymphoplasmacytic clonal expansion in the marrow. Historically recurrent chromosomal abnormalities including deletion of the long arms of chromosome 6 in 21% to 55% of cases and trisomy 4 in approximately 20% of cases have been reported. In contrast to other B-cell disorders, abnormalities of *IGH* at 14q32 as detected by FISH are rarely observed. WGS of WM lymphoplasmacytic cells has led to the identification of a recurring sequence variant at position 38182641 in chromosome 3p22.2. A single-nucleotide change from T to C in the *MYD88* gene results in a leucine-to-proline change at amino acid position 265. *MYD88* (3p22 locus) mutations can be detected by PCR in the peripheral blood of patients at presentation. The *MYB88* L265P mutation is highly specific and is the most frequent mutation in WM. It is found in over 91% of cases, including those with a gain of chromosome 3 (approximately 12%). This mutation may be considered as the first detectable genetic hit in WM that promotes NF-κB and JAK-STAT signaling pathways. *MYD88* L265P mutation is also seen in SMZL and MALT lymphoma. *MYD88* L265P cannot be used to differentiate between WM and IgM MGUS. Patients with mutated *MYD88* have a shorter survival than patients with unmutated *MYD88*. The *CXCR4* (2q22.1 locus), one of the main regulators of B-cell homing, is mutated in almost 30% of patients with WM and 20% of patients with IgM MGUS. Collectively these results indicate that *CXCR4* is an activating mutation in WM and has a critical role in WM pathogenesis.

Until recently, little progress has been made in delineating recurrent chromosomal abnormalities in Hodgkin lymphoma (HL) (see Chapters 78–80) because of the rarity of Reed-Sternberg cells (less than 1% of the cells in HL are Reed-Sternberg cells-HRS) in the involved lymph nodes. Until about 5 years ago, the most specific chromosomal abnormalities in HL were hyperdiploidy/tetraploidy with tremendous variations in chromosome number, indicating heterogeneity from patient to patient. Even with use of nine different centromeric probes, a specific numerical chromosomal abnormality was not identified. Deletions of 1p, 4q, 6q, and 7q were recurrent, and *JAK2*, located on 9p21, frequently was found amplified in patients with HL (see Table 57.19). Another gene, *REL*, on chromosome 2, band region p14–p15, was amplified in ~70% of patients. Of note, *REL* is under the influence of NF-κB and constitutive NF-κB activation is a critical prerequisite for Reed-Sternberg cell survival and proliferation. Progress in microdissection, whole genome amplification (WGA), and FISH led to clarifying the genetic origins of HRS cells. Laser microdissection of HRS cells ($n = 1200$ to 1800 cells per case) from 34 biopsies revealed that ~90% of patients had a variety of JAK-STAT pathway gene alterations (Tables 57.20 and 57.21). These include *JAK2* copy gains mutational disruption of the *SOCS1* and *PTPN1* genes as well as *JAK2* activating mutations along with recurrent mutations of STAT6 (32% of cases). Another study using full-exome deep sequencing of HRS cells in 10 patients revealed inactivating mutations in β2-microglobulin gene (*B2M*, localized at 15q21.1) in 7 of 10 patients. These mutations lead to the loss of major histocompatibility complex class I (*MHC1*) expression. A lack of *MHC1* expression in HRS cells was previously reported as an independent adverse prognostic factor. Therefore one of the molecular mechanisms leading to MHC1 downregulation in HL is through inactivating mutations in *B2M* gene.

TABLE 57.20 Currently Known Recurrent Copy Number Alterations in Classic Hodgkin Lymphoma[a]

Location	Frequency	Affected Genes, Pathways, and Biological Processes
2p-Gain	28%–54%	
4q-Loss	7%–25%	*REL* (NF-KB pathway)
6q-Loss	5%–30%	
9p-Gain	24%–40%	*JAK2* (JAK/STAT pathway), *PD-L1, PD-L2* (immune evasion)
11q-Loss	3%–25%	
12q-Gain	37%–40%	*MDM2* (cell cycle, apoptosis)
13q-Loss	22%–35%	
14q-Gain	7%–30%	
16p-Gain	24%–30%	*ABCC1* (multidrug resistance)
17p-Gain	25%–40%	
17q-Gain	20%–70%	*MAP3K14* (NF-KB pathway)
19q-Gain	25%	
20q-Gain	15%–23 15%	*CD40* (NF-KB pathway)

[a] Locations, frequencies in three major studies and possibly affected genes and pathways are given in the respective columns.

TABLE 57.21 Reported Frequencies of Genetic Alterations in Major Hallmarks of Classic HD Pathology

Pathway/Gene	Genomic Alteration	Frequency (%)
NF-KB		
NFKBIA	SNV	25–40
NFKBIE	SNV	17–27
REL	CNV gain/amp	28–70
MAP3K14	CNV gain/amp	25
TNFAIP3	SNV	40–45
	CNV loss	21–60
BCL3	CNV gain/amp	15–70
	SR	10
JAK-STAT		
JAK2	CNV gain/amp	35–40
SOCS1	SNV	41
PTPN1	SNV	20
STAT6	SNV	31–45
Immune Escape		
CIITA	SR	15
CD274/PDC1LG2	CNV gain/amp	38–75
B2M	SNV	21–70
CD58	CNV loss	23
TNFRSF14	CNV loss	13–42

amp, Amplification; *CNV*, copy number variation; *SNV*, single-nucleotide variants (including small deletions); *SR*, structural rearrangement.

Blastic Plasmacytoid Dendritic Cell Neoplasms (Chapter 64)

BPNDCN is a rare and clinically aggressive hematopoietic malignancy derived from precursor plasmacytoid dendritic cells. In 2016, for the first time, WHO classified this malignancy as a separate entity. Most patients present with cutaneous lesions followed by systemic dissemination involving lymph nodes, bone marrow, and rarely extranodal sites. An international survey of 398 adult patients with BPDCN indicated the median survival to be 18 months.[25] Cytogenetics was available for 96 patients and an abnormal karyotype was detected in 54%. Major chromosomal abnormalities associated with BPDCN include 5q (70%), 12p (63%), 13q (60%), 6q (52%), and 15q (39%), as well as monosomy 9 (20%). Monosomal and/or complex karyotypes were observed in 36% of patients, and 86% of cases with disseminated disease had this pattern. Most frequent loss of chromosomes include chromosome 13 (38%); and 19% of patients demonstrated loss of chromosomes 5, 7, 8, 9, 15, and 17. Only 15 patients were screened with FISH technology and *ETV* rearrangements were detected in 20%.

HAIRY CELL LEUKEMIA (CHAPTER 77)

Recurrent chromosomal aberrations have not been identified in hairy cell leukemia (HCL) although as shown in Fig. 57.71 some patients may have a complex bone marrow karyotype at diagnosis (Chapter 77). HCL is a mature B-cell malignancy with unique immunophenotypic features. High-density genome-wide SNP genotyping has shown a remarkably balanced genomic profile. In 2011, a *BRAF*-V600E mutation was described for the first time in every one of 47 patients. The *BRAF*-V600E mutation defines HCL, is present in virtually all patients with HCL, and is absent in other B-cell malignancies except a small number of patients with MM. BRAF is a kinase within the RAS-RAF-MEK-ERK pathway. Quantitative sequence analysis revealed a mean *BRAF*-V600E-mutant allele frequency of 4.9% in human hematopoietic stem cells from patients with HCL and functional studies showed that these cells have self-renewal capacity, indicating that this mature B-cell malignancy originates within the hematopoietic stem cell compartment. Detection of the *BRAF*-V600E mutation by PCR is the gold standard for the genetic diagnosis of HCL.

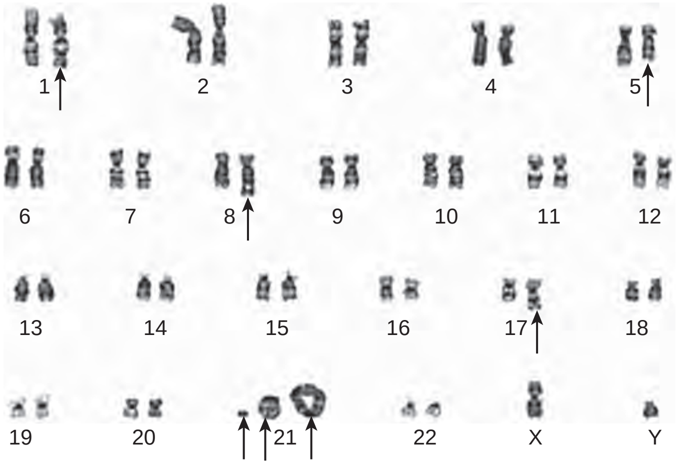

Figure 57.71 A COMPLEX KARYOTYPE FROM A PATIENT WITH HAIRY CELL LEUKEMIA. This complex karyotype with nine complex structural abnormalities, as indicated by *arrows*, 47, XY, del(5)(q15;q31), der(8)t(3;8)(p21p26;q24), der(17)t(1;17) (p36.1;p13)t(17;21)(q25q22.2), −21, +r(21)×2, is an example of profound chromosomal rearrangements in hairy cell leukemia.

T-Cell Lymphoproliferative Neoplasms (Chapter 89)

This is a diverse group of hematologic disorders that includes T-cell ALL and T-cell CLL/PML, as well as several indolent T-cell disorders, large granular lymphocyte leukemia (LGL) (Chapter 33), natural killer leukemia/lymphoma, and anaplastic large cell lymphoma (ALCL) (Chapter 89). Approximately 80% of T-cell ALL harbor oncogenic driver lesions. The WHO and the International Lymphoma Study Group denominated both T-ALL and T-LBL (T-cell lymphoblastic lymphoma) as T lymphoblastic leukemia/lymphoma in an updated Revised European-American Classification of Lymphoid neoplasms and WHO classification but without further specification.

T-cell ALL represents 15% of childhood ALL cases and 25% of adult ALL cases. At diagnosis, approximately 50% of patients have a normal karyotype. Table 57.22 lists recurrent cytogenetic and molecular genomic changes associated with T-cell ALL and Table 57.23 lists the frequency of recurrent chromosomal abnormalities in T cell-ALL. Immunophenotypic and gene expression analyses are consistent with genetic heterogeneity in T-cell ALL, reflecting, to some degree, distinct stages of T-cell maturation arrest.

One of the common themes in T-lymphoid malignancies is the juxtaposition of the *TCR* gene enhancer element adjacent to a variety of transcription factors located at or near breakpoints on the partner chromosome. The chromosomal bands most frequently involved are 14q11, where *TCRA* and *TCRD* are located (Fig. 57.72); 7q35, the site of *TCRB*; and 7p15, the site of the *TCRG*. *TCR* translocations are found in approximately 35% of T-cell ALL cases (see Table 57.22). The rearrangements of *TCRB* and *TCRG* are relatively rare, whereas 14q11 rearrangements involving both *TCRA* and *TCRD* are frequent in T-cell neoplasms (see Table 57.22).

In children, the overall frequency of T-cell ALL (Chapters 66 and 67) translocations is 40% to 50%, and several molecular/cytogenetic abnormalities have prognostic implications (see Table 57.23). *TAL1* rearrangements include t(1;14)(p32;q11), t(1;7)(p32;q35), rare t(1;3)(p32;p21), t(1;5)(p32;q31), and t(14;19)(q11.2;q13.1) (see Fig. 57.72). In general, *TAL1* rearrangements are submicroscopic and best identified with FISH. Disruption of *TAL1* is frequently associated with a submicroscopic interstitial deletion (90 kb) between the 5′ untranslated region of the *TAL1* (1p32) and the *SIL* (*STIL*) genes (1p32) in 9% to 26% of cases depending on the different studies. The *SIL-TAL1* fusion product gives rise to inappropriate expression of TAL1 protein. Among 382 children with T-cell ALL 16% possessed *SIL-TAL1*, which was more frequently observed in older children. These 1p32 rearrangements are less frequent in adult T-cell ALL. *TAL1*-positive ALL is characterized by an arrest in differentiation at the CD4+CD8+ stage of thymocyte development, when the *TAL1* gene is normally silent. The *TAL1* gene encodes a transcription factor and several of the core components of the transcription complex include *GATA3*, LIM domain only, and *RUNX1*.

TAL2, residing at 9q32, is detected in the t(7;9)(q34;q32) rearrangement as a result of juxtaposition of *TAL2* to *TCRB*. *LYL1*, originally described as a fusion partner for *TCRB* in(7;19)(q34;p13), is associated with a poor prognosis. Rearrangements of *HOX11L2*, which include cryptic t(5;14)(q35;q32), t(5;7)(q35;q21), and other variants, occur in 24% of children with T-cell ALL and represents

TABLE 57.22 **Frequency of T-Cell Receptor Rearrangements Using Conventional Cytogenetics Versus Fluorescence In Situ Hybridization**

		FISH (%)	
Locus	Conventional Cytogenetics (%)	Total Karyotype	Abnormal Karyotype

a predictor of poor outcomes. Similarly, the presence of t(10;11)(p13;q14), which results in the *CALM-MLL10* fusion gene and occurs in 2% to 5% of children, may be associated with poor outcome. Abnormalities of *HOX11* are more common in adults than in children with T-cell ALL (31% versus 7%) and are associated with t(10;14)(q34;q24) and t(7;10)(q34;q24). t(10;14) is the most frequent chromosomal translocation in patients with T-cell ALL. It is associated with excellent outcome in both children and adults with t(10;14) and in these patients the homeobox gene *HOX11* is fused with *TCRD*. The coding regions of *HOX11* are not disturbed by the translocation. In the variant translocation t(7;10)(q35;q24), *HOX11* is juxtaposed to *TCRB*, which results in overexpression of normal *HOX11* by bringing *HOX11* under the influence of *TCR* promoter sequences.

KMT2A rearrangements are present in 8% of T-cell ALL cases (see Fig. 57.40). The most frequent *KMT2A* translocation partners in T-cell ALL include *ENL*, which results from t(11;19)(q23;p13.3) and is associated with a more favorable prognosis than T-cell ALL with other fusion partners. GEP has characterized T-cell ALL with *KMT2A* rearrangements as a distinct molecular subtype. Homeobox genes, regulators of embryonic development, are known targets of KMT2A and are overexpressed in patients with T-cell ALL and KMT2A rearrangements.

The most predominant oncogenic event in adult T-cell ALL is the aberrant activation of *NOTCH1* signaling through *NOTCH1* activating mutations, rearrangements, or loss of its negative regulator (Chapter 66). Dysregulation of tyrosine kinase genes (*ABL1, JAK2*)

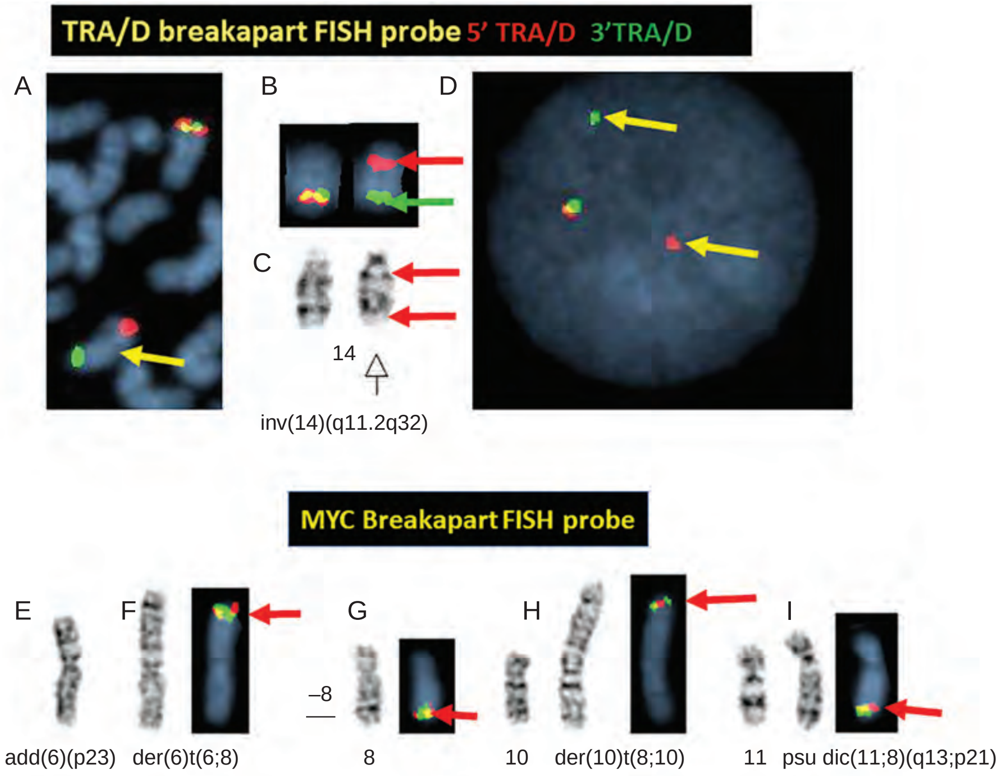

Figure 57.72 REARRANGEMENTS OF T-CELL RECEPTOR (TCR) GENES (TRA/D) AND MYC IN T-CELL MALIGNANCIES. (A) A partial metaphase cell after FISH hybridization with breakapart dual color probe *TRA/D*. Yellow arrow indicates a separation of the 3′ probe red and the 5′ probe *(green)* as a result of inv(14). (B) Isolated a pair of chromosome 14, left shows a normal chromosome 14 with a colocalization of 3′ *(red)* and 5′ *(green)* at 14q32. The right chromosome 14 shows a paracentric inversion with separation of the 3′ and the 5′. (C) An isolated chromosome 14 showing a paracentric inversion (14)(q11.2q32) *(red arrows)*, a characteristic cytogenetic abnormality in T-cell lymphoma. (D) Interphase nuclei after FISH with TRA/D demonstrating a separation of the *TRAD/A* probe *(yellow arrow)* confirming *TCR* rearrangement in a non-diving cell. (E) In addition to the *TCR* rearrangements T-cell lymphoma are characterized by the complex chromosomal rearrangements. This patient, as shown in (F), (G), (H), and (I), had a gain of four copies of 8q as a result of chromosomal abnormalities: der(6)t(6;8)(p25;q13) (F)I, der(10)t(8;10)(q13;p15) (H) and psu dic(11;8)(q13;p21)(I). In each of the 8q rearrangements the *MYC* gene was not rearranged and was present in 4 copies, suggesting a dosage effect. *FISH*, Fluorescence in situ hybridization.

and LIM domain genes (*LMO1, LMO2*) is also common in T-cell ALL. *NOTCH1* is a fusion partner of *TCRB* in t(7;9)(q34;q34.3). These mutations are present in 56% of T-cell ALL cases. The *NOTCH1* gene is important in lymphoid lineage specification, and resequencing of functional domains of *NOTCH1* have revealed that activating *NOTCH1* mutations are present in most primary pediatric and adolescent molecular cases of T-ALL as well as in adult ALL. Mutations in the heterodimer domain as well as ITD result in constitutive ligand-independent activation of *NOTCH1*.

The *LIM* family of genes is found at the breakpoint of rare but consistent chromosomal translocations in T-cell ALL. *LMO1*, located at 11p15, is involved in t(11;14)(p15;q11). *LMO2*, located at 11p13, is involved in t(11;14)(p13;q11) and t(7;11)(q35;p13). As an oncogenic transcription regulator, *LMO2* overexpression in erythroid and T cells leads to an arrest in differentiation, which is a prerequisite for development of T-cell malignancies.

Second in prevalence in T-cell ALL is 9p21 deletions or altered methylation status of *CDKN2A/B* usually accompanied by mutations in *PTEN, NRAS, and P13KCA* genes. Chromosomal rearrangements affecting 9q34 occur in approximately 10% of T-LBL patients compared to 1% to 3% of T-cell-ALL patients and frequently involve t(9;17)((q34;q22–23) rearrangement. The locus at 9q34 includes various oncogenes such as *SET*, *ABL1*, *NUP214*, and *NOTHC1*. Also various T-LBL (Chapter 89) patients have been described to have t(7;14)(p15;q32) aberration in which the TCR gamma chain locus is coupled to the *TCL1A* oncogene.

The *MYB* gene, which is localized on chromosome 6, band q23.3, is rearranged in a rare T-cell ALL subtype observed in young patients (median 2.2 years). Two types of recurrent *MYB* genomic alterations are found in T-cell ALL: (a) a reciprocal t(6;7)(q23;q34) that results in juxtaposition of *MYB* near *TCRB* regulatory sequences on chromosome 7 and (b) a short genomic tandem duplication, identified using genome-wide copy-number analysis. Both rearrangements are cytogenetically cryptic. The breakpoints in t(6;7) are subtelomeric and usually missed. The translocation was discovered using a locus-specific FISH probe for *MYB*. The tandem *MYB* duplication is cryptic using both conventional cytogenetics and locus-specific FISH. LOH 6q is detected in ~13% of T-cell-ALL and 19% of T-LBL. In T-LBL 6qLOH is associated with poor outcome but this was not found to be true for T-ALL. Deletion 6q chromosomal band differs between the two clinical entities, affecting chromosomal band 6q14-15 in T-ALL and 6q16 in T-LBL. 6q deletions are almost exclusively found in patients denoted as TALLMO subtype.

Although only 1% of Ph+ ALL have a T-cell phenotype, the *ABL1 gene* is also involved in fusion with *NUP214* (9q34.11), creating the *NUP214-ABL1* chimeric gene/t(9;22)(q34.11–q22.1), which is identified in up to 6% of T-cell ALLs. This fusion gene is found amplified only in T-cell ALL. When identified with FISH using the *ABL1* probe, it appears as an amplified episome between the chromosomes in metaphase cells, usually showing 5 to 50 copies/cell and is very rarely identified with conventional cytogenetics (Fig. 57.73). The most common fusion gene involves the breakpoint in exon 2 of *ABL1* and the breakpoint in exon 31 of *NUP214*, although variant breakpoints in both genes have been reported. *NUP214-ABL1* is a constitutively activated tyrosine kinase activating similar pathways as *BCR-ABL1* and is sensitive to inhibition with TKIs (nilotinib and dasatinib). These patients usually have homozygous or heterozygous deletions of *CDKN2A* at 9p21 chromosomal site

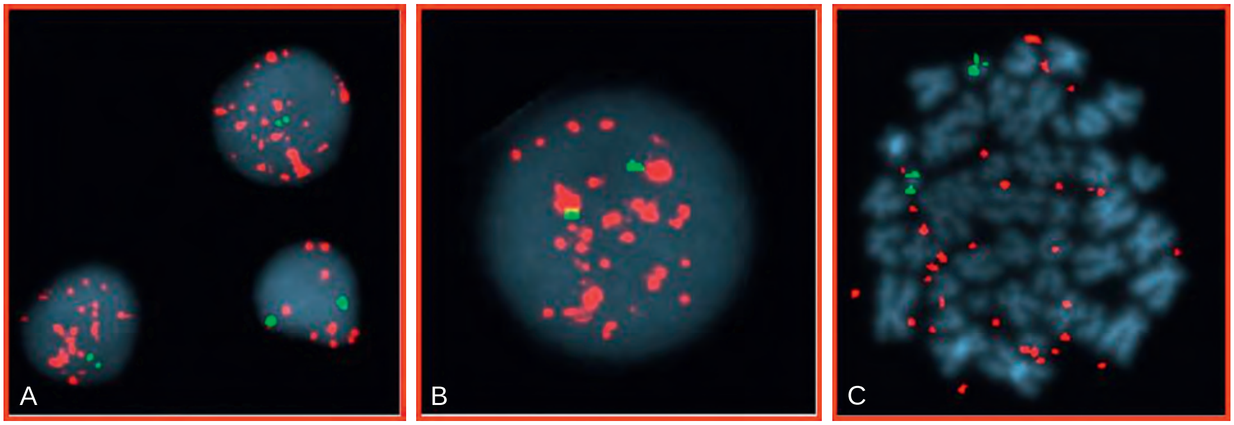

Figure 57.73 *ABL1* AMPLIFICATION IN T-CELL NEOPLASMS. *ABL1* amplification as a result of *NUP214-ABL1* chimeric gene resulting from t(9;22)(q34.11;q22.1) chromosomal translocation in a patient with Ph-positive T-cell acute lymphoblastic leukemia. (A) Three interphase cells showing 2 *BCR* loci *(green)* and numerous copies of *ABL1 (red)*. (B) More than 40 copies of *ABL1 (red)* were identified in this bone marrow nucleus. (C) Approximately 30 copies of *ABL1 (red)* were shown as an amplified episome between the chromosomes in this bone marrow metaphase cell.

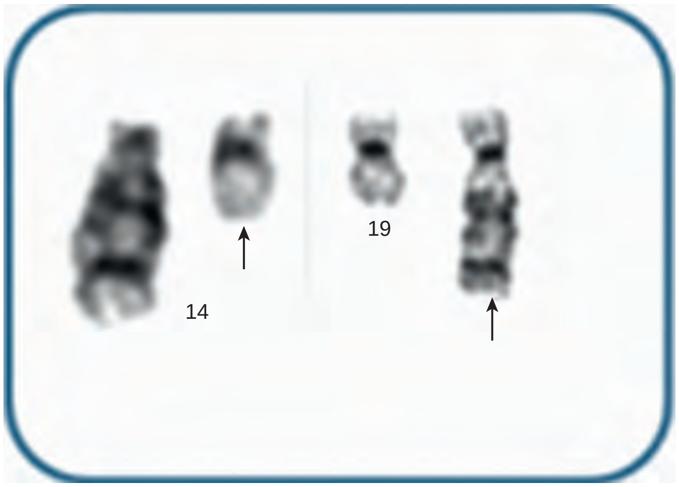

Figure 57.74 A PARTIAL KARYOTYPE FROM A PATIENT WITH T-CELL LEUKEMIA AND t(14;19)(q11.2;q13.1) KARYOTYPE.

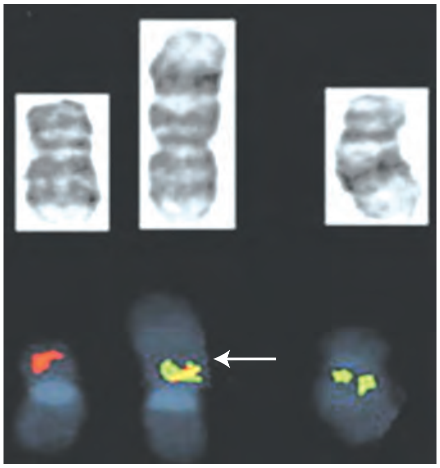

Figure 57.76 JAK-TEL FUSION. Partial karyotype of t(9;12)(p24;q23) *(top)* and after FISH study *(bottom)* with JAK2 *(red)* and TEL/ETV6 *(green)*, showing *JAK2-TEL* fusion *(yellow)* at 9p24.

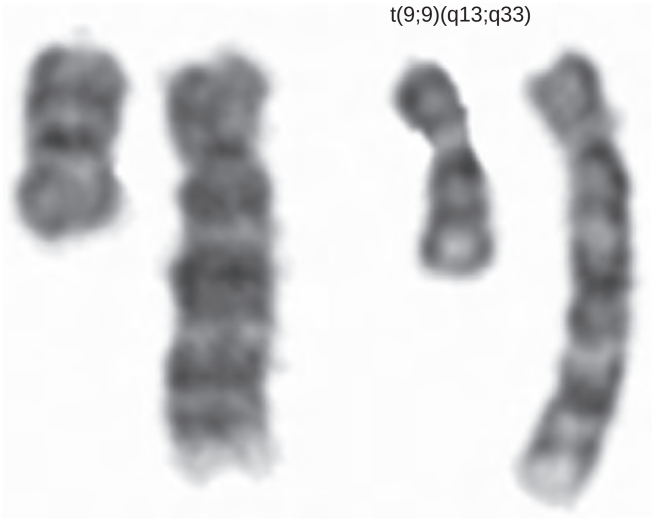

Figure 57.75 A PARTIAL BONE MARROW CHROMOSOME 9 KARYOTYPE FROM TWO METAPHASE CELLS FROM A PATIENT WITH T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA. The rare variant t(9;9)(q22;q34) also results in *SET-NUP214* fusion.

as well as trisomy 8, t(7;10)(q35;q24), or t(10;14)(q24;q11) or (14;19)(q11;q31), indicating that *NUP214-ABL1* is not a primary genetic event (Fig. 57.74). Patients with *NUP214-ABL1* usually present with high-risk T-cell ALL and their outcome is poor. del(9)(q34.11–q34.13) or rare t(9;9)(q34;q34) results in the formation of a *SET-NUP214* fusion gene frequently observed in T-cell ALL (Fig. 57.75). In rare cases of T-cell ALL, *JAK2* has been identified as a partner with *ETV6* in t(9;12)(p24;q13), with *PCM1* in t(8;9) and in multiple amplified copies (Figs. 57.76–57.78), two of the three *JAK2* fusion transcripts seen in other hematologic malignancies (Chapter 72).

Adult T-cell ALL is characterized by an aberrant karyotype in almost 70% of cases and by recurrent acquisition of somatic mutations in 93% (see Table 57.22). The most frequent recurrent molecular lesions observed in adult T-cell ALL include mutations in the following genes: *NOTCH1* (71%), *PHF6* (39.5%), *FBXW7* (18.9%), *DNMT3A* (17.8%), *RUNX1* (15.5%), *PTEN* (10%), *FLT3-IDT* (2.2%), *FLT3-TKD* (1.1%), and *CDKN2A* (3.3%). Combining these data with frequent *CDKN2A/B* deletions and aberrant *CDKN2B* methylation status, 98.9% of adult T-cell ALL have a minimum of one genetic defect. *DNMT3A* and *RUNX1* mutations are preferentially found in early immature T-cell leukemias and are associated with a poor OS.

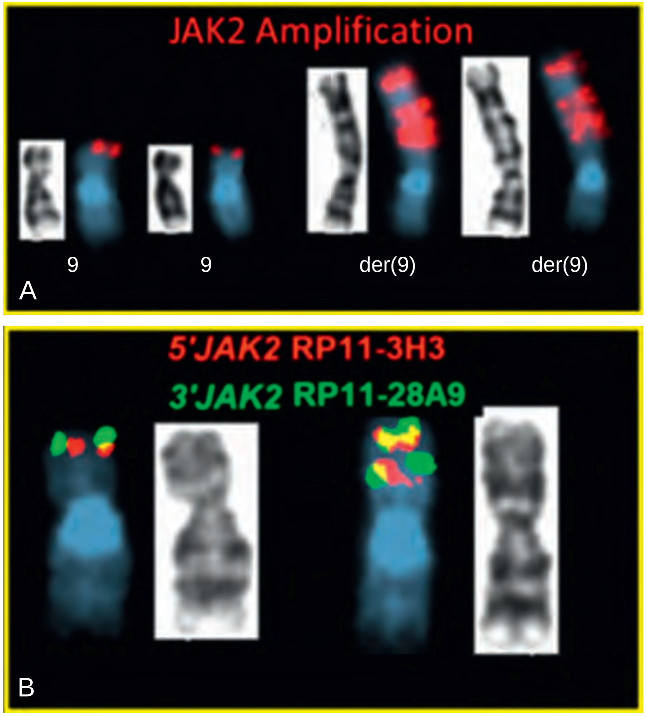

Figure 57.77 GAIN OF *JAK2* IN ADULT T-CELL LEUKEMIA/LYMPHOMA. (A) A partial karyotype of der(9) chromosome from a patient with adult T-cell leukemia/lymphoma showing *JAK2 (red)* amplification. (B) A partial dup(9)(p24) karyotype showing duplication of *JAK2* (*red* is *5′ JAK2*, *green* is *3′ JAK2*).

Early T-cell precursor ALL (ETP) is an aggressive subtype of T-cell ALL that comprises up to 15% of T-cell ALL cases. WGS of 94 T-cell-ALL cases revealed a mutational spectrum similar to AML. ETP ALL is characterized by activating mutations in genes regulating cytokine receptors and RAS signaling (67% of cases: *NRAS*, *KRAS*, *FLT3*, *IL7R*, *JAK3*, *JAK1*, *SH2B3*, and *BRAF*), inactivating lesions disrupting hematopoietic development (58% of cases: *GATA3*, *ETV6*, *RUNX1*, *IKZ1*, and *EP300*), and histone modifying genes (48% of cases: *EZH2*, *EED*, *SUZI2*, *SETD2*, and *EP300*).

MYC translocations identify a genetic subtype of T-cell ALL, which occurs in about 6% of cases, including both children and adults. Two types of translocations have been observed: those involving the *TCR* loci and those with other partners. Specifically, *MYC* translocations were significantly associated with TAL/LMO subtype of T-cell ALL and trisomies for chromosomes 6 and 7. GEP has revealed that *MYC* translocations occur as secondary abnormalities present either in subclones at diagnosis or during disease progression.

In contrast to childhood B-cell ALL, the majority of childhood T-cell ALL cases develop after birth. In utero origin of this form of leukemia is rare.

T-cell CLL and prolymphocytic leukemia is characterized by T-cell leukemia 1 (*TCL1*) gene rearrangements. These include inv(14)(q11q32.1), t(14;14)(q11;q32.1), t(X;14)(q28;q11), and as mentioned above, t(7;14)(q35;q32.1). Approximately 90% of T-CLL and T-PLL have chromosome 14 genomic changes. In these patients *TCL1* is found to be dysregulated. The second most recurrent abnormalities in T-PLL affects chromosome 8 and include idic(8)(p11) t(8;8) and trisomy 8q. Other reported recurrent abnormalities include loss of 11q23 along with additional losses of 6q, 9p, 12p, 13q, 17p, and 22q as well as gains of 22q and 6p. Up to 50% of patients with T-PLL are haplodeficient for *CDKN1B* as a result of 12p13.1 deletion which implicates this gene in the pathogenesis of T-PLL.

Adult T-cell leukemia/lymphoma is associated with human T-cell lymphotropic virus type 1. The most frequent genetic lesions include altered expression of *CDKN2* (cyclin-dependent kinase inhibitor) gene on 9p21 (15% to 20%) and loss of heterozygosity at 6q15 to q21. The most frequent chromosomal abnormalities are gain of 3p, 7q, and 14q and loss of 6q and 13q. Translocations involving 14q32 or 14q11 are frequently observed.

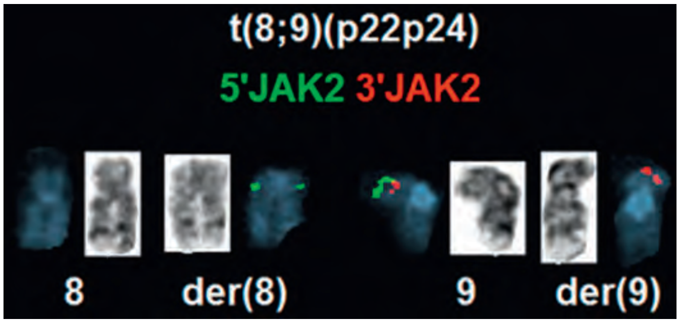

Figure 57.78 t(8;9)/PCM1-JAK2 IN T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA. (T-ALL) A partial karyotype from a patient with T-ALL showing t(8;9)(p22;p24) resulting in *PCM1-JAK2* fusion also observed in patients with Ph-negative myeloproliferative neoplasms. In this translocation 5′ JAK2 *(green)* is translocated from 9p24 to 8p22 using *JAK2* two-color breakapart FISH probe. *FISH*, Fluorescence in situ hybridization.

Natural killer lymphoma/leukemia is a group of highly aggressive lymphoid malignancies of natural killer cell origin. They exhibit chromosomal rearrangements in greater than 80% of cases by conventional karyotyping. The most frequent abnormalities include del(6)(q21–23) and gain of the X chromosome. FISH, CGH, and spectral karyotyping have confirmed the presence of del(6) in $CD3^{-}CD56$ tumor cells. Other less common but recurrent karyotypic changes include isochromosome 1q, 6p, and 17q, as well as del(11q), 13q, and 17p, and trisomy 8.

Angioimmunoblastic T-cell lymphoma and unspecified peripheral T-cell lymphoma (Chapter 89) are the most frequent nodal T-cell lymphomas. Losses of 5q/10q/12q, identified by CGH, characterize a subtype of peripheral T-cell lymphoma associated with a more favorable prognosis. Gain of 11q13 may represent a primary change in angioimmunoblastic T-cell lymphoma. In general, chromosomal imbalances are more common in unspecified peripheral T-cell lymphoma than in angioimmunoblastic T-cell lymphoma. Both disorders may share similar genomic imbalances.

The molecular basis of ALCL is the result of t(2;5)(p23;q35), which fuses part of the *NPM* gene on 5q35 with part of the *ALK* receptor tyrosine kinase gene on 2p23 to produce a chimeric *NPM-ALK* gene (Chapter 85). WHO 2017 recognizes both *ALK*-positive (*ALK*+) and *ALK*-negative (*ALK*−) entities. ALK+, chimeric proteins have activated kinase function. *ALK* is thought to play a direct role in the malignant transformation of lymphoid cells, probably by aberrant phosphorylation of intracytoplasmic substrates. ALCL is a distinct clinical entity, with t(2;5) detected by cytogenetics in 60% to 85% of patients. The *NPM-ALK* fusion can be identified by FISH (Fig. 57.79) and by RT-PCR assay in 88% of pediatric patients and 60% of adult patients. The other cases of ALCL have variant translocations with at least 25 different fusion genes and include rearrangements with *TPM3* (1q24), *EML4* (2p24), *RANBP2* (2q13), *ARIC* (2q35), *TCG* (3q21), *SEC31A* (4q21), *CARS* (11p15), *CLTC* (17q23), *ALO17* (17q25), *TPM4* (19p13), *CLTC1* (22q11), *MYH* (22q11.2), and *MSN* (Xq11). Detection of *ALK* rearrangements by FISH corresponds to a cytoplasmic staining pattern associated with translocations other than t(2;5) in 100% of cases. Recently two copies of *NPM-ALK* and *TPM3-ALK* fusions have been reported in children with an aggressive form of ALCL.

The prognosis of patients with t(2;5) or variant translocations is excellent, with 5-year survival rates of 70% to 90%. By contrast, *ALK*− ALCL is associated with a 5-year survival rate of 40% to 60% and is predominantly a disease of adults (median age 55 to 60 years). The true nature of *ALK*− ALCL remains obscure. Most cases have

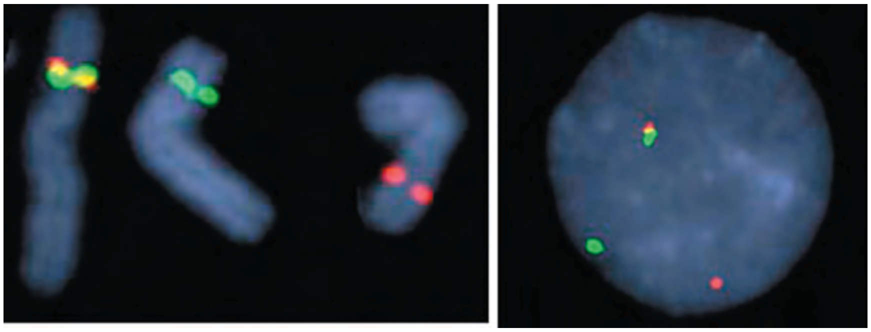

Figure 57.79 FISH STUDY WITH BREAKAPART ALK GENE AT 2P23 IN A PATIENT WITH ANAPLASTIC LARGE CELL LYMPHOMA. Partial karyotype shows a normal chromosome 2 *(left)* with yellow signal, as the 3′ end and the 5′ end of *ALK* gene are in close proximity on chromosome 2. The other chromosome 2 homologue *(middle)* has only a single green signal (5′ end) as a result of t(2;5)(p23;q35), the most frequent translocation in anaplastic large-cell lymphoma. The 3′ end *(red)* of the ALK gene is translocated to 5q35. Abnormal *ALK* gene is also shown in interphase cell *(right)*. *FISH*, Fluorescence in situ hybridization.

clonally rearranged *TCR* genes. Recurrent rearrangements of the *DUSP22-IRF4* locus on 6p25.3 has been identified in about 30% of *ALK*− ALCLs resulting in t(6;7)(p25.3q32.3). Other recurrent rearrangement in *ALK*− cases involves inv(3)(q26q26) resulting in *TBL1XR-TP63* fusion. CGH has shown that *ALK*− ALCL have more complex copy number abnormalities than *ALK*+ ACLC, specifically gains of 1q41-ter, 5q, 6p, 8q, 12q, and 17q and losses of 6q21 and 13q21–22. The interferon regulatory factor 4 (*IRF4*), localized at 6p25.3, is highly expressed in both *ALK*+ and GEP of *ALK*− ALCLs has revealed that *MYC* is the primary target of *IRF4* and essential for ALCL cell survival. Collectively these observations indicate that ALCL is dependent on *IRF4* and *MYC* signaling. Another recurrent alteration, detected in 8% of cases, is rearrangement of the *TP53* homolog, *TP63* (3q23), which is associated with a very poor prognosis. NGS has identified recurrent gene mutations in 18% of ALK− ALCL and they include mutations in *JAK1* and *STAT3* resulting in constitutively activation of the JAK-STAT signaling pathway.

Even though the *ALK* fusion is a key oncogenic event in the pathogenesis of ALK+ ALCL, additional genetic imbalances have been described. By CGH array, 58% of the ALK+ ALCL have chromosomal imbalances including loss of 4q13-q28, 6q13-q22, 11q14-q23, and 13q and gains of 7p11-pter and chromosome 17. By SNP array analysis, ALK+ ALCL displayed losses of 17p13.3-p12 and 6q21 in 35% of the case, and gains of 1q, 7q32.3, and 7p22.3-p21.3 in 15% of samples. The significance of these additional alterations in the pathogenesis of the disease and prognosis is unclear and further studies are required using integrating next generation sequencing approach in order to better define the genomic landscape of ALK+ ALCL.

A variety of genomic rearrangements are seen in the T lymphocytes of patients with mycosis fungoides (MF) and Sézary syndrome (Sz) (Chapter 89). Using aCGH+SNP recurrent copy number abnormalities in Sz include gain of loci on chromosome 17q24 and 8q24 and loss of regions on 17p13 and 10q25, occurring in up to 85% of patients.

Additional evaluation of candidate oncogenes and tumor suppressor genes residing in loci with chromosomal alteration point to dysregulation of the *MYC* oncogene, several of its regulators, and IL-2 receptor signaling pathway components in Sz.

Numerical chromosomal alterations most frequently observed in MF include gain of 7q21–36 and 1p36.2 and loss of 5q13 and 9p21. Amplification of the locus containing the *MYC* gene on 8q24 have been observed in 75% of patients with Sz, but its association with an increased expression of this oncogenic transcription factor is found only in a minority of patients with MF. Interestingly, the most frequently observed CNA, gain of an *MCR* on chromosome 7q36 affecting 59% of MF patients, was associated with an increased expression of the *FASTK* gene. Finally, patients with MF who demonstrated loss of the *MCR* on 9p21, gain 8q24.3, or gain of 1q21–1q22 appear to have significantly poorer survival rates than patients with tumor cells not affected by these CNAs. The integration of high-resolution copy number and gene-expression data has afforded novel insights into molecular genetic alterations underlying MF. Overexpression of *FASTK*, *MCL1*, and *SKAP1* associated with chromosomal gains and reduced expression of *CDKN2A*, *RB1*, and *DLEU1* related to loss are important candidate oncogenic events in MF. In malignant lymphocytes from patients with Sz/MF, *STAT6* (localized at 12q14.1) is constitutively activated. *STAT6* regulates several common pathways in Sz/MF malignant lymphocytes that are associated with control of cell cycle progression and genomic stability.

Post-transplant lymphoproliferative disorder (PTLD) (Chapter 87) is a morphologically diverse group of lymphoid disorders that occurs in immunosuppressed organ transplant recipients. Chromosomal abnormalities are detected in 51% to 72% of B-cell variants and in almost all T-cell variants, as measured by CGH, FISH, and conventional karyotyping. In general, three groups of nonrandom abnormalities are of importance. The pathogenetic roles of abnormalities known to be involved in lymphomas, such as *MYC*, *TP53*, and 18q21 associated with *BCL2* and *MALT1*, and those associated with large genomic imbalances, such as 2p24–25, 9q22–34, 12q22–24, and 14q32, await elucidation. Trisomy of chromosomes 9 and 11 appears to be associated with EBV PTLD and prolonged survival. In contrast, patients with PTLD showing *MYC* rearrangements (about 50%) are associated with BL, an aggressive clinical course. T-cell PTLD develops late after transplantation. These disorders are EBV-negative and are associated with a poor outcome and short survival.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Molecular and cytogenetic analyses can be used to characterize the origin of engrafted cells and the development and evolution of recurrent malignancies after allogeneic HSCT. Hematopoietic cells that emerge after allogeneic HSCT may be of host origin, donor origin, or both. Genetic studies of post-transplant hematopoiesis are termed *chimerism analysis*. Chimerism should be distinguished from mosaicism, which is characterized by two or more different cell populations originating from one zygote. Monitoring chimerism in recipients of allogeneic HSCT is essential to identify early engraftment, monitor residual disease, predict relapse, and optimize post-transplantation therapy in case of graft failure.

Historically, karyotype analyses were used to evaluate engraftment after sex-mismatched allogeneic HCT. Polymorphism of chromosomes 1, 9, and 16, as well as satellite polymorphism of chromosomes 13, 14, 15, 21, and 22, have been used to differentiate donor from recipient cells in sex-matched allogeneic HCT. Karyotype analyses can identify not only chimerism but also recurrence of the hematologic malignancy. However, this is a time-consuming process and has low sensitivity (5%). In the past two decades, many additional methods for detection of chimerism have been developed. All follow the basic principle of using the differences in polymorphic genetic markers to distinguish donor from recipient hematopoiesis. These methods include restriction fragment length polymorphism, red cell phenotyping, and interphase FISH. The most widely used technique is PCR for a variable number of tandem repeats/short tandem repeats (VNTR/STR-PCR). This technique has a sensitivity of 3% to 5%, but the quantitation of donor and recipient cells may be cumbersome. The method that allows study of chimerism in all patients involves fluorescence labeling of the primers and resolution of PCR products with capillary electrophoresis. It provides a high degree of quantitative accuracy with 1% to 5% sensitivity. Real-time PCR or RQ-PCR for analysis of the *SRY* gene on the Y chromosome allows identification of male cells in the background of 100,000 female cells, providing high sensitivity for mixed chimerism. However, this approach is limited to the 50% of patients who receive sex-mismatched transplants. Nevertheless, it remains the most sensitive and the fastest method of chimerism analysis, providing reliable quantitative results within 2 hours.

Detection of SNPs by chimerism analysis (SNP-PCR) is a highly sensitive approach. In one study using 11 different SNP loci, SNP-PCR analysis identified independent predictors of relapse after HSCT. The two most commonly used methods for detection of chimerism after HSCT are fluorescence-based PCR amplification of short tandem repeats (STR-PCR) and interphase FISH. Both methods are accurate and reproducible. The sensitivity of both methods approaches 1%; however, STR-PCR is sex-chromosome independent and can be applied to all patients. FISH analysis, on the other hand, permits simultaneous evaluation of chimerism and residual disease in the same cell when high sensitivity is not a requirement. FISH analysis for diagnostic genomic abnormalities in conjunction with conventional cytogenetics remains useful and reliable in determining the presence of MRD (Fig. 57.80).

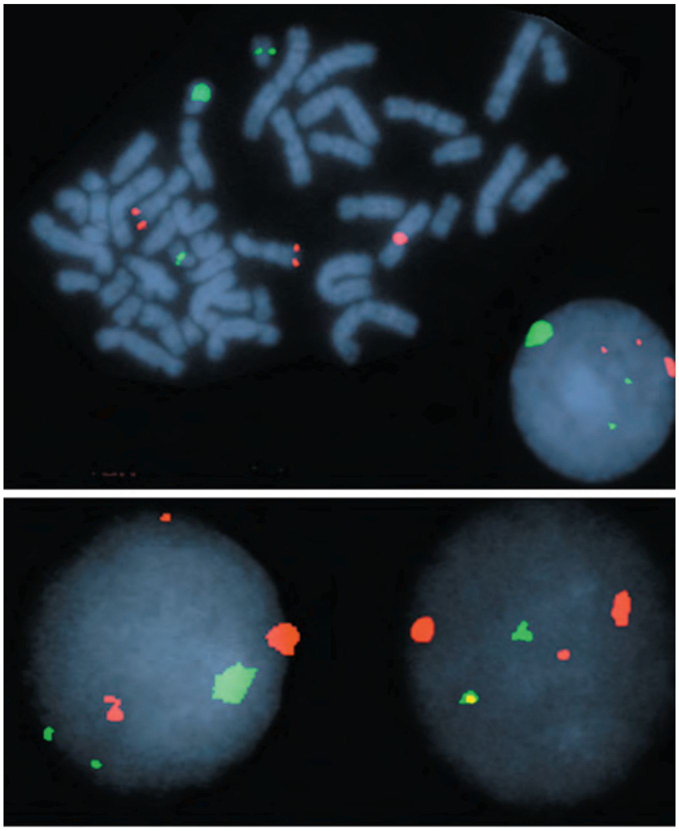

Figure 57.80 DETECTION OF ENGRAFTMENT AND RESIDUAL DISEASE WITH FISH IN SEX-MISMATCHED HEMATOPOIETIC CELL TRANSPLANTATION. Metaphase and non-dividing cell *(blue)* after DAPI counterstaining, hybridized with X *(large red)* and Y *(large green)* for detection of engraftment and with ABL *(small red)* and BCR *(small green)* for detection of residual chronic myelogenous leukemia *(top panel)*. Left nucleus *(bottom panel)* shows a donor male (XY) cell origin and lack of BCR-ABL fusion. In contrast, a host female (XX), BCR-ABL fusion *(yellow)*–positive cell is shown on the *right*. Combination of XY FISH probes with diagnostic genomic markers is a powerful and fast FISH method for simultaneous detection of chimerism and minimal residual disease. *FISH*, fluorescence in situ hybridization.

Donor cell leukemia (DCL) after HSCT is a rare complication occurring in 0.12% to 5% of cases. Careful genetic analysis of relapse cells is essential. VNTR, restriction fragment length polymorphism, STR analysis, or FISH XY analysis alone may not definitively assign the origin of the leukemic clone because genomic deletions or amplifications of chromosomal segments may occur during transplantation or disease progression. The increased use of unrelated cord blood as a source of stem cells for HSCT raises the concern that HSCs containing preleukemic clonal molecular rearrangements may be inadvertently transplanted. Systematic screening of unselected cord blood samples has revealed putative preleukemic rearrangements such as *ETV6-RUNX1* and *RUNX1-RUNXT1*. Cord blood grafts have been reported to be at the highest risk of leading to DCL. The median duration between the occurrence of DCL following cord blood and bone marrow transplantation has been reported to be 14.5 and 36 months, respectively ($P < .0001$). Among 30 patients who developed DCL between 2005 and 2018, an abnormal karyotype involving chromosome 7 were observed in 52.4% of cord blood recipients and 17.3% of marrow recipients ($P < .003$). Patients with DCL generally have a poor prognosis. Proposed mechanisms underlying DCL include: (a) sustained host-origin antigenic stimulation, (b) impaired hematopoietic microenvironment and a defective microenvironmental support system, (c) immune surveillance escape secondary to posttransplant immunosuppressive therapy, (d) similar genetic susceptibility in cases of related donors, (e) viral driven pathogenesis (cytomegalovirus, EBV), (f) delayed effects of conditioning regimens, and (g) transfection of host cell oncogene into donor cells. Most likely, the underlying cause is a combination of these mechanisms operating in individual cases. A very compelling hypothesis underlying DCL is the "2-hit" hypothesis. A donor HSC that has an inherent susceptibility to malignant transformation (hit 1) is placed within a defective microenvironment that elaborates repeated stress signals (hit 2), inducing additional genetic or even epigenetic mutations promoting the appearance of DCL. An examination of every graft prior to transplantation is suggested to determine whether the graft contain abnormal clones (Fig. 57.81).

FUTURE DIRECTIONS

Molecular diversity is the genetic hallmark of many leukemias, lymphomas, and even within a single disease entity such as AML or T-cell ALL. We are at the threshold of understanding additional genetic events, common genetic pathways, and intratumor heterogeneity. Such knowledge is crucial to designing molecular interventions for abnormalities involving specific genetic pathways underlying each hematologic malignancy. It is clear that the genetic revolution has already changed the practice of clinical hematology. Cytogenetics, FISH, aCGH+SNP, and NGS have enhanced the understanding of hematologic malignancies pathogenesis and the origin and evolution of mutations and their temporal sequence, increasing the power for subclassifying these malignancies and allowing earlier diagnosis and more appropriate treatment options. Perhaps most dramatically, the complementary application of these genetic methods has demonstrated intratumor heterogeneity. Nonetheless, modern genomic studies provide a snapshot portrait of the total DNA within the tumor along with a mixture of normal and abnormal cells. Systematic interrogation of subclonal genetic complexity and clonal architecture or phylogeny currently poses a technical challenge because three categories of mutational change—fusion genes, CNVs, and SNPs—need to be identified in a single cell. Currently, we are at the threshold of revolutionary impact of novel single cell technologies which in the near future will provide evidence of single cell tracking, spatial and temporal transcription atlas, as well as the ability to probe the epigenetic landscape at the single cell level. The challenge remains to translate this large body of data into easily interpretable results accessible to the hematologist for the purpose of more accurate and effective therapies.

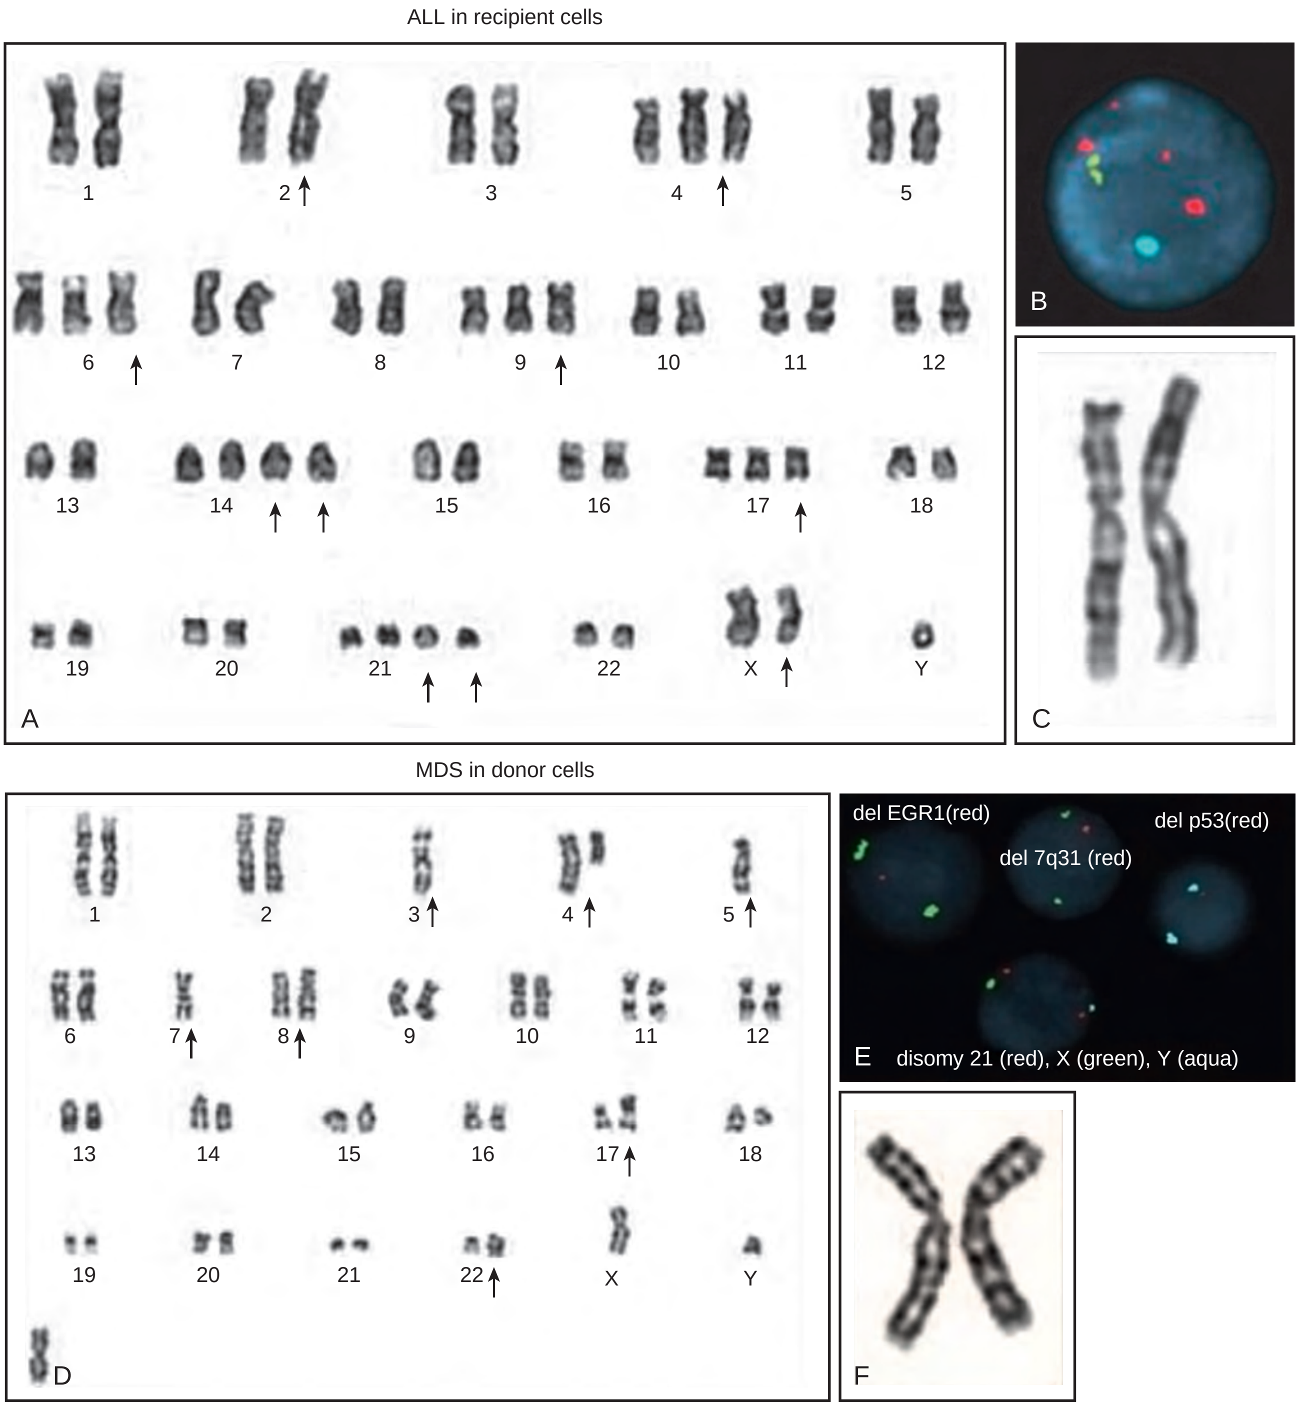

Figure 57.81 DONOR-DERIVED MYELODYSPLASTIC SYNDROME FOLLOWING CORD BLOOD TRANSPLANTATION IN ACUTE LYMPHOBLASTIC LEUKEMIA. (A) At diagnosis of acute lymphoblastic leukemia, in January 2006, cytogenetic analysis of bone marrow revealed a 56, XY, +X, inv(2)(p11.2q13), +4, +6, +9, +14, +14, +17, +18, +21, +21 hyperdiploid karyotype (*arrows* indicate abnormal chromosomes). (B) A bone marrow nucleus from a specimen obtained in January 2007 after FISH showed 5% of cells with tetrasomy 21 *(red signals)*, two copies of X chromosome *(green signals)*, and one copy of Y chromosome *(aqua)*. (C) A partial karyotype of chromosome 2 from the peripheral blood specimen, PHA-stimulated for 72 hours, obtained in May 2006, showing a constitutional inversion (2)(p11.2q13). (D) At the time of the diagnosis of MDS in May 2011, bone marrow cytogenetic analysis revealed 65% of cells with a 44, XY, −3,del(4)(q23q33), der(5;17)(p10;q10), −7,t(8;22)(p21;q13), +mar karyotype (arrows indicate abnormal chromosomes). (E) Five bone marrow nuclei after FISH studies from the June 2011 specimen showing 75% cells with deletion of *EGR1* at 5q31 chromosomal location *(red)* and deletion of P53 at 17p13.1 chromosomal localization *(red)* as a result of der(5;17); 71% showing a loss of 7q31 locus as a result of monosomy 7, as well as disomy 21 *(red)*, one X *(green)*, and one Y *(aqua)* chromosome. (F) A partial bone marrow karyotype of chromosome 2 from May 2011 specimen showing a normal chromosome 2 from the donor cells and absence of inv(2) observed in the bone marrow and PHA-stimulated PB at the time of diagnosis . *FISH*, Fluorescence in situ hybridization. *(Reproduced with permission from Cotter R, Najfeld V, Isola L, et al. CHAPTER 58

PHARMACOLOGY AND MOLECULAR MECHANISMS OF ANTINEOPLASTIC AGENTS FOR HEMATOLOGIC MALIGNANCIES

Stanton L. Gerson, Paolo F. Caimi, Ehsan Malek, and Benjamin Tomlinson

The treatment of patients with hematologic malignancies has been revolutionized over the past decades as new therapeutic targets continue to be identified through cellular and molecular studies of these conditions. These investigations have spawned the discovery, clinical evaluation, and US Food and Drug Administration (FDA) approval of new mechanistic-based therapeutic agents. A surprising number of these agents have progressed rapidly from the discovery phase to validation, animal modeling, and successful clinical testing. The results have led to an explosion in the therapeutic armamentarium and an increase in the spectrum of drugs, including small molecules, monoclonal antibodies, radiolabeled antibodies, drug immunoconjugates, immunotoxins, and complex delivery systems. This chapter provides information on new and existing therapeutic agents available for the treatment of patients with hematologic malignancies. The chapter reviews the "classic" agents as well as the newly developed, target-based agents. Both cytotoxic and growth-inhibitory agents are covered; however, the use of therapeutic antibodies and antibody conjugates is reviewed within the chapters dealing with specific diseases.

TUMOR CELL HETEROGENEITY OF HEMATOLOGIC MALIGNANCIES

Whereas hematologic malignancies are of clonal origin (i.e., they are derived from a single transformed cell), individual neoplastic cells from a patient's malignancy exhibit a great deal of phenotypic diversity and acquire secondary mutations that affect proliferation, drug sensitivity, and resistance. This diversity likely arises from the progeny of clonal populations and subsets of stem cells. In animal models, it has been shown that the clones themselves can give rise to progeny that can transmit the clonal malignancy after transplantation into secondary recipients, suggesting that stem cells are not required to transmit the malignant phenotype.

New evidence indicates that leukemia stem cells are more quiescent, have higher levels of protective proteins such as efflux pumps for drugs, and have higher levels of DNA repair proteins or antiapoptotic proteins than the more abundant cell making up the circulating population of cells. Tumor cell heterogeneity arises as a consequence of spontaneous mutational events, changes in gene promoter methylation, abnormal expression of transcription factors, lymphoid reactivity, and cytokine responsiveness. For example, a mutation or change in expression that renders a hematopoietic cell clone autonomous or growth factor–independent would be expected to render such cells less susceptible to adverse environmental conditions (e.g., growth factor withdrawal). Similarly, one would also predict that a genetic change facilitating cell cycle entry or disruption of cellular maturation would ultimately lead to overgrowth of affected clones. For obvious reasons, mutations that interfere with drug metabolism or the cell death pathway itself would provide a net survival advantage, particularly under the selection pressure of cytotoxic drug treatment.

Malignant myeloid and lymphoid cells have many reasons to have increased mutational rates. Genomic instability can arise from dysregulation of the cell cycle machinery because of a number of events, including perturbations of cyclins leading to MYC overexpression; AKT (protein kinase B) activation; disruption of replication sequences; loss of DNA repair enzymes such as mismatch repair (MMR) enzymes; loss of proper homologous recombination from a defect in the BRCA (BReast CAncer gene 2)–Fanconi pathways; and loss of ATM (ataxia telangiectasia mutated)/ATR (ataxia telangiectasia and Rad3 related) kinases, which can give rise to chromosomal recombination, loss, and microsatellite instability, and loss of checkpoint regulation. These events can give rise to intraclonal emergent point mutations, translocations, and intragenic losses that might not only result in malignant transformation, but also lead to disruption of genomic stability and selection in favor of proliferative and apoptosis-resistant subclones. Leukemic clonal evolution favors drug resistance.

Common mechanisms may be involved in events associated with malignant transformation and the development of mutations that result in tumor heterogeneity. For example, the cell cycle checkpoint and tumor suppressor gene, *TP53*, is induced during DNA damage, leading to G_1 arrest and, if the damage is too severe to repair, cell death by apoptosis occurs. The presumed goal of this process is to eliminate cells that develop deleterious mutations as a result of damage to the genome. Loss of *TP53* may not only increase cellular survival by inhibiting the cell death process, but may also promote the transmission of mutations that would otherwise be deleted. In this manner, a defect of the cell death pathway can have multiple consequences, including (1) selection of cells exhibiting a growth advantage over their normal counterparts, (2) development of drug resistance, and (3) promotion of mutations that result in either (1) or (2), as well as neoplastic cell heterogeneity. Age-dependent changes in these processes may explain the more favorable behavior of leukemias and lymphomas in response to chemotherapy in young patients than older patients.

A model of the relationship between tumor growth rate, the occurrence of spontaneous mutations, and the development of drug resistance was first described by Goldie and Coldman and is referred to as the Goldie and Coldman hypothesis. In this model, the size of a tumor depends on a complex interaction between tumor growth rate and cell loss, the latter stemming from the status of the cell death process, exhaustion of available nutrients, and outstripping of the blood supply. As tumors increase in size, the cell death rate tends to increase. The heterogeneous nature of additional mutations makes it likely that multiple mechanisms of resistance will develop as well. From an operational standpoint, this model has clear implications for the rational design of therapeutic strategies and provides a basis for early and intensive combination drug therapy. The successful implementation of this strategy is exemplified by the administration of dose-intensive multidrug regimens (i.e., the BEACOPP [bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine (Oncovin) procarbazine, and prednisone] regimen in Hodgkin lymphoma, CODOX-M-IVAC [cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate alternating with ifosfamide, etoposide and high-dose cytarabine] in Burkitt lymphoma [non-Hodgkin lymphoma (NHL)]) and combinations of cytotoxic agents with monoclonal antibodies, such as CHOP (cyclophosphamide, hydroxydaunorubicin, vincristine [Oncovin], and prednisone)–rituximab, which are potentially curative when given early in the course of the disease. Other examples include combined use of multitargeted agents such as lenalidomide and bortezomib for myeloma, fludarabine, cyclophosphamide and rituximab for chronic lymphocytic leukemia (CLL), or maneuvers to overcome resistance of pretreated disease outside of cell-based therapies. However, as predicted by the model, administration of these or other intensive regimens in patients with relapsed or late-stage disease generally fails because of a generalized resistance of tumor cells to all classes of chemotherapeutic agents.

DEVELOPMENT OF CHEMOTHERAPEUTIC AGENTS

The quest for anticancer agents for hematologic malignancies began with the nitrogen mustard class of compounds developed from the chemical warfare agent sulfur mustard gas used in World War I. Since that time, the National Cancer Institute (NCI) and the pharmaceutical industry have developed complex approaches to drug development, screening, and evaluation. Initial screening consisted of toxicity assessment against murine tumor cell lines. Currently, screening is directed toward numerous cell targets, including receptor and downstream signaling kinases; inducers of cell death pathways, including those at the cell surface; mitochondrial enzymes; nuclear DNA and DNA replication, processing and repair proteins, including base excision repair (BER), poly ADP ribose polymerase (PARP), checkpoint kinase 1 (CHK1), topoisomerases, and telomerase; and inhibitors of histone deacetylase (HDAC) and histone methylation, cell cycle proteins, proteasomes, and the mitosis and spindle machinery. Therapeutic agents targeting microenvironment, angiogenesis, and immune checkpoints round out the spectrum of therapeutic approaches. Whereas killing cells had been the backbone of chemotherapeutic approaches to human malignancies, the field of antineoplastic agent development, which in the first decade of the 21st century was at a tipping point, has now embraced novel targeted and highly effective compounds that block the function of specific kinases with surprising efficacy, even at late stages of disease. Ultimately a balanced approach is likely, with much more precision in drug selection, use of mechanism-based combinations, and attention toward and anticipation of tumor heterogeneity, complex subclonality, and emergence of predictable resistance patterns that dictate proactive drug selection and utilization.

Examples include Bruton tyrosine kinase (Btk) and phosphatidylinositol 3-kinase (PI3K) inhibitors in lymphoid malignancies as well as Janus kinase (JAK) inhibitors for treatment of myelofibrosis and polycythemia vera. A number of differentiating agents (including methyltransferase inhibitors altering DNA methylation and gene expression), kinase inhibitors, and immunomodulatory and cytostatic agents complete the antineoplastic armamentarium. The field of drug development also has to contend with much more complex assessments of toxicities due to both on- and off-target effects, as well as normal tissue effects. In the sections that follow these toxicities will be noted because they restrict the utility of many drugs and toxicities need to be monitored when using new drug combinations.

Screening for Antitumor Activity Among Chemotherapeutic Agents

Identification of critical targets for therapy in cancer cells and the microenvironment starts with the recognition of a known or novel target that appears critical for cancer development, dormancy, growth, or metastasis. The NCI Division of Cancer Treatment has a well molecularly characterized cell bank of malignancies that are available for new drug screening. A more contemporary cell line resource is the Cancer Cell Line Encyclopedia (CCLE), developed to assist in drug analysis. It is a compilation of gene expression, chromosomal copy number, DNA sequence, and RNA data from 947 human cancer cell lines collected across databases and repositories. Many cell lines have drug sensitivity profiles from more than 20 anticancer drugs. Both academia and pharma utilize high-throughput gene knockdown (shRNA and siRNA) library approaches, drug screening using large compound libraries, and in silico screening based on protein and drug structures for docking analysis. Repurposed drugs that are FDA approved or for which there are extensive data provide a rich resource for lead compound identification. Medicinal chemistry can then be applied to improve potency and specificity, solubility, kinetic profile, and tissue penetration and residence. For instance, to screen for a kinase inhibitor, cells overexpressing an activated kinase may be used. After an initial in vitro screen, human tumor cell activity is evaluated using a series of athymic mouse xenograft studies targeting tumors from tissues that show promise in in vitro assays. More informative data is generated from banks of patient-derived tumor cell lines, often using Rho-associated kinase (ROCK) inhibition, and using patient-specific tumor xenografts for drug screening. These in vivo models consist of primary malignancies grown in immunodeficient mice, typically NSG (NOD [non-obese diabnetic] scid gamma) mice. Some genetically engineer mice to express needed human cytokines that promote leukemic cell growth, or reconstitute mice with a human immune system to evaluate immunomodulatory drugs and cell-based immune responses. Another model system mimics the human disease by establishing mice with specific chromosomal translocations and oncogene mutations found in human cancers. Drug efficacy endpoints are complex, since target effects may produce cell death, senescence, apoptosis, differentiation, polyploidy, inhibition of metastasis, and loss of cancer stem cell populations. Drugs with promising efficacy and novel mechanisms of action then go on to formulation and toxicology testing, and are ultimately developed for phase I clinical testing through academic centers, industry, or the NCI Cancer Therapy Evaluation Program. Effective drug screening includes evidence of target effect specificity and potency, consideration of effects across tumor types, recognition of predictors of sensitivity and resistance that depend on the mechanism of action and known pathways of resistance, characterization of genetic changes associated with resistance and acquired resistance, and pharmacokinetic preclinical analysis. In all instances, animal studies often fail to provide accurate prediction of therapeutic efficacy, pharmacokinetics, emergence of resistance, or even toxicities.

Variants of patient-derived and specific tumor xenograft (PDX) models, which allow for direct passage of human tumors in mice, include orthotopic models that assess the tissue microenvironment for tumor growth and drug efficacy, metastatic models that allow for removal of primary tumor and metastasis to the brain, lungs, and bone, and direct implantation and metastasis, for instance into colon, spleen, or marrow sites.

Phase I Clinical Trial Design

New anticancer agents are assessed through a series of clinical trials termed *phase I*, *phase II*, and *phase III* (Table 58.1). The purpose of phase I clinical trials is to establish the safe and optimal biochemically active dose of the compound in question with acceptable toxicity that can be used in disease-targeted phase II testing. During phase I development, pharmacokinetics and pharmacodynamic measures are studied in detail so that appreciable information can be forthcoming from the very first set of patients targeted for treatment and to allow confirmation of these observations in larger phase II disease-focused trials. Dose schedule and route of administration are key considerations in early phase I development. Numerous considerations have guided dose-escalation strategies that accompany phase I trial development. The starting dose is typically 10% of the lethal dose in animals adjusted for species dose equivalency. In classic phase I development, a modified Fibonacci dose schedule is used. Groups of three patients are treated at each of the following doses until the maximum tolerated dose is observed: 1N (N, the starting dose), 2N, 5N, 7N, 9N, 12N, and 16N. Typically, the maximum tolerated dose is defined as the maximum dose not causing irreversible toxicity of any type and causing less than grade 4 toxicity in any organ. Newer agents often have off-target toxicities, and these complicate drug evaluation because the dose-dependent toxicities are replaced by rashes, cardiac effects from prolonged QTc intervals, activation or inhibition of other pathways, and unusual side effect profiles such as pleural and pericardial polyserositis. Typically, if one dose-limiting toxicity is observed, the patient cohort is expanded to six patients, and if two patients develop dose-limiting toxicity, typically defined as grade 4 toxicity except as

TABLE 58.1 Clinical Trial Design

Phase	Patient number	Objective	Patient population	Dosing	Comments
0	Limited. Usually up to 20.	• Feasibility • Pharmacokinetic analyses	Eligible subjects may have different diseases	Limited dosing Usually under therapeutic threshold	Phase 0 trials in oncology are infrequent
I	20 to 200	• Dose finding (maximum tolerated dose) • Recommended phase II dose (RP2D) • Safety profile of drug or drug combination • Pharmacokinetic and pharmacodynamic analyses • Very early efficacy signals	Eligible subjects from one of several cancers vs. studies restricted to a group of disease or a single disease	Escalating doses Range from therapeutic to supra-therapeutic dosing	Classic and adaptive designs available
II	50 to >100	Early efficacy signals. Disease response, survival and progression Extended safety profile Administration schedule evaluation	Eligible subjects restricted to one or few disease targets	Most often fixed dose at therapeutic range May have one or more dosing schedules	Classic and adaptive designs available Randomized phase II trials may be done
III	100 to >1000	• Definitive efficacy signals • Comparison with an accepted standard of care	Eligible subjects restricted to one or few disease targets	Most often fixed dose and schedule Done at therapeutic range	Most frequently are randomized, may be placebo controlled and blinded
IV	100 to >1000	• Post regulatory approval evaluation • Long-term efficacy and safety	Eligible subjects restricted to one or few disease targets	Most often dosing at approved range	Usually observational No randomization

previously noted, then further entry at this dose is not pursued, and the next lower dose level is used to establish the maximum tolerated dose with a total of six patients accrued at that dose level.[1]

Alternative strategies of drug escalation have included the use of toxicity grades to enhance dose escalation in early drug development, allowing that if no toxicity is observed, fewer patients might be accrued to each dose. Using the modified Fibonacci scheme, one patient is entered at each dose level until grade 2 toxicity is observed, at which point cohorts of three patients are entered at each level. Early in drug development, level skipping may take place if no toxicity is observed. The overall impact of this is to reduce the number of patients treated at suboptimal doses of therapy and to increase the number of patients evaluated at biologically active doses. Other dose escalation strategies include Bayesian optimized interval design studies, which permit variable cohort size and incorporate methods to dose escalation of two drugs in combination.[2]

More importantly, biomarker-driven studies can be used to optimize inhibition of the target rather than treating to toxicity. This can then be extended in phase II to determine whether the drug effects on its biochemical target correspond to efficacy and tolerance.

Phase II Drug Development

Phase II drug development uses the dose established in phase I to evaluate therapeutic efficacy. Early phase II studies are conducted typically in a two-stage design, whereby a certain number of responses need to be observed in the first stage to proceed to full trial accrual.[3,4] Modifications include seamless phase Ib/II designs in specific diseases with dose escalations and efficacy assessments in a disease-specific manner. Phase II combination therapies optimize therapeutic efficacy, often with dose escalation of one or both agents. For instance, topotecan was found in phase I testing to have efficacy against refractory leukemias, leading to combinations of topotecan with ara-C. When a new agent is combined with an established agent, the new agent undergoes dose escalation. In the past, strategies for combination chemotherapeutic agents have included the use of non–cross-resistant agents with nonoverlapping toxicities. Mechanism-based therapeutic combinations have been more successful. In rare diseases, and now with genomic-driven studies, randomized phase II trials in a specific disease comparing standard to novel therapy can be used as evidence for drug approval, a “registration” trial.

Phase III Clinical Trials

Most phase III trials randomize patients between an established standard therapy and a new therapy that has appeared promising in the phase II setting. These studies are usually multi-institutional, and many involve large national (e.g., National Clinical Trials Network) and international cooperative groups. The endpoint of these studies is disease response, time to progression (TTP), survival, and patient tolerance. Phase III trials are often registration trials designed with the FDA and intended to guide drug approval for a disease indication. All trials must have rigorous objective data collection, safety and quality review, and reporting. All clinical trials should be registered at clinicaltrials.gov with public reporting of results.

TRADITIONAL CYTOTOXIC ANTINEOPLASTIC AGENTS TARGETING THE CELL CYCLE AND DNA

Targeting Tumor Cell Growth Kinetics

Malignant hematopoietic cells proliferate more and differentiate less than their normal counterparts. The cell cycle consists of a series of stages through which normal and neoplastic cells proceed during the course of cellular replication (shown schematically in Fig. 58.1). The cell cycle is divided into G_1 (pre-DNA synthetic phase), S phase (in which DNA replication takes place), G_2 (post-DNA synthetic phase), and mitosis (M), during which chromosomal division and segregation occur. In addition, nonproliferating, resting cells reside in G_0, a phase that may theoretically last for an indefinite period. Such cells remain in G_0 until they are induced to cycle (at G_1) by specific triggers (e.g., hematopoietic growth factors). The growth fraction of a tumor represents the percentage of cycling cells relative to the total cell population. The generation time represents the time required for a cell to proceed through a single cell cycle (generally 24 to 36 hours for hematopoietic tissues). Surprisingly, in the case of acute myeloid leukemia (AML), the generation time of leukemic blasts is not shorter than that of normal hematopoietic progenitors and may be longer. The proliferative advantage of malignant hematopoietic cells (and of many nonhematopoietic tumors) stems, at least in part, from the fact that a higher percentage of cells are in cycle at any one point

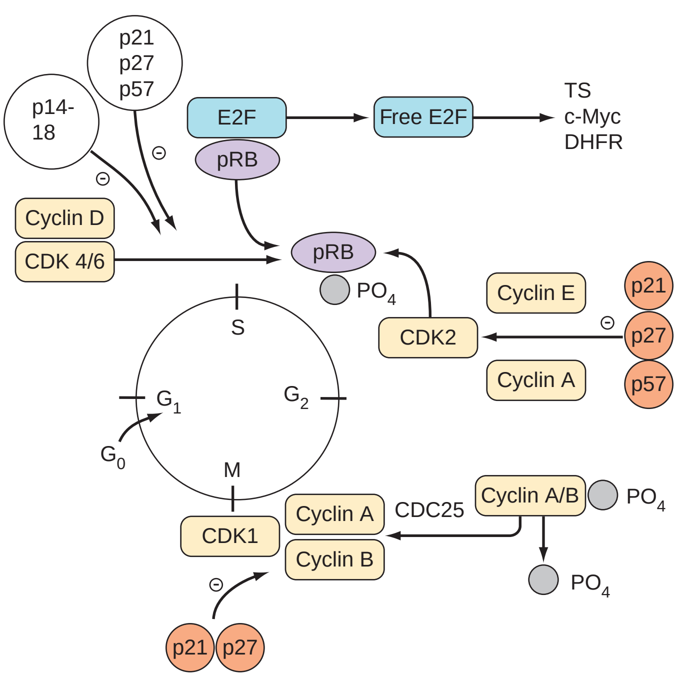

Figure 58.1 Progression through the cell cycle is controlled through complex interactions among cyclins, cyclin-dependent kinases, and cyclin-dependent kinase inhibitors. Progression across the G_1S interface and through S phase involves the E2F transcription factor, which activates numerous enzymes (e.g., thymidylate synthase, dihydrofolate reductase) required for DNA replication. The pRb in its dephosphorylated state binds to and inactivates E2F in conjunction with DP proteins, thereby inhibiting S-phase progression. Conversely, phosphorylation of pRb antagonizes binding to E2F allowing S-phase events to proceed. Phosphorylation of pRb results from activation of (1) CDK2:cyclin A/E and (2) CDK4/6:cyclin D complexes. The former complexes are inhibited by the CDK1s p21, p27 (and p57), and the latter are inhibited by the low-molecular-weight CDK inhibitors (p14–18) but also by p21 and p27. The complex formed by CDK1 ($p34^{cdc2}$) and cyclins A and B regulates G_2M progression and is inhibited by the "universal" CDK inhibitor, p21. Moreover, its phosphorylation status, which plays a major role in determining activity, is regulated by the phosphatase cdc25. Proteins such as pRb, E2F, p21, and p27 can influence the response of cells to chemotherapeutic agents by controlling cell cycle progression and possibly via cell cycle–unrelated actions. *CDK*, Cyclin-dependent kinase; *CDK2*, cyclin-dependent kinase-2; *DHFR*, dihydrofolate reductase; *pRb*, retinoblastoma protein; *TS*, Thymidine synthase.

in time (i.e., the growth fraction is higher). The doubling time represents the period required for a tumor to double in mass and is, in general, inversely related to the tumor's growth fraction. Tumor-doubling times range from longer than 120 days in the case of some solid tumors (e.g., lung and colon) to less than 2 weeks (in some leukemias and lymphomas). Tumors with high growth fractions and short doubling times tend to be more sensitive to chemotherapy than slowly growing neoplasms with low growth fractions and long doubling times.

Cell cycle progression is governed by a complex network of proteins consisting of cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors. Progression through S phase is regulated primarily by CDK2 in association with cyclins A and E; progression through G_2M is regulated by CDK1 (p34cdc2) and cyclins A and B; and progression through G_1 involves CDKs 4 to 6 in conjunction with cyclin D. CDK inhibitors fall into two major categories: the low-molecular-weight inhibitors (pINK14, -15, -16, -17, and -18), which primarily inhibit cyclin D (and to some extent, CDK2) complexes, and the higher molecular-weight inhibitors, p21, p27, and p57, which are more universal in their actions and inhibit most or all CDKs. Signals for the progression of cells through G_1S are essential for maintenance of the neoplastic phenotype. In the commonly accepted model of G_1S progression, inactivation of the retinoblastoma protein (pRb) is required. In quiescent cells, pRb is in an active dephosphorylated state and bound to the transcription factor E2F. Phosphorylation of pRb by CDK4, CDK6, and CDK2 leads to release of E2F, which is then free to activate diverse genes essential for S-phase progression, such as MYC (also known as c-Myc), TS (thymidylate synthetase), and DHFR (dihydrofolate reductase). Conversely, induction of CDK inhibitors (e.g., by transforming growth factor-β [TGF-β] or differentiation-inducing agents) results in inactivation of CDK4, CDK6, and CDK2, dephosphorylation of pRb, inactivation of E2F, and inhibition of the progression through S phase. Aberrant expression of cyclins and CDK inhibitors is commonly encountered in hematopoietic malignancies.

In addition to growth control, cell cycle proteins are intimately involved in the regulation of programmed cell death (apoptosis) and checkpoint control mechanisms. Consequently, cell cycle regulatory proteins can exert a major influence on the response of neoplastic cells to cytotoxic agents. For example, when cells undergo DNA damage, they may arrest in G_2M or G_1, during which repair occurs, or if the damage is too severe, the cells undergo apoptosis. In particular, the tumor suppressor gene TP53 and its downstream inducible target p21 have been implicated in the G_1 arrest process after genotoxic insult. Dysregulation of various cell cycle regulatory proteins can have a major impact on the sensitivity of neoplastic cells to chemotherapeutic agents. Loss of the TP53 gene renders cells resistant to diverse chemotherapeutic agents, presumably by preventing cells from undergoing repair in G_1 and thereby inhibiting the cell death processes and allowing DNA damage to accumulate, culminating in cellular transformation. Conversely, transfection of P53-negative cells with wild-type P53 restores responsiveness to most drugs. Dysregulation of the CDK inhibitors p21 (a downstream target of P53) and p27 increases the sensitivity of neoplastic cells to various cytotoxic agents, possibly by uncoupling S-phase progression and mitosis. After DNA damage, checkpoints block the cell cycle, but loss of the CDK inhibitors p21 or p27 prevents cells from arresting in G_1 and cells die during G_2M. Mutations in the E2F protein have been shown to lengthen S phase and increase the sensitivity of malignant cells to S-phase–specific agents. Furthermore, cells lacking functional pRb have been shown to be significantly less sensitive to the actions of antimetabolites, including methotrexate.

In vivo the growth of tumors is limited by various factors such as vascular supply, nutritional requirements, and possibly physical restraints. Consequently, the rate of tumor growth declines as the number of cells increases. To the extent that tumor-doubling times are inversely correlated with drug responsiveness, large, late-stage tumors are less susceptible to cytotoxic drugs than early-stage tumors, with higher growth fractions. Most chemotherapeutic drugs kill by first-order kinetics. The implication of this phenomenon is that it requires the same drug dose to reduce the number of tumor cells from 10^4 to 10^1 cells as it does to reduce the tumor burden from 10^{10} to 10^7 cells.

Hematopoietic malignancy-initiating or stem cells, such as leukemia stem cells, appear to explain resistance and treatment failure. These cells express high levels of hematopoietic stem cell proteins and markers and are resistant to cell cycle–specific agents because of an increase in quiescent cell populations. They overlap with normal hematopoietic stem cells (HSCs) and there appears to be a set of HSCs that contain preleukemic-promoting mutations that both predispose and may be sufficient for conversion to leukemic stem cells. The proteins expressed by these cells have become targets of therapy, including alterations in DNA damage, quiescent cell cycle factors such as the thrombopoietin receptor, MPL, stem cell proliferation signals such as NOTCH and WNT protein families, and niche occupancy proteins such as KIT.

Cytotoxic agents may be divided into several categories with respect to their effects on the cell cycle or the cell cycle specificity of their actions, or both.

1. *Noncycle-active drugs* kill both cycling and noncycling cells in all phases of the cell cycle. Examples include steroids and antitumor antibiotics (except bleomycin).

2. *Cycle-active, nonphase-specific drugs* are more active against cycling cells and can kill cells in each phase of the cell cycle. However, such drugs may preferentially kill cells in a particular phase of the cell cycle. Examples include alkylating agents, cisplatin, and 5-fluorouracil (5-FU).
3. *Cycle-active, phase-specific drugs* primarily kill cells in a specific phase of the cell cycle. Examples include most antimetabolites, which are active against cells engaged in DNA synthesis (S-phase cells), and microtubule-active drugs (e.g., vinca alkaloids, taxanes), which kill cells in G_2M.

An example of a cytokinetically rational approach to chemotherapy involves the combination of a noncycle-active agent (e.g., daunorubicin) with a cycle- and a phase-specific agent (e.g., ara-C, fludarabine, decitabine, gemcitabine, clofarabine, and nelarabine). From a theoretical standpoint, administration of a noncycle-active agent may reduce tumor mass, leading in turn to an increase in the growth fraction caused by recruitment of cells into cycle. Such cells would then be more susceptible to a cycle- and phase-specific agent, particularly one administered over a prolonged interval. In the case of hematopoietic malignancies, attempts have been made to recruit neoplastic cells into the more susceptible S phase of the cell cycle through the use of hematopoietic growth factors. The success of such a strategy has been limited because of several factors, including the inability of growth factors to increase the S-phase fraction significantly, the lack of selectivity of this strategy, and the theoretical possibility that growth factors may protect neoplastic cells from apoptosis.

Unfortunately, cytokinetic differences between normal and neoplastic tissues have been difficult to exploit. Both normal hematopoietic stem cells and hematologic malignant stem cells have a low proportion of cells in G_1. However, prolonged dosage schedules can provoke these malignant cells into cell cycle and may explain their efficacy. Consequently, rapidly dividing normal tissues such as gastrointestinal epithelium and normal hematopoietic progenitors tend to be very sensitive to most chemotherapeutic agents. As a result, mucositis and myelosuppression represent frequent dose-limiting toxicities for many cytotoxic drugs.

Newer agents that target cell cycle proteins are often first utilized in patients with hematologic malignancies. As noted in the section on CDK and CHK1 inhibitors, these agents can have potent cytotoxic effects on dividing cells.

PHARMACOLOGY OF TRADITIONAL CHEMOTHERAPEUTIC AGENTS

Traditional agents are classified by their site of action, and as such all have a targeted mechanism, albeit not that of newer kinase targeted agents. They are divided into alkylating agents, antimicrotubule agents, antimetabolites, topoisomerase I or II inhibitors, platinum analogs, and miscellaneous agents. The pharmacology and cellular mechanisms of action of these agents are schematically presented in Fig. 58.2.

Alkylating Agents

Drug treatment for cancer began with the use of the mustard class of alkylating agents, initially mechlorethamine (nitrogen mustard), which entered into clinical use in the mid-1940s. Alkylating agents are used in many regimens but are rapidly being supplanted by newer classes of agents.

All alkylating agents undergo molecular rearrangements to form covalent bonds to DNA bases. Some form monoadducts, while others form cross-links either with intrastrand or interstrand bases, or with adjacent proteins. All alkylating agents are cytotoxic to tumor cells through interruption of DNA replication, induction of DNA damage repair and stress response, or through checkpoints in the cell cycle that result in apoptosis, senescence, or necrosis. All alkylating agents induce DNA strand breaks directly or through the damage response. Alkylating agents can also cause DNA mutations that can induce a cytotoxic response or can alter proteins, leading to immune responses to novel protein sequences.

Mechanisms of Resistance

Efficient removal of the DNA adducts reduces the lesion burden, while loss of DNA damage recognition can invoke damage tolerance, as in the case of loss of MMR and temozolomide tolerance. Detoxifying enzymes (glucuronidating enzymes and metabolizing enzymes residing in the liver) can serve as acceptor molecules for alkylation, alter the agent prior to DNA attack, or metabolize the parent compound. Loss of TP53 results in loss of cell cycle checkpoint induction of DNA repair signals. Increased AKT signaling promotes cell proliferation to compensate for the DNA damage response-associated toxicity.

Nitrogen Mustard

The nitrogen mustard class includes mechlorethamine, cyclophosphamide, 4-hydroperoxy cyclophosphamide, ifosfamide, chlorambucil, and melphalan. These drugs all share a common bischloroethyl group attached to nitrogen and a substituted “R” group that provides drug specificity (Fig. 58.3). All nitrogen mustards react with DNA in an SN2 reaction, a bimolecular nucleophilic displacement reaction also called a second-order reaction. Although numerous sites are targeted for alkylation, nucleophiles in DNA, including nitrogen (N), oxygen (O), and phosphate (P), attract the chloroethyl moiety attached to the R–N backbone, and the chlorine is displaced by the nucleophilic atom to form an aziridinium moiety. The remaining chloroethyl group is then attracted to a second nucleophilic atom, forming a second aziridinium intermediate, leading to a second alkylation, forming a cross-link. Both intrastrand and interstrand cross-links are formed. The N7 guanine position is the most critical for cytotoxic cross-link formation. Clinical use of mechlorethamine is limited because the MOPP regimen (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) has been replaced by ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine [DTIC]) in Hodgkin lymphoma (see Chapters 78 and 80). Local use of mechlorethamine occurs in a dermatologic suspension for the treatment of cutaneous T-cell lymphomas (CTCLs; see Chapter 89).

Cyclophosphamide is a nitrogen mustard with a ringed structure off the end-chloroethyl backbone that decreases spontaneous decomposition (see Fig. 58.3). Enzymatic activation is required through multifunction P450 enzymes in the liver. Phenobarbital and corticosteroids may alter activation. The bioavailability of cyclophosphamide orally and intravenously is quite similar, although most use of the drug is by bolus IV injection. Cyclophosphamide is detoxified through oxidation to 4-keto-cyclophosphamide and carboxyphosphamide by aldehyde dehydrogenase. Cyclophosphamide is used in doses as small as 50 to 100 mg/day orally and in bolus doses of 400 to 700 mg/m^2 for solid tumors and 750 mg/m^2 in combination with doxorubicin and vincristine and prednisone as part of the CHOP regimen for NHLs, or alone or with bortezomib for patients with myeloma. It is also used at doses of up to 60 mg/kg/day for 4 days in autologous and allogeneic bone marrow (BM) transplantation protocols. Cyclophosphamide is used in numerous treatment protocols for NHLs and high-dose therapy regimens designed to eradicate tumor and BM in patients with lymphomas and leukemias and those undergoing BM transplantation. It is commonly used with granulocyte colony-stimulating factor (G-CSF) for mobilizing hematopoietic stem cells to be collected before autologous transplantation.

Cyclophosphamide is metabolically activated by cytochrome P450 mixed function oxidases in the liver to 4-hydroxycyclophosphamide. 4-Hydroxycyclophosphamide is further converted to aldophosphamide and then to phosphoramide mustard, the alkylated species, and acrolein. High levels of aldehyde dehydrogenase detoxify cyclophosphamide in hematopoietic stem cells and, thus, high doses are

Figure 58.2 OVERVIEW OF SITES AND MECHANISMS OF ACTION OF THE MOST USEFUL CHEMOTHERAPEUTIC AGENTS. *5-FU*, 5-Fluorouracil; *6-MP*, 6-mercaptopurine; *ara-C*, cytarabine; *ara-G*, 9′-β-D-arabinofuranosylguanine; *DTIC*, dacarbazine; *Topo*, topoisomerase.

not marrow ablative. Acrolein is a highly reactive aldehyde and the cause of hemorrhagic cystitis. Mercaptoethane sulfonate (Mesna) is used to provide prophylaxis against hemorrhagic cystitis caused by cyclophosphamide and ifosfamide, and is now standard for doses of cyclophosphamide and ifosfamide above 1000 mg/m^2. Mesna is given in divided doses every 4 hours or as a continuous infusion for 18 to 24 hours in a dose equivalent to either cyclophosphamide or ifosfamide. Other than hemorrhagic cystitis, BM suppression is dose limiting and can be rescued by reinfusion of autologous or allogeneic hematopoietic progenitor cells. Other toxicities include alopecia and cardiac toxicity, which is unusual and most often seen after high-dose therapy.

4-Hydroperoxycyclophosphamide, a chemically stable form of the reactive intermediate of cyclophosphamide, 4-hydroxycyclophosphamide, is more toxic to committed hematopoietic progenitors such as colony-forming unit–granulocyte/macrophages (CFU-GM), burst-forming unit–erythroids (BFU-E), and colony-forming unit–erythroids (CFU-E).

Melphalan, or phenylalanine mustard, has an amino acid side chain that alters its cellular uptake and stabilizes its structure, allowing PO administration (see Fig. 58.3). It is available in both PO and IV forms, and has a similar effect on DNA cross-linking as cyclophosphamide and the other nitrogen mustards. Melphalan uptake by cells is by means of a neutral amino acid transporter. Its rate of cross-link formation is much slower than that of mechlorethamine, presumably because of delayed metabolism. Oral melphalan is used predominantly for the standard treatment of multiple myeloma (MM) and IV in high-dose regimens in preparation for stem cell transplantation (see Chapter 91) for MM patients.

Chlorambucil has been used for more than 40 years for the treatment of CLL. Chlorambucil is the phenylbutyric acid derivative of nitrogen mustard and is very stable, entering the cell by diffusion rather than by a specific uptake mechanism. It is typically administered orally on a daily basis or intermittently. It appears to have greater bioavailability than melphalan and a more consistent half-life of approximately 2 hours.

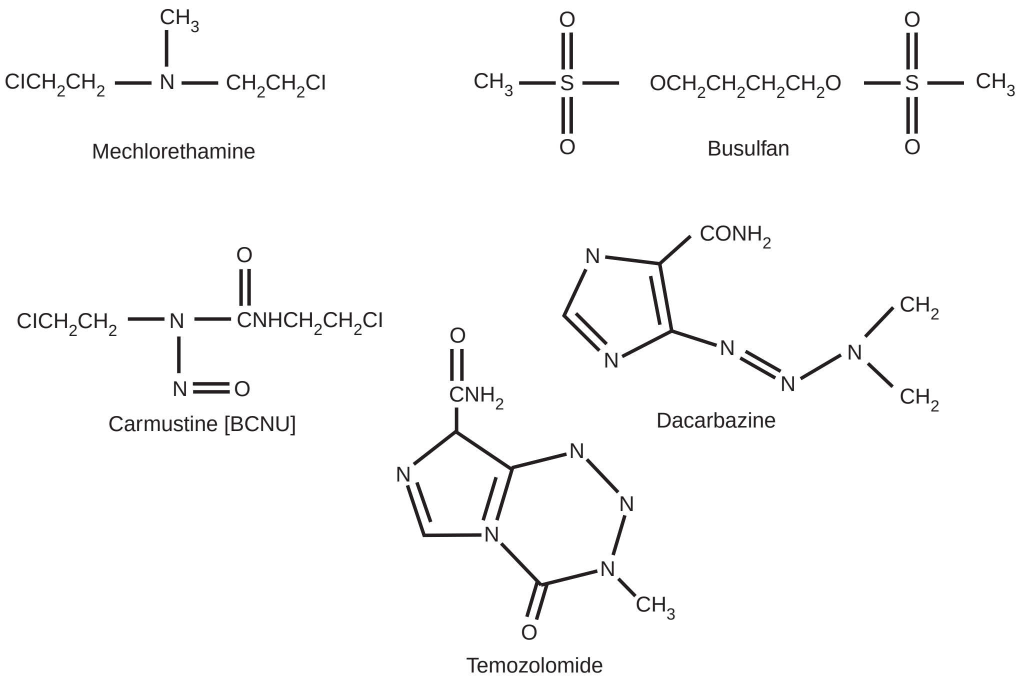

Figure 58.3 STRUCTURE OF COMMON ALKYLATING AGENTS.

Busulfan is an alkylsulfonate unique among alkylating agents because of two sulfur groups and lack of a chloroethyl moiety (see Fig. 58.3). Busulfan, similar to the nitrogen mustards, reacts predominantly at the N^7 position of guanine and produces an N^7–N^7 biguanyl DNA cross-link, although the precise nature of this cross-link appears different than that of the nitrogen mustards. The pharmacokinetics of busulfan is important for its use in high-dose therapy for ablation of the BM in patients undergoing autologous transplantation for acute leukemia or allogeneic stem cell transplantation (see Chapters 104–107). Because the incidence of veno-occlusive disease is lower in patients receiving high-dose busulfan with predosing pharmacokinetics performed, this is now recommended in high-dose regimens, the target being an area under the curve (AUC) of 1125 μ mol/L × min (range 900 to 1350) with every 6-hour dosing. Busulfan is a potent stem cell toxin, killing both early and late hematopoietic progenitor cells and damaging the BM stroma. Other toxicities of busulfan include nausea and vomiting, and pulmonary interstitial and intra-alveolar edema leading to fibrosis. The pulmonary fibrosis is distinct from the interstitial pneumonitis, which accompanies allogeneic stem cell transplantation and is not related to cytomegalovirus (CMV) or other viral infections.

Nitrosoureas

Four chloroethyl nitrosoureas and one methyl nitrosourea are in clinical use. These agents are different from the nitrogen mustards in that they alkylate through an SN^1 reaction, forming a highly reactive intermediate in the presence of N, O, and P nucleophiles in DNA. The commonly used clinical agent is (2-chloroethyl)-*N*-nitrosourea (BCNU). *N*-([4-amino-2-methyl-5-pyrimidinyl] methyl)-*N*-(2-chloroethyl)-*N*-nitrosourea (ACNU) is commonly used in Japan. A third agent, *N*-(2-chloroethyl)-*N*-cyclohexyl-*N*-nitrosourea (CCNU), is used predominantly as an PO nitrosourea in children with brain tumors. All of these compounds have high hydrophobicity, actively penetrating the blood–brain barrier.

The DNA alkylation sites include N^7 and O^6 of guanine. Chloroethylation at the O^6 position of guanine appears critical to cytotoxicity. DNA cross-linking by chloroethyl nitrosoureas include at 1-(3-cytosinyl), 2-(1-guanyl) ethane, and 1-2-bis(7-guanyl) ethane. The former is responsible for much of the cytotoxicity observed with the chloroethyl nitrosoureas. It is formed after alkylation at the O^6 position of guanine. This adduct undergoes intramolecular rearrangement to a circular intermediate, N^1. O^6 ethanoguanine is formed, which can then rearrange by attack at the opposite hydrogen-bonded base N^3 of cystine, forming the interstrand cross-link. This is a unique DNA cross-link and is poorly recognized by DNA repair processes, leading to marked cytotoxic potency of this cross-link.

The pharmacokinetics of the chloroethyl nitrosoureas reveal a very short half-life. BCNU is predominantly used for high-dose treatment of recurrent lymphomas. Regimens including BCNU induce sustained complete remission (CR) rates of approximately 40% to 60%. Doses of between 300 and 600 mg/m^2 have been safely administered. The chloroethyl nitrosoureas cause profound and cumulative BM suppression at conventional doses of 120 to 150 mg/m^2, limiting treatment to three to five cycles at 6-week intervals.

Complications of high-dose BCNU therapy include pulmonary toxicity and renal toxicity at doses higher than 600 mg/m^2. Pulmonary toxicity, as evidenced by a decrease in the DLCO (diffusing capacity of the lung for carbon monoxide), occurs in up to 40% of patients. It can be managed with high-dose oral steroids during the inflammatory phase. Interstitial nephritis with glomerulosclerosis, interstitial fibrosis, and dropout of tubules has been reported with BCNU or CCNU.

Methylating Agents

Four methylating alkylating agents are in clinical use. These include procarbazine, DTIC, streptozotocin, and temozolomide. Procarbazine and DTIC are triazines. Streptozotocin is a monofunctional methyl nitrosourea derivative with an attached sugar moiety, and temozolomide is an imidazotetrazine. All react with DNA by undergoing SN^1 reactions forming a methyldiazonium ion, resulting in methylation of N^7 guanine (67%), O^6 guanine (9%), O^4 and O^2 thymine (2%), and N^3 adenine (3%). None form DNA cross-links. However, all induce high levels of DNA methylation, and their recognition and repair results in both single- and double-strand breaks. N^7 methylguanine is removed through the BER system. Recognition by the *N*-methylpurine glycosylase results in removal of the adducted base with formation of an abasic site that is recognized by the apurinic (AP) endonuclease, which then cleaves the backbone at the AP site. Subsequently, the free 5′ sugar is released by DNA lyase, with repair initiated by β-polymerase and DNA ligase. BER effectively removes N^7 methylguanine and N^3 methyladenine, and restores DNA to normal. Inhibition of BER by the investigational agent methoxyamine (TRC102) blocks this pathway and increases toxicity.

O^6 methylguanine mispairs with thymine during DNA synthesis, resulting in a lesion recognized by the MMR system. Mispair recognition proteins are MSH6, MSH3, and MSH2. Recognition of the mispair recruits additional proteins to the complex, including MLH1 and PMS1/PMS2. These proteins initiate exonuclease cleavage of a long patch in the newly synthesized strand of DNA. This is then repaired by polymerases-δ and -ε. If unrepaired, a thymine is repeatedly inserted opposite the O^6 methylguanine, resulting in multiple single-strand breaks. Cells expressing high levels of the DNA repair protein for O^6 methylguanine, O^6 methylguanine-DNA methyltransferase (MGMT), are approximately 10-fold more resistant to methylating agents than MGMT-negative cells. Cells lacking MMR are very resistant to methylating agents. Acquisition of MMR defects is associated with acquired resistance to methylating agents and cisplatin, which is also recognized by this protein complex.

Procarbazine was synthesized as a monoamine oxidase inhibitor and has been used since the 1950s for the treatment of Hodgkin lymphoma and NHL, as well as a component of combination therapies for gliomas. DTIC is metabolically activated by cytochrome P450 microsomal oxidoreductases, ultimately leading to formation of the methyldiazonium ion and DNA methylation. DTIC is used in combination with ABVD for treating Hodgkin lymphoma (see Chapters 79 and 80) and is also used for patients with metastatic malignant melanoma in combination with BCNU, cisplatin, and tamoxifen. Activation of DTIC requires hydroxylation of one terminal methyl group caused by demethylation forming 5-[3-methyl-triazen-1-yl]-imidazole-4-carboxamide (MTIC), with spontaneous decomposition to the methyldiazonium ion, which alkylates the DNA, as noted earlier. Maximum tolerated doses of DTIC are approximately 1000 mg/m^2, with myelosuppression and gastrointestinal toxicity (including severe watery diarrhea) being the most common side effects.

Temozolomide represents an imidazotetrazinone. It differs from DTIC in that it is chemically degraded to the monomethyl triazine, MTIC, at neutral pH and does not require P450 enzymatic demethylation. Compared with DTIC, temozolomide has much more consistent pharmacokinetic parameters, including peak serum concentrations, volume of distribution and clearance, and conversion to MTIC. Clinical studies documented considerable activity in acute leukemias. The dose-limiting toxicity was thrombocytopenia and, less frequently, neutropenia, with maximum tolerated doses of 1000 mg/m^2 given over 5 days on a daily or twice-daily regimen. Nausea and vomiting were the other common side effects, easily controlled with antiemetics.

Bendamustine

Bendamustine is comprised of a 2-chloroethylamine nitrogen mustard alkylating group, a benzimidazole ring, and a butyric acid side chain. Its mechanism of action is unknown but appears to be different than other alkylating agents, causing DNA damage that is repaired predominantly by the base-excision repair system and has activity against lymphoid cell lines resistant to alkylating agents. Myelosuppression with leukopenia and thrombocytopenia is the most frequent side effect, with mild nonhematologic side effects including nausea, fatigue, constipation, and diarrhea. Phase III studies comparing standard treatment with bendamustine and rituximab in front-line treatment of CLL and indolent lymphomas (see Chapter 76) have established this combination as a first-line treatment. Bendamustine is also active against MM, and combinations with steroids and bortezomib or the immunomodulatory agents thalidomide and lenalidomide have been reported to result in high response rates in patients with relapsed or refractory disease.

Alkylating Agent–Induced Leukemias

Alkylating agents induce dose-limiting myelosuppression and cause sublethal DNA damage to hematopoietic progenitors, causing mutational events that lead to malignant transformation to preleukemic and leukemic states. A concern exists about the use of hematopoietic growth factors after exposure to alkylating agents (see Chapter 59). There is evidence of increased cytotoxicity to hematopoietic progenitors during simultaneous exposure to these agents and growth factors. Treatment-related AML (t-AML) accounts for approximately 15% of all adult AML. Approximately 50% of t-AML patients have a preleukemic phase compared with only 10% of patients with de novo AML. CRs are achieved in 15% to 30% of patients with t-AML and a mean remission duration of 2 months. Chromosomal abnormalities and gene mutations characteristic of t-AML establish this as a distinct disease requiring novel therapeutic approaches. Loss or deletion of all or part of the long arm [q] of chromosomes 5 or 7 is common, as are trisomy 8 and deletions of the short arm of chromosomes 12, 17, and 21.

Historically, patients with Hodgkin lymphoma treated with mechlorethamine and procarbazine in the MOPP regimen or with CCNU were at the highest risk if exposed to radiation as well as an alkylating agent combination. Patients with polycythemia vera treated with chlorambucil were at much higher risk than patients treated with phlebotomy alone, which can contribute to a shift in treatment strategy. Patients with myeloma and ovarian cancer have developed t-AML, especially after prolonged exposure to alkylating agents. Patients treated with alkylating agents for benign diseases such as nephritis, lupus, psoriasis, rheumatoid arthritis, and Wegener granulomatosis also have an increased risk of t-AML. The mean latency between exposure and t-AML from alkylating agents is 4 to 5 years, in contrast to t-AML from etoposide, which has a latency period as short as 1 year. The cumulative risk of developing t-AML is between 10% and 17% at 4 to 6 years for myeloma patients treated with melphalan and between 2% and 10% at 7 to 10 years in patients with Hodgkin lymphoma. Alkylating agent-associated t-AML has also been recognized in patients with breast and colon cancer.

Antimicrotubule Agents

The antimicrotubule drugs include the vinca alkaloids (e.g., vincristine, vinblastine, vinorelbine and vindesine), taxanes (e.g., paclitaxel and docetaxel), and epothilones (ixabepilone).

Molecular Targets

The vinca alkaloids are naturally occurring (vincristine and vinblastine) or semisynthetic (vinorelbine) nitrogenous bases derived from the pink periwinkle plant, *Catharanthus roseus*. Paclitaxel was originally isolated from the bark of the Pacific yew, *Taxus brevifolia*. Paclitaxel can also be isolated from other members of the *Taxus* genus and from a fungal endophyte that grows on the Pacific yew. Docetaxel is derived semisynthetically from 10-deacetyl-baccatin III, which is obtained from the needles of the European yew, *Taxus baccata*.

The vinca alkaloids bind to the protein tubulin at a site distinct from that of the taxanes and, at low concentrations, inhibit microtubule dynamics. At higher concentrations, these vinca alkaloids disrupt microtubules and mitotic spindle, resulting in cell cycle mitotic arrest and apoptosis of cells (see Fig. 58.3). In contrast, after binding to α -tubulin, taxanes kinetically stabilize microtubule dynamics at their plus ends and shift the equilibrium toward tubulin polymerization into microtubule bundles. This also causes mitotic arrest and apoptosis of cells. The mitotic arrest caused by antimicrotubule drugs is associated with phosphorylation of the B-cell lymphoma (BCL2) protein and increased intracellular levels of the BCL2-associated X protein (Bax), which promote apoptosis.

As natural products, overexpression of the efflux pump multidrug resistance gene-1 (MDR-1) and the ABCB-1 transporter mediate resistance. Intracellular resistance to mitotic spindle and microtubule formation is mediated by numerous pathways and proliferative signals including MYC, nuclear factor kappa-B (NFκB), and AKT.

Antimicrotubule agents, particularly the vinca alkaloids, are used in the management of lymphomas and leukemias, and continue to be used in the mainstay of clinical chemotherapeutic regimens. Because of their mechanism of action, they are best used in multiagent combinations, in which potentiation of efficacy with other classes of agents, such as antimetabolites and DNA-damaging agents, provide better therapeutic responses and well-tolerated treatments.

Inhibitors of Nucleotide Synthesis

Within this class are two important agents used for hematologic malignancies, hydroxyurea and methotrexate. They both serve to disrupt nucleotide synthesis, and slow or stop DNA and RNA synthesis.

Hydroxyurea

Hydroxyurea inhibits ribonucleotide diphosphate reductase, blocking de novo synthesis of purines and pyrimidines. S-phase arrest is commonly observed. Given this exquisite cell cycle specificity, resting and quiescent cells are rarely affected and there is virtually no hematopoietic stem cell toxicity. As a consequence of disruption of nucleotide synthesis and direct binding to telomere binding factors, telomere synthesis and function are compromised in leukemic cells. In cells arrested in S phase, apoptosis and senescence are observed.

Hydroxyurea is used in the treatment of myeloproliferative neoplasms including essential thrombocythemia, polycythemia vera, and myelofibrosis (see Chapters 69–72). It may also be used for acute cytoreduction prior to induction therapy of AML and for management of chronic myelomonocytic leukemia. It is commonly used for extended periods of time to induce fetal hemoglobin and reduce sickle crisis in patients with sickle cell anemia (see Chapters 42 and 43).

Folic Acid Analogs (e.g., Methotrexate)

Folic acid analogs block the formation of thymidine by inhibition of thymidylate synthase, resulting in accumulation of uridine-5'-monophosphate (UMP), leading to high levels of uridine-5'-triphosphate (UTP) which is incorporated into DNA and causes purine nucleotide pool imbalance, slowing DNA synthesis. These agents bind thymidylate synthase and DHFR and disrupt cell cycle progression and cell division. Methotrexate polyglutamation results in higher affinity binding to DHFR and improved inhibition. Aminopterin, the first antifolate, was used by Sidney Farber (reported in 1948) and became one the first chemotherapeutic agents to be administered with success to children with acute lymphocytic leukemia (ALL). Methotrexate is the agent currently used in hematologic diseases, while the family of agents includes pemetrexed and trimetrexate. Inhibition of folate-dependent methyl transfer enzymes disrupts purine synthesis pathways. Toxicity of methotrexate is reversed by N^5-formyl FH_4, or leucovorin, which serves as a direct folate coenzyme. Since it has no tumor selectivity, normal tissues in active cell cycle are affected, including mucosa, BM, and hair follicles, resulting in mucositis, pancytopenia, and alopecia. Prolonged use is associated with pulmonary and liver fibrosis. High-dose therapy and excessive periods of high blood levels result in interstitial nephritis, sometimes requiring dialysis.

The most common resistance is due to amplification of DHFR expression by upregulation of translation and gene amplification, including the establishment of minichromosomes with the DHFR gene. A second mechanism is decreased affinity of DHFR to methotrexate. A third mechanism is decreased thymidylate synthase, and the fourth mechanism of resistance is impaired methotrexate polyglutamate formation.

While use has diminished in recent years, methotrexate remains part of the regimen for maintenance in children and adults with ALL (see Chapter 66). It is also used to depress T-lymphocyte proliferation after allogeneic stem cell transplantation to prevent acute graft-versus-host disease (GVHD). High-dose methotrexate, with careful blood level monitoring to prevent acute renal toxicity and mucositis, and leucovorin rescue, is effective in the management of CNS leukemias, primary CNS lymphoma, and highly proliferative fraction (c-myc-positive and high KI67) intermediate- and high-grade lymphomas, including Burkitt.

Nucleoside Analogs

The nucleoside analogs exhibit structural similarities to naturally occurring nucleosides and are incorporated into either DNA or RNA with lethal consequences. Alternatively, they block key enzymes in de novo purine or pyrimidine biosynthesis. There are two broad categories:

1. Pyrimidine analogs (e.g., ara-C, 5-azacytidine, gemcitabine)
2. Purine analogs (e.g., 6-thioguanine [6-TG], 6-mercaptopurine, fludarabine, chlorodeoxyadenosine, deoxycoformycin, clofarabine, nelarabine)

These categories are not mutually exclusive; for example, some nucleoside analogs (e.g., ara-C and 6-TG) also inhibit enzymes involved in DNA or deoxyribonucleotide biosynthesis. These agents are predominantly cycle-active agents and in most cases are phase-specific, being primarily active against cells in S phase. Because the growth fraction of hematologic malignancies tends to be higher than that of nonhematologic malignancies, nucleoside analogs are particularly useful in the former disorders. In contrast to alkylating agents, nucleoside analogs have limited carcinogenic and leukemogenic potential. The fluorinated pyrimidines (e.g., 5-FU) are generally not used in treating hematologic disorders and are not discussed further.

Ara-C has been used in the treatment of acute leukemias—particularly acute nonlymphocytic leukemias, aggressive lymphomas including Burkitt, and CNS lymphomas for over 30 years. It is incorporated into DNA during replication and inhibits polymerase-α, is cell cycle specific, and penetrates the blood–brain barrier. In rapidly replicating cells, it stalls polymerase function, leading to replication fork collapse and strand breaks at the replication fork, signaling apoptosis and differentiation.

Mechanisms of Resistance

Although ara-C remains the backbone of therapy for aggressive hematologic malignancies, resistance has been observed that is both specific to the drug and nonspecific. Specific resistance could be due to nucleotide transport down regulation, uncommon in dividing cells. Inside the cell, ara-C is phosphorylated by deoxycytidine kinase to the active 5′-triphosphate derivative ara-cytidine triphosphate (CTP), whereas catabolism of ara-C by cytidine deaminase (CDD) to the nontoxic metabolite arabinoside uridine is a major pathway of detoxification that can be overcome by high-dose therapy. Low penetration into the cerebrospinal fluid is overcome by bolus administration of very high doses: 1 to 2 g/m^2 over 1 hour. Other resistance mechanisms appear nonspecific and result in leukemia tolerance to cell cycle arrest and induction of apoptosis, tolerance to DNA strand breaks, and rapid cell division after therapy.

Clinical Use

Standard induction therapy for AML includes a 5- to 7-day continuous infusion of 100 to 200 mg/m^2 or high-dose ara-C at doses of 1 to 3 g/m^2 over 1 hour every 12 hours. Many modifications to these schedules have improved tolerance without sacrificing efficacy. For CNS leukemia, a depo form of ara-C has been developed with improved tolerance and sustained cerebrospinal fluid levels.

Subcutaneous (SC) administration has provided responses in older individuals with AML or myelodysplastic syndromes (MDS) who do not respond well to more intensive induction therapy.

5-Azacytidine and Decitabine

These agents were initially developed as antimetabolites but are more effective at low doses that inhibit the function of histone demethylation and are described below.

Gemcitabine

Developed as an agent for the treatment of pancreatic cancer, gemcitabine has gained therapeutic attention for use in patients with Hodgkin lymphoma and NHL, particularly in the relapsed state.

Like other nucleotide analogs, gemcitabine is a prodrug that is phosphorylated by deoxycytidine kinase to gemcitabine diphosphate (FdCDP) and gemcitabine triphosphate (dFdCTP), which, when incorporated into DNA, stalls the polymerase-α, which adds one more deoxynucleotide to the elongating strand. The polymerase replication complex then falls off the DNA, causing replication fork collapse and chain termination. In addition, FdCDP is a potent inhibitor of ribonucleoside reductase, causing depletion of deoxyribonucleotide pools and further encouraging dFdCTP incorporation while disrupting DNA synthesis.

Specific resistance is caused by upregulation of deoxycytidine deaminase, which metabolizes gemcitabine to 2,2′-difluorodeoxyuridine. Nonspecific resistance emerges due to upregulation of membrane transporters, although their role in clinical resistance is less clear.

Numerous studies have identified the utility of adding gemcitabine to cisplatin and other agents for the treatment of both relapsed Hodgkin lymphoma and NHL, and CTCLs. The combination of oxaliplatinum or cisplatin and gemcitabine is effective and well tolerated, and the majority of patients remain eligible for autologous stem cell collection and transplantation.

Fludarabine

Fludarabine was introduced 25 years ago as an agent with potent activity against lymphoid malignancies and remains an active agent in CLL and other low-grade lymphomas. It has since emerged as an agent in combination that is effective in leukemias, and in induction therapy for nonmyeloablative conditioning prior to allogeneic stem cell transplantation. It is recognized for its immunosuppressive function and inducing tolerance to allografts transplantation. Fludarabine phosphate is the 2-fluoro, 5′-monophosphate derivative of vidarabine (9′-β-D-arabinofuranosyladenine [ara-A]) and is converted to the di- and triphosphate by intracellular kinases, as are gemcitabine and ara-C. It has greater potency because it confers resistance to deamination by adenosine deaminase (ADA) and improved solubility. It is incorporated into DNA as a nucleotide and causes chain termination. It is a potent inhibitor of cytosolic 5′-nucleotidase II. It is also a substrate for uracil glycosylase, causing abasic sites as the first stem in BER and has recently been used in combination with TRC102, which binds to these sites and prevents their repair. Like other nucleoside analogs, it causes replication fork collapse, double-strand breaks, and induction of P53, leading to apoptotic signaling. Its efficacy against normal lymphoid T and B cells appears linked to both cytotoxicity against proliferating cells and resting cells; the latter effect is mediated by interference with the normal activity of the nucleotide excision repair pathway.

Fludarabine is a complex agent. Resistance is multifactorial including active transport, decreased cytosolic 5′-nucleotidase II and deoxycytokine kinase, and Ku80 binding to telomerase. Other nonspecific mechanisms include mutations in *p53* or loss due to chromosome deletion, which is important in many cases of CLL, and other proliferation-associated genes such as *NOTCH1*, *SF3B1*, and *BIRC3*. Low-level miR-34a is also associated with fludarabine resistance.

Fludarabine, at a standard dose of 25 mg/m^2 for 5 days and rituximab with or without cyclophosphamide were the mainstay of primary treatment for CLL (see Chapter 76). Fludarabine has also been used in refractory leukemias, marginal cell and other low-grade lymphomas. Recognition of the appearance of lymphopenia after treatment led to studies establishing fludarabine as part of the nonmyelosuppressive preparative regimens for allogeneic transplantation. This is most often at a dose of 30 to 35 mg/m^2 for 5 days and used in combination with radiation, melphalan, or cyclophosphamide. In addition to lymphopenia, multiple cycles are associated with prolonged myelosuppression and a chronic peripheral neuropathy.

Clofarabine

Clofarabine (2-chloro-2′-arabino-flouro-2′-deoxyadenosine) is a purine analog with activity in patients with relapsed acute leukemia. Its activation requires cellular uptake and conversion to the triphosphate nucleotide. It then decreases ribonucleotide reductase; alters nucleotide precursors; inhibits and reduces the function of antiapoptotic proteins such as Bcl-X(L), Mcl-1, and Bax with dephosphorylation of akt; and inhibits DNA synthesis.

It appears to be more active against B-cell than T-cell, especially in AML and MDS. It is well tolerated. Recent studies show its significant efficacy in ara-C–refractory AML. Reversible liver toxicity and myelosuppression can be dose-limiting (see Chapters 60–62).

Nelarabine

Nelarabine (9-β-D-arabinofuranosylguanine) is another FDA-approved purine analog for the treatment of refractory T-cell leukemias and lymphomas (see Chapters 66–68).

As a nucleotide analog, it preferentially accumulates in T cells and is incorporated into DNA, causing chain termination and inhibiting DNA synthesis. The FDA approved this drug after analyzing the results of two phase II clinical trials, one in pediatric T-cell ALL and the other in adults with T-cell lymphoblastic lymphoma. In both cases, patients had relapsed after at least two induction regimens. Because CRs were seen in 13% of the 39% of pediatric patients and in 18% of the 28 adult patients, the FDA granted approval. Neurologic toxicity is dose limiting. Good response rates, including CRs, have been seen in patients with refractory T-cell leukemias.

Reduced ara-G incorporation into DNA is likely due to altered nucleotide transport, increased nucleotidase activity, reduced nucleoside kinase activity, and nonspecific resistance mechanisms as described earlier for this class of agent.

Inhibitors of DNA Topoisomerase I and II

Inhibitors of DNA topoisomerases I and II include such drugs as doxorubicin, daunorubicin, mitoxantrone, etoposide, and topotecan. Before describing the specific inhibitors, a brief review of the drug targets (topoisomerase enzymes) will be presented (Table 58.2).

DNA Topoisomerase I

Topoisomerase I is a ubiquitous enzyme whose function in vivo is to relieve the torsional strain in DNA, specifically to remove positive supercoils generated in front of the replication fork and to relieve negative supercoils occurring downstream of RNA polymerase during transcription. Topoisomerase I is catalytically active as a 100-kDa monomer and is concentrated in nucleoli, although smaller amounts are found in a diffuse nuclear distribution. The gene for this enzyme is located on human chromosome 20q12–13.2. Topoisomerase I does

TABLE 58.2 **Characteristics of Mammalian DNA Topoisomerases**

	Topoisomerase I	Topoisomerase IIα and Topoisomerase IIβ	
Size of monomer (kDa)	100	170	180
mRNA (kb)	4.2	6.2	6.5
Chromosome	20q12–13.2	17q21–22	3p24
DNA cleavage	Single-strand breaks	Double-strand breaks	Double strand
Covalent intermediate	$3'PO_4$-Tyr^{723}	$5'PO_4$-Tyr^{804}	$5'PO_4$-Tyr^{821}
ATP requirement	No	Yes	Yes
Nuclear location	Nucleoli, diffuse	Nuclear matrix and scaffold, nucleoli	Nucleoli Nuclear matrix
Cell cycle dependence	None	Yes, maximum in G_2/M	None
Nuclear localization signal	NH_2-end	COOH-end	COOH-end
Phosphorylation	By CK II and PKC (increases activity)	By CK II, PKC, p34^{odc2}, MAPK	Increases mass to 190 kDa
Role	In replication, transcription, and recombination	In replication, transcription, chromosome condensation/segregation, and recombination	rRNA transcription
Inhibitors	Camptothecins	(see Table 58.3)	

MAPK, Mitogen-activated protein kinase; *PKC*, protein kinase C.

not require adenosine triphosphatase (ATP) for catalytic activity. It binds double-strand DNA over 15 to 25 bp (with a preference for supercoiled or bent DNA) followed by cleavage of one DNA strand and forming a transient covalent phosphotyrosyl bond at the 3′-end of DNA. DNA torsional strain is then relieved by a "controlled rotation" mechanism (see Fig. 58.1), subsequent to which the cleaved DNA is religated. The three-dimensional crystal structure of human topoisomerase I, both in covalent and noncovalent complexes with DNA, has defined the structural elements of the enzyme that contacts DNA. The association between topoisomerase I and the 3′-end of cleaved DNA has been termed the *cleavable complex*, which is stabilized by topoisomerase I inhibitors.

DNA Topoisomerase II

Two isoforms of human topoisomerase II (α and β) exist. They act as homodimers to cleave double-stranded DNA and require ATP for full activity. Their role in vivo is to relieve torsional strain in DNA, and their cellular distribution is determined by nuclear localization signals contained in the C-terminal domain. These isoforms are distinct in that they have different-size monomers (see Table 58.2), their genes are located on separate chromosomes, their nuclear distribution is different, and only the α-isoform shows cell cycle variations in amount and activity (with maximal activity being in G_2/M). The mechanism of action of topoisomerase II involves several steps (Fig. 58.4): DNA recognition and binding (curved and supercoiled DNA, as well as DNA crossovers, are preferred), the sequential cleavage of the two strands of DNA with covalent attachment of a monomer to each 5′-end of the cleaved DNA, passage of another DNA duplex through the break site (e.g., to relieve DNA torsional strain or decatenate daughter chromosomes at the end of replication), religation of the cleaved DNA, and ATP hydrolysis-dependent enzyme turnover. The binding of ATP by topoisomerase II is required for the strand passage reaction. Again, the association between topoisomerase II monomers and the 5′-end of the cleaved DNA has been termed the *cleavable complex*, the stabilization of which generally correlates with the cytotoxic activity of specific topoisomerase II inhibitors.

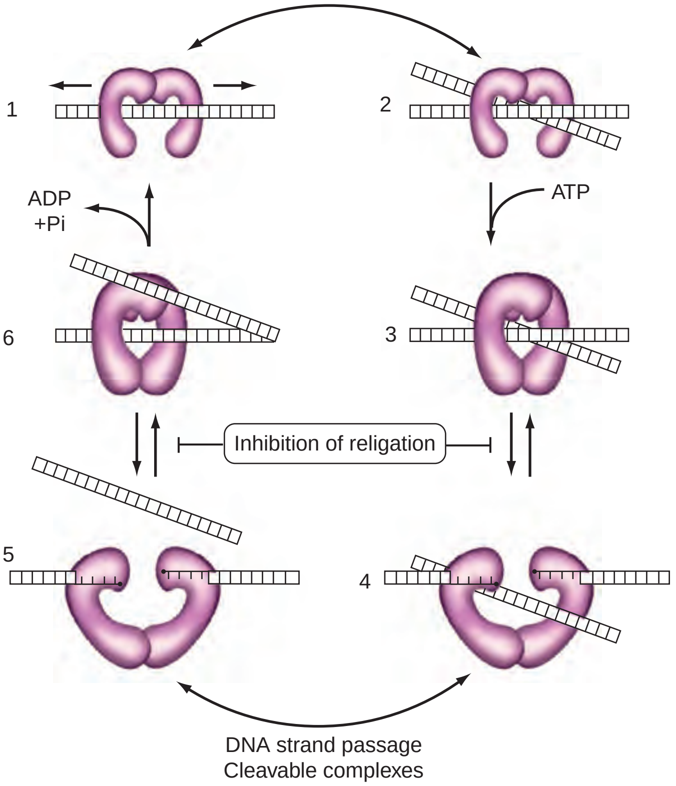

Figure 58.4 DNA TOPOISOMERASE II CATALYTIC CYCLE. (1) Noncovalent binding of DNA by the topoisomerase II homodimer. (2) DNA recognition and preferential binding to crossovers by topoisomerase II. (3) Binding of ATP promotes the formation of a topologic complex. (4) DNA cleavage with covalent linkage of each topoisomerase II monomer to the 5′-DNA terminus of the break. (5) Poststrand passage cleavable complex. (6) Religation of the cleaved DNA is followed by ATP hydrolysis and enzyme turnover. DNA topoisomerase II inhibitors generally increase cleavable complexes by inhibiting the religation activity.

Because topoisomerase I and II inhibitors convert their respective enzymes into DNA-damaging agents, it is usually true that the more enzyme target a cell contains (provided it is in the nucleus), the more cytotoxic is the specific inhibitor. An exception to this generalization is CLL cells, which have abundant topoisomerase I but are not very sensitive to topoisomerase I inhibitors because topoisomerase I inhibitors are S-phase-specific and CLL cells have very few cells in S phase. Finally, in addition to topoisomerase I and II, a mammalian DNA topoisomerase III has been described and found to be essential for early embryogenesis in the mouse. In addition to the presumed lethality of a homozygous deletion of the topoisomerase II gene, topoisomerases I and III appear to be essential for cell growth and division in mammals. The specific role of topoisomerase III in humans is unknown at present.

DNA Topoisomerase I Inhibitors

Camptothecin (CPT-11 or irinotecan) is a plant alkaloid first identified in 1966 from the tree *Camptotheca acuminata*. Early clinical studies with camptothecin were stopped primarily because of hemorrhagic cystitis resulting from conversion of the sodium salt form to the active lactone form owing to its acidic pH in the bladder. Renewed interest in camptothecin occurred in 1985 when topoisomerase I was identified as the target of this drug and as new more water-soluble analogs became available. At present, two topoisomerase I inhibitors have been approved by the FDA as second-line agents for the treatment of ovarian carcinoma and colorectal cancer; these are topotecan and irinotecan (CPT-11; Fig. 58.5). Topotecan has been shown to be active in the treatment of MDS and inactive in the treatment of CLL. Responses to topotecan have also been seen in refractory MM, refractory large-cell lymphoma, and refractory acute leukemia.

The lactone forms of topotecan and SN-38 (the active form of CPT-11 generated in vivo by the action of a carboxylesterase) are as much as 1000-fold more active inhibitors of DNA topoisomerase I than are their carboxylate forms. The lactone form predominates at an acidic pH. Topoisomerase I inhibitors stabilize the DNA-enzyme cleavable complex and thus inhibit DNA religation, but the production of DNA double-strand breaks results from a collision of the DNA replication fork with the ternary drug-enzyme-DNA complex, which is the lethal event (see Fig. 58.4). Topoisomerase I inhibitors are considered S-phase-specific agents because they require ongoing DNA synthesis to exert their cytotoxic effect.

DNA Topoisomerase II Inhibitors

Inhibitors of DNA topoisomerase II are commonly used for the treatment of hematologic malignancies. Three general types of topoisomerase II inhibitors exist (Table 58.3). The first are the topoisomerase II poisons, typified by etoposide, which results in the stabilization of cleavable complexes. The second group are the catalytic inhibitors, represented by aclarubicin, merbarone, and the bis-2,6-dioxopiperazine derivatives (ICRF-193, ICRF-159, ICRF-187); these are drugs that, except for aclarubicin, do not bind DNA and do not stabilize cleavable complexes, but rather interfere with some aspect of topoisomerase II catalytic activity (e.g., ICRF-187 inhibits topoisomerase II ATPase activity). The final class includes drugs that can inhibit both DNA topoisomerases I and II, and are represented by intoplicine and saintopin.

	C-10	C-9	C-7
Camptothecin	H	H	H
Topotecan	OH	$(CH_3)_2NCH_2$	H
9-Aminocamptothecin	H	NH_2	H
SN-38	OH	H	CH_3CH_2
CPT-11		H	CH_3CH_2

Figure 58.5 STRUCTURE OF CAMPTOTHECIN ANALOGS.

DNA topoisomerase II poisons (see Fig. 58.5 for structures) are most likely cytotoxic because they trap DNA topoisomerase II complexes on nascent DNA in the nuclear matrix. The topoisomerase II poison-stabilized enzyme–DNA complex likely acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells. Whereas experiments in yeast show that although DNA synthesis is a major determinant for cell killing by topoisomerase I inhibitors, topoisomerase II poisons are also cytotoxic during other phases of the cell cycle.

Drug Resistance to Topoisomerase Inhibitors

Essentially all of the topoisomerase II poisons (see Tables 58.2 and 58.3) are substrates for the drug efflux pump P-glycoprotein (PGP), and many are substrates for multidrug-resistance protein (MRP) and lung resistance-related protein. In addition, several point mutations and gene deletions have been defined in the gene for topoisomerase II, resulting in the production of an enzyme with altered catalytic or cleavage activity. The third mechanism of resistance is a decrease in expression of the enzyme such that there is less target for the inhibitor to "convert" to a DNA-damaging agent. This can result from a proliferation-dependent or cell cycle–dependent decrease in topoisomerase II, from a specific attenuation of topoisomerase II, or from an intrinsic absence of topoisomerase II (identified in some acute and chronic leukemias). The fourth resistance mechanism involves alterations in the subcellular distribution of the enzyme. Truncation of the COOH-end of topoisomerase II has resulted in the cytoplasmic distribution of enzyme caused by a loss of nuclear localization signals, so that the enzyme cannot interact with DNA in the presence of an inhibitor and the cell is resistant. However, mutations in the gene for topoisomerase II do not appear to be common, because only a single patient with AML has been found to have a point mutation. By contrast, CLL cells are resistant to topoisomerase II inhibitors because they express very low levels of the protein.

Platinum Analogs

Mechanism of Action

During a study of the effects of electric current on growing bacteria, the antibacterial and, later, the antitumor activities of the platinum compounds were fortuitously discovered. The antitumor agent cisplatin, its *cis*-carboxylester analog, carboplatin, and the diaminocyclohexane-containing oxaliplatin, are heavy-metal platinum complexes. They are activated when one of their ligands (cisplatin; chloride and carboplatin; carboxylester) is displaced by water, leading to the formation of positively charged aquated platinum complexes, allowing platinum to stably bind DNA, RNA, proteins, or other critical biomacromolecules (see Fig. 58.2). With DNA, platinum complexes form covalent links to the N^7 position of guanine and adenine. The N^7 adducts at d(GpG) or d(ApG) result in intrastrand or interstrand DNA cross-links that bend the DNA helix and inhibit DNA synthesis. The cytotoxicity of platinum analogs correlates with the total platinum binding to DNA, as well as with the intrastrand or interstrand cross-links. This results in DNA damage, which triggers apoptosis of sensitive cells.

Clinical Activity

Cisplatin, carboplatin, and oxaliplatin are used in the treatment of refractory lymphomas in a variety of combinations, and as part of high-dose and intensification therapy for lymphomas as definitive treatment including prior to autologous stem cell transplantation.

Miscellaneous Agents

Among the agents included in this category, only plicamycin, bleomycin, L-asparaginase, gallium nitrate, and glucocorticoids are of current interest to hematologists.

PHARMACOLOGY OF TARGETED ANTINEOPLASTIC AGENTS

Since the year 2000, the therapeutic arsenal available for treatment of hematologic malignancies has expanded to include a group of drugs that have collectively been termed as “targeted agents.” Traditional chemotherapeutic drugs affect specific targets, many times identified after the cytotoxic and clinical activity of these agents have been demonstrated. Dobbelstein and Moll describe three “waves” or “epochs” in anticancer drug development.[5] The first wave includes traditional chemotherapeutic agents, comprised mostly of drugs that affect DNA replication, repair and cell division; these drugs are nonspecific and can affect normal cells, but take advantage of the increased proliferation of cancer cells to exert their cytotoxic activity. Second-wave drugs target cellular signals, including those mediated by surface receptors and protein kinases. Monoclonal antibodies are included in this second wave. The targets of signaling inhibitors are diverse, and include the products of oncogenes, essential for the development and survival of neoplasms (“oncogene addition”). The prototype of this class of agents is imatinib, targeting the chimeric product of BCR-ABL in chronic myelogenous leukemia (CML).

Other cellular signaling proteins are not the product of oncogenes but have an essential role in intracellular processes of malignant cells. This state is known as “nononcogene addiction” and has expanded the number of targets that can be used for cancer treatment with signaling inhibitors. Examples of the latter agent class include inhibitors of mammalian target of rapamycin (mTOR) and BTK. The third wave of anticancer drugs target cellular mechanisms and effector systems distinct from those targeted by drugs of the first two waves, but that are still essential for the survival of cancer cells. The cellular processes targeted by drugs of the third wave are those that contain several types of constitutive stress experienced by cancer cells (separate from replicative stress), including proteotoxic stress leading to abnormal protein folding and increased protein degradation (targeted by heat-shock protein inhibitors and proteasome inhibitors), DNA damage (targeted by PARP inhibitors), DNA modifications (targeted by hypomethylating agents and HDACs), prosurvival balance in organelles governing cell survival (targeted by BCL2 inhibitors), increased need for protein transport (inhibited by nuclear transport inhibitors), as well as transcriptional, ribosomal, metabolic, and oxidative stress, targeted by several other drugs in development. Other agents not easily included in these three waves include immunomodulatory drugs (thalidomide, lenalidomide, and pomalidomide), as well as agents promoting cancer cell differentiation (all-*trans* retinoic acid).

Signaling Inhibitors (Table 58.4 and Fig. 58.6)

Imatinib Mesylate and Other BCR-ABL Kinase Inhibitors

Imatinib Mesylate

Imatinib mesylate is a phenylaminopyrimidine developed as an inhibitor of the constitutively active tyrosine kinase BCR-ABL, expressed in the leukemic cells of most patients with CML. The recognition that the constitutively active BCR-ABL played a central role in the pathogenesis of CML led to the search for potential inhibitors. The introduction of the tyrosine kinase inhibitor (TKI) imatinib for treatment of CML is a major milestone in the development of targeted therapy for hematologic and neoplastic disorders. The role of the BCR-ABL kinase in the pathogenesis of CML and ALL and the use of BCR-ABL inhibitors in the treatment of these disorders is discussed in Chapters 67–69.

Imatinib mesylate is the founding agent in the class of TKIs. It causes direct inhibition of the BCR-ABL kinase[6] but is not absolutely specific for this molecule, as it also inhibits other kinases, including KIT, platelet-derived growth factor (PDGF), stem cell factor (SCF), and TEL-ARG.[7]

TABLE 58.4 Targets and Approvals for Signaling Inhibitors

Agent	Target	Approved indication
Acalabrutinib	BTK	CLL, MCL
Alectinib	ALK, RET	Alk positive metastatic NSCLC
Asciminib	BCR-ABL	
Azacitidine	DNA methyltransferase	MDS, CML, and AML
Belinostat	Histone deacetylase	PTCL
Bortezomib	Proteasome	Multiple myeloma, MCL AL amyloidosis
Bosutinib	BCR-ABL, KIT, Src, HCK, Lyn, MAPK1-2	CML
Carfilzomib	Proteasome	Multiple myeloma
Ceritinib	ALK	NSCLC
Copanlisib	PI3K-alpha and PI3K-delta	Follicular lymphoma
Crenolanib	FLT3, PDGFRα, PDGFRβ, c-KIT	
Crizotinib	ALK, HGFR	ALK-positive non-small–cell lung cancer
Dabrafenib	BRAF	Melanoma with BRAF V600E mutation
Decitabine	DNA methyltransferase	AML
Enasidenib	IDH2	AML
Everolimus	mTOR	Renal cell carcinoma
Fedratinib	JAK2, FLT3, RET	Intermediate - 2 or high-risk myelofibrosis
Gilteritinib	FLT3	AML, MDS
Glasdegib	Hedgehog pathway	AML
Ibrutinib	BTK	CLL, MCL, Waldenström's macroglobulinemia, Marginal zone lymphoma, GVHD
Idelalisib	PI3Kδ	Relapsed CLL, SLL, and follicular lymphoma
Ipatasertib	AKT	
Ivosidenib	IDH1	AML, cholangiocarcinoma
Ixazomib	Proteasome	Multiple myeloma
Lenalidomide	IMiD	Multiple myeloma, MCL, 5q- syndrome, DLBCL (in combination with tafasitamab)
Midostaurin	FLT3, c-KIT	AML
Nilotinib	BCR-ABL, Kit, Lck, Ephrins, PDGFRβ, MAPK11, ZAK	CML
Omacetaxine	Ribosomal protein translation	CML with resistance or intolerance to tyrosine kinase inhibitors
Pacritinib	JAK2, FLT3	
Panobinostat	Histone deacetylase	Multiple myeloma, myelofibrosis
Ponatinib	BCR-ABL, Kit, PDGFRα, VEGFR, Src, Lyn, Lck, FGFR1–4, FLT3, TEK	CML with T315I mutation
Quizartinib	FLT3, CRS1R, SCFR, PDGFR	
Romidepsin	Histone deacetylase	CTCL, PTCL
Ruxolitinib	JAK1, JAK2,	Intermediate or high-risk myelofibrosis, GVHD
Sonidegib	Hedgehog pathway	Basal cell carcinoma
Sorafenib	BRAF, VEGFR, FLT3, PDGFRβ, Kit, FGFR1, Ret	Hepatocellular carcinoma
Tazemetostat	EZH2	Follicular lymphoma, epithelioid sarcoma
Temsirolimus	mTOR	Renal cell carcinoma
Thalidomide	IMiD	Multiple myeloma
Umbralisib	PI3K-delta and CK1-epsilon	
Vemurafenib	BRAF	Melanoma with BRAF V600E mutation
Venetoclax	BCL2	CLL, AML
Vismodegib	Hedgehog pathway	Basal cell carcinoma
Vorinostat	Histone deacetylase	CTCL, PTCL
Zanubrutinib	BTK	MCL

ALK, Anaplastic lymphoma kinase; *ALL*, acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *BTK*, Bruton's tyrosine kinase; *CLL*, chronic lymphocytic leukemia; *CML*, chronic myelogenous leukemia; *CTCL*, cutaneous T cell cymphoma; *JAK*, Janus kinase; *FLT3*, fms-like tyrosine kinase 3; *HGFR*, hepatocyte growth factor receptor; *IDH*, isocitrate dehydrogenase; *IMiD*, immunomodulatory imide drugs; *MCL*, mantle cell lymphoma; *MDS*, myelodysplastic syndrome; *mTOR*, mechanistic target of rapamycin; *NSCLC*, non-small cell lung cancer; *PDGFR*, platelet-derived growth factor receptor; *PI3K*, phosphatidylinositol 3-kinase pathway; *PTCL*, peripheral T cell lymphoma; *SCF*, stem cell factor; *SLL*, small lymphocytic lymphoma; *STAT5B*, signal transducer and activator of transcription 5B; *VEGFR*, vascular endothelial growth factor receptor.

Radiographic crystallography studies show that imatinib mesylate competitively binds to the ATP-binding site of the ABL kinase and stabilizes it in an inactive conformation. The 50% inhibitory concentration (IC_{50}) of imatinib mesylate for BCR-ABL is in the submicromolar range, and is substantially lower than the supramicromolar levels achievable in the plasma of patients receiving the drug by the oral route.

Despite the success with imatinib mesylate in the treatment of chronic-phase CML and, to a lesser extent, accelerated or blast-phase CML, the preexistence or development of resistance represents a major therapeutic challenge that can occur at any stage of the disease. Primary or secondary resistance can develop through a variety of mechanisms. BCR-ABL–dependent mechanisms correspond to the emergence of mutations in ABL kinase domain, which can be located in the imatinib binding site, the P loop, the catalytic domain, or the activation loop. Many of these mutations are present at the time of diagnosis and resistant clones emerge after exposure to imatinib. Resistance mechanisms independent of BCR-ABL include development of multidrug resistance mechanisms (e.g., PGP related); decreased levels of human organic cation transporter; acquisition of additional genetic abnormalities (clonal evolution) including acquisition of an additional Philadelphia-positive chromosome (Ph+), trisomy 8 and isochromosome 17q, increased expression of the BCR-ABL protein, and Src kinase overexpression.

Imatinib also has activity in diseases dependent on other kinases, such as PDGF receptor PDGFRα, PDGFRβ, or KIT, and is active against myeloproliferative disorders associated with eosinophilia and FIP1L1/PDGFRα or PDGFRβ fusion genes, as well as against systemic mastocytosis without KIT^{D816V} mutation (see Chapters 71 and 72).

Figure 58.6 SCHEMATIC REPRESENTATION OF THE THERAPEUTIC ARMAMENTARIUM IN MALIGNANT HEMATOLOGY.

Common adverse events due to imatinib include fluid overload and edema, and development of heart failure, fatigue, rash, and myelosuppression. Gastrointestinal side effects are common, and nausea and vomiting are frequent reasons for poor compliance.

Dasatinib

Dasatinib is a second-generation ABL kinase inhibitor approved for the treatment of CML. Dasatinib is an oral multikinase inhibitor, affecting BCR-ABL, KIT, PDGFR, and Src kinases. It binds the ATP binding site of ABL in an opposite direction to imatinib, can inhibit active and inactive forms of the kinase, and requires fewer points of contact. This reduced structural stringency in kinase inhibition allows for inhibition of all kinase mutations, with the exception of the *T315I* mutation.

Compared with imatinib, dasatinib is several hundred times more potent as an inhibitor of ABL. Initial studies demonstrated dasatinib-induced responses in patients who had developed resistance to imatinib treated in the chronic, accelerated, and blast phase of CML. There is a high response rate in patients with wild-type sequences of *BCR-ABL* and also in patients with mutations in the ABL protein conferring resistance to imatinib, including *E255V* and *Y253H*. The notable exception is *T315* mutations.[8]

As a multikinase inhibitor, dasatinib has a role in myeloid-lymphoid neoplasms with eosinophilia and recurrent genomic translocations. Dasatinib has a broad toxicity profile, with pulmonary edema, pleural effusions, and thrombocytopenia being the more frequent adverse effects. Recently, higher rates of pulmonary hypertension have been observed in patients receiving dasatinib.

Nilotinib

Nilotinib is another second-generation ABL kinase inhibitor approved for treatment of CML. Nilotinib is structurally related to imatinib, but has structural modifications that increase affinity for the ABL kinase site, binding with an improved topological fit to the kinase site in its inactive form. Nilotinib is 10 to 30 times more potent that imatinib.

In contrast with imatinib and dasatinib, nilotinib is a selective inhibitor of BCR-ABL. Nilotinib is active in chronic- and accelerated-phase CML patients who have developed resistance to imatinib. As with dasatinib, nilotinib was compared with imatinib in a phase III randomized trial as initial therapy for chronic-phase CML patients, with nilotinib achieving higher rates of complete cytogenetic and major molecular responses, and with fewer cases of CML phase progression or clonal evolution in the nilotinib-treated cohorts.[9] Nilotinib is active against all *BCR-ABL* mutations that confer resistance to imatinib, with the exceptions of *T315I*.

Common adverse events with nilotinib include rash, gastrointestinal disturbances (nausea, vomiting, diarrhea), as well as neutropenia and thrombocytopenia. Pleural effusion and peripheral edema are less common than with dasatinib. In addition, QTc prolongation and risk of pancreatitis are serious side effects of nilotinib. Post-approval studies and cross-sectional studies have found nilotinib to also be associated with a risk of peripheral arterial disease.

Bosutinib

Bosutinib is a dual kinase inhibitor of Src and ABL kinases. Although originally described as a Src-selective TK inhibitor, cell line screening assays allowed discovery of its ABL inhibitory activity. ABL kinase assay studies showed the IC_{50} was 1.4 nM. Cell line and animal studies supported the potential therapeutic activity of bosutinib against CML. Bosutinib has does not inhibit wild-type c-KIT of PDGFR, although recent studies have shown inhibitory activity of other kinases, including C-terminal Src-kinase (Csk), erythropoietin-producing hepatoma (Eph) receptors, Trk, Tek, and Axl kinases, as well as some epidermal growth factor receptor (EGFR) and KIT mutants.

Bosutinib docks inside the intermediate conformation of the ATP binding site of ABL (in contrast to imatinib, which binds to the inactive conformation of the site). Binding to the intermediate conformation overcomes the resistance to imatinib conferred by mutations

Y253F, *E255K*, and *D276G*, but does not confer activity against cells expressing *T315I*. In addition, Bosutinib appears to be a poor substrate of multidrug resistance (MDR) transporters, overcoming this additional mechanism of resistance. Bosutinib, like dasatinib and nilotinib before it, was approved for frontline use in chronic-phase CML patients with a phase III trial demonstrating statistically significantly higher rates of cytogenetic and molecular responses.[10]

Common adverse events observed with bosutinib include gastrointestinal upset (diarrhea, vomiting, and abdominal pain), whereas the more common serious adverse events include diarrhea, myelosuppression, and elevated serum lipase and transaminases.

Ponatinib

Ponatinib is a third-generation, dual Src-ABL inhibitor. It was developed using computational and structure-based design to have activity against BCR-ABL forms with mutations that convey resistance to other TKIs, in particular *T315I* mutation. Ponatinib binds ABL in its inactive form as imatinib. Differences in the chemical structure allow ponatinib to maintain interaction with ABL even in the presence of isoleucine in position 315, in cases with a *T315I* mutation. Initial cell- and murine-based studies showed that ponatinib inhibits cells expressing mutant or native *BCR-ABL* with IC_{50} values ranging from 0.37-2 nM. Subsequent human studies demonstrated that ponatinib had activity in CML, including those with *T315I* mutation. Toxicities observed in early clinical trials included pancreatitis and elevation in pancreatic enzymes, fatigue, rash, and elevated aminotransferase levels. Ponatinib received FDA-accelerated approval in 2012 for the treatment of resistant or intolerant CML and Ph+ ALL. However, subsequent trials showed increased arterial thrombosis as well as hypertension events in patients randomized to ponatinib arms, leading to limitations in the indications for ponatinib and the requirement for thrombosis prevention strategies in subjects treated with this drug.[11]

Given the structural similarity to imatinib, as expected ponatinib has activity as an inhibitor of several other targets, including FLT3, c-KIT, vascular endothelial growth factor receptor (VEGFR), PDGFR, and c-SRC. However, ponatinib is yet to be used clinically outside of BCR-ABL–containing hematologic malignancies.

Asciminib

Asciminib, also known as ABL001, is an allosteric inhibitor of BCR-ABL. Unlike imatinib, dasatinib, nilotinib, bosutinib, and ponatinib which bind to the ATP-binding pocket, asciminib binds to the myristoyl pocket of the N-terminus of ABL1 kinase. This pocket normally downregulates the kinase activity, but the function is lost with the formation of the fusion protein. Asciminib was designed to change the conformation and restore the regulatory function of the region of the protein. In BCR-ABL positive cell lines, asciminib inhibits growth at concentrations of 1-10 nM while having little effect on the growth of wildtype cells.

As a result of the disparate binding site and mechanism of action, it has been shown to be clinically active regardless of the mutations around the ATP binding pocket, including in patients with *T315* mutations. In the phase I study,[12] examples of resistance did emerge with a *G463S* mutation located at the myristoyl pocket.

The toxicity profile of asciminib had some overlap with other BCR-ABL1 signal blocking TKIs. Elevation of amylase and lipase were relatively common, but reversible. Clinically evident pancreatitis also occurred, and also appeared to be reversible with cessation of drug. Other adverse events described in the phase I study included fatigue, rash, headache, arthralgia, and hypertension with a majority of reported events grade 1 or 2.

Bruton Tyrosine Kinase Inhibitors

Bruton tyrosine kinase (BTK) is a member of the Tec family nonreceptor kinase. BTK plays a central role in the B-cell receptor activation pathway, fundamental in B-lymphocyte development, differentiation, and signaling.[13] This pathway is also critical for the emergence and progression of several B-cell lymphoid malignancies, including CLL, mantle cell lymphoma (MCL), and others. [14] Activation of BTK is followed by 1-phosphatidylinositol-4,5-biphosphate phosphodiesterase gamma-2 (PLCγ2) activation, leading to release of intracellular calcium, diacylglycerol (DAG), and inositol triphosphate (IP3), with activation of nuclear factor kappa B (NF-κ B) and inhibiting the apoptosis of the normal and malignant B cells. [15] BTK inhibitors have demonstrated activity in preclinical models of B-cell malignancies and may also have activity in treatment of autoimmune disorders.[16]

Ibrutinib is the first BTK inhibitor to receive approval, inactivating BTK through an irreversible covalent bond with a cysteine residue (Cys-481) in the kinase domain, blocking also BTK autophosphorylation at Tyr-223. Acalabrutinib and zanubrutinib also form a covalent bond with Cys-481, with higher selectivity for BTK over other kinases. The latter agents have been denominated second-generation BTK inhibitors by some authors, although mechanistically, they do not differ from ibrutinib. Noncovalent inhibitors of BTK do not require interaction with Cys-481 for BTK inhibition, thus overcoming resistance conferred by C481S mutations, a common mechanism of resistance to covalent BTK inhibitors. Noncovalent BTK inhibitors under development have promising activity in lymphoid malignancies but have not yet received regulatory approval.

Class toxicities of BTK inhibitors include an increased risk of opportunistic infections, including Pneumocystis jirovecii and fungal infections[17]; the mechanisms of increased infection are not fully explained, but do not appear to be limited to B-cell function impairment.[18] Other common complications observed across this class of agents include diarrhea and increased bruising, with increased risk of hemorrhagic complications, the latter resulting from inhibition of collagen-induced platelet activation and aggregation. Cardiovascular toxicities are well recognized and have been observed with all three approved agents, including arterial hypertension and atrial fibrillation in up to 15% of patients. There are no sufficient data to indicate the rates of complications are higher with any one agent.

Ibrutinib, acalabrutinib, and zanubrutinib are substrates of CYP3A4. Relevant interactions with CYP3A4 inhibitors azole antifungal agents as well as antiretroviral agents and grapefruit juice. BTK dose should be reduced if concomitant administration with these agents is necessary. Use with CYP3A4 agents is not recommended. There are no dosing modifications for impaired renal function, and doses should be reduced for mild hepatic impairment and use should be avoided with advanced liver failure.

Efficacy of BTK inhibitors

BTK inhibitors have established efficacy in several B lymphoid malignancies. In chronic lymphocytic lymphoma, BTK inhibitors achieve overall response rates (ORR) in 68% to 94% of cases (with or without deletion of 17p).[19–21] In randomized trials, ibrutinib resulted in higher rates of overall survival than ofatumumab in relapsed CLL patients. In the RESONATE-2 trial, continuous treatment with ibrutinib resulted in higher rates of overall and progression free survival.[19,21] Acalabrutinib, alone or in combination with Obinutuzumab had superior outcomes than chlorambucil combined with Obinutuzumab for previously untreated CLL patients. In mantle cell, initial reports showed ibrutinib achieved response rates of 68%, with 21% complete responses,[22] and a subsequent phase III trial showed similar response rates.[23] While studies with acalabrutinib and zanubrutinib have been reported to achieve response rates between 80 and 90%,[24] complete responses still occur in a fraction of subjects. BTK inhibitors have remarkable activity in Waldenström macroglobulinemia, with responses for ibrutinib of 91%, 73% of which were major responses.[25] Initial studies suggest that this class of agents has activity in activated B-cell center diffuse large B-cell lymphoma, but this was not confirmed in a recent phase III trial, with future emphasis on more specific selection of DLBCL patients for whom this class of agents will be effective. BTK inhibitors have limited activity against follicular lymphoma.

PI3K/AKT/mTOR Inhibitors

The PI3K/AKT/mTOR pathway is involved in the regulation of diverse cellular functions, including cell growth, protein synthesis, cell cycle regulation, glucose metabolism, and motility. PI3K represents a family of enzymes with multiple subunits. These subunits cooperate to transduce upstream signals (from RTKs, G-protein–coupled receptors, and other intracellular stimuli) into the enzymatic conversion of phosphatidylinositol diphosphate (PIP$_2$), to phosphatidylinositol triphosphate (PIP$_3$). The dual-specific phosphatase and tensin homolog (PTEN) opposes the actions of PI3K. PTEN is one of the most frequently mutated tumor suppressor genes in human malignancies, with inactivating mutations, genetic losses, and epigenetic silencing leading to PTEN loss. Phosphatidylinositol triphosphate, through phosphoinositide-dependent kinase-1 (PDK1), leads to the phosphorylation and activation of the serine/threonine kinase AKT.

AKT signals to multiple downstream targets, in particular mTORC1, to promote cell survival and growth. Additional targets of AKT include molecules involved in cell survival and proliferation (e.g., Bad, Bim, procaspase 9, CREB, forkhead transcription factors [FHKR], IB), cell cycle regulators (p21^{CIP1}, p27^{KIP1}, cyclin D$_1$), glycogen synthesis (GSK3), and protein synthesis (FRAP1, p70^{S6K}).

The mechanistic target of rapamycin (also known as mTOR) operates through two complexes: mTORC1 (mTOR-Raptor) and mTORC2 (mTOR-Rictor). mTORC1 is activated by AKT and mediates its downstream proliferation, growth, and survival signaling, specifically through phosphorylation and inactivation of the repressor of mRNA translation initiation factor 4E-binding protein 1 (4E-BP) and ribosomal protein S6 kinase 1 (S6K1; see Fig. 58.7), resulting in enhanced translation of transcripts relevant to lymphoma pathogenesis, including CCND1, MYC, and MCL1. The mTORC1 complex is activated by AKT whereas mTORC2 is capable of activating AKT. The majority of the downstream canonical functions are conducted by mTORC1.

Because of the frequency of PTEN losses or mutations (less common in hematologic malignancies) in transformed cells and the dependence of numerous cancers on an intact PI3K/AKT/mTOR pathway for survival, this cascade has become an attractive therapeutic target.

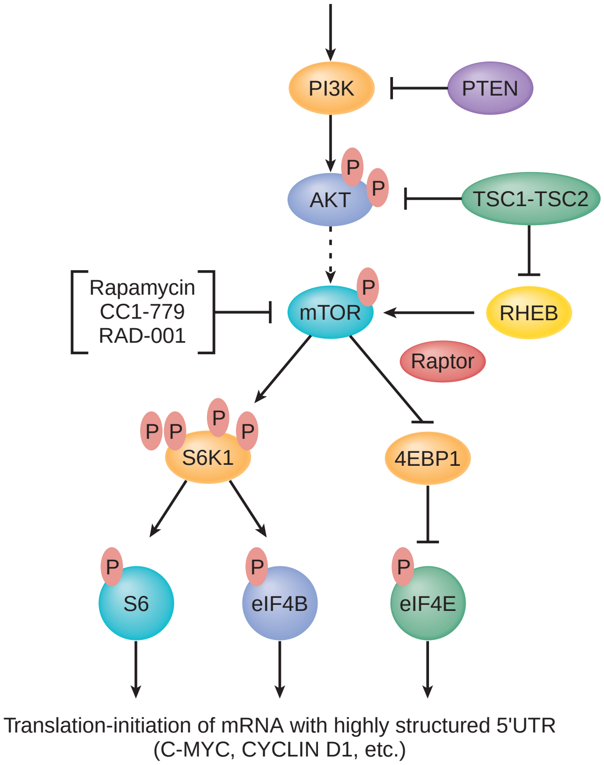

Figure 58.7 RAPAMYCIN OR ITS ANALOGS INHIBIT MAMMALIAN TARGET OF RAPAMYCIN AND THE DOWNSTREAM PHOSPHORYLATION OF S6K1 AND 4EBP1, THEREBY ATTENUATING THE TRANSLATION INITIATION OF mRNAS WITH HIGHLY STRUCTURED 5′-UTR. Activation of the receptor *(FLT-3)* or cytosolic tyrosine kinase (e.g., BCR-ABL) can lead to increased activity of PI3K/AKT. Although it can directly phosphorylate mTOR, AKT activity inhibits the TSC1–TSC2 complex, thereby derepressing RHEB and activating mTOR. The phosphorylation and activation of S6K1, and phosphorylation and inactivation of 4E-BP through Raptor, results in the phosphorylation of S6, eIF4B, and eIF4E, which are involved in the cap-dependent translation of mRNAs with highly structured 5′-UTR. *eIF*, Eukaryotic translation initiation factor; *mTOR*, mammalian target of rapamycin; *PI3K*, phosphatidylinositol 3-kinas; *PTEN*, phosphate and tensin homolog; *RHEB*, Ras homolog enriched in brain; *TSC*, tuberous sclerosis; *UTR*, untranslated region.

PI3K Inhibitors

Phosphatidyl inositol 3-kinases (PI3K) are a family of lipid kinases with highly conserved ATP binding sites that phosphorylate phosphatidylinositides at the 3′ position if the inositol ring.[26] They are classified according to their substrate, and class I PI3Ks perform the enzymatic conversion of phosphatidylinositol diphosphate (PIP2), to phosphatidylinositol triphosphate (PIP3) as a result of upstream signals (from receptor tyrosine kinases [RTKs], G-protein–coupled receptors, and other intracellular stimuli). Class I PI3Ks are heterodimers, with a regulatory subunit p85 and a catalytic subunit, p110. Upstream signals result in activation of the regulatory subunit, which results in release of the catalytic subunit, which then localizes to the cell membrane to convert PIP2 to PIP3. Phosphatidylinositol triphosphate, through phosphoinositoside-dependent kinase-1 (PDK1), leads to the phosphorylation and activation of the serine/threonine kinase AKT, which in turn signals to multiple downstream targets, including mTORC1, BCL2 family members, FOXO, and others, promoting cell survival and growth.

There are four class I PI3K isoforms (PI3Kα, PI3Kβ, PI3Kγ, and PI3Kδ), defined by the p110 catalytic isotype. Each member of class I has a well-defined physiologic role, with variable degree of functional overlap among class members.[27] PI3Kα is ubiquitously expressed and plays a role in insulin signaling and glucose homeostasis, whereas PI3Kβ enhances the actions of integrin $\alpha_{IIb}\beta_3$ on platelet adhesion and signaling. PI3Kγ and PI3Kδ have more restricted expression to the hematopoietic system and are involved in lymphocyte activation, mast cell degranulation, and chemotaxis.[28]

The role of PI3Ks and the PI3K/AKT/mTOR pathway in cancer is well recognized. Mutations and abnormal expression of PI3K members are well recognized in solid tumors and in a minority of hematologic malignancies.[27] In addition, the dual-specific PTEN, which opposes the actions of PI3K, is one of the most frequently mutated tumor suppressor genes in human malignancies, with inactivating mutations, genetic losses, and epigenetic silencing leading to PTEN loss. Of note, the relevance of PI3K in hematologic malignancies is not secondary to genetic activations of the PI3K pathway, but rather the central role that PI3Kδ and PI3Kγ play in lymphocyte signaling (i.e., B-cell and T-cell receptor signaling pathways) and microenvironmental responses to tumors.

There are several PI3K inhibitors approved for treatment of hematologic malignancies, and several others are in development. Their mechanism of action is associated with the specific p110 isoform inhibited. Idelalisib (CAL-101, GS 1101) is a highly selective inhibitor of the p110d isoform of PI3Kδ, whereas duvelisib (IPI-145) inhibits the isoforms of PI3Kδ and PI3Kγγ, and copanlisib (BAY-80-6946) is a pan PI3K inhibitor with predominant activity against PI3Kα and PI3Kδ (Table 58.5). The difference between pan-PI3K inhibitor and isoform-specific inhibitors appears to be related to the conformation adopted by the drugs in the adenine-binding pecked of the catalytic p110 subunit. Pan-PI3K inhibitors (i.e., copanlisib) adopt a flat conformation, whereas isotype-specific inhibitors (i.e., idelalisib, duvelisib) adopt a "propeller shaped" conformation.[29]

TABLE 58.5 **Isoform Selectivity Profile of PI3K Inhibitors**

	IC_{50} (nM)			
	Alpha	**Beta**	**Delta**	**Gamma**
Idelalisib	820	855	2.5	89
Duvelisib	1602	85	2.5	27
Umbralisib	>10,000	>10,000	6.2	1400
Copanlisib	0.5	3.7	0.7	6.4
Buparlisib	52	166	116	262
Pictilisib	3.0	33	3.0	75
AZD8835	6.2	431	5.7	90
ME-101	22,867	30	1	>20,000

The adverse event profile of PI3K inhibitors is closely related to their isoform-specific actions. Studies done with idelalisib have predominantly reported autoimmune and infectious adverse events. Autoimmune events have included pneumonitis, rash, hepatitis (manifested by increase in transaminase concentrations) as well as non-infectious colitis. Most events respond to discontinuation of the drug and use of corticosteroids for severe instances. In cases of isolated transaminase elevation, re-exposure to lower doses of idelalisib may be considered. The incidence of autoimmune adverse events appears to have been higher in patients treated earlier in the course of their disease[30] or when the drug is combined with other immunomodulatory agents.[31] An additional gastrointestinal adverse event includes the risk of intestinal perforation, which may occur in the absence of significant diarrhea. Subsequent research has shown that PI3Kdelta is relevant to the function of regulatory T cells (Tregs).[32]

Opportunistic infections have also been reported, specifically *Pneumocystis jirovecii* pneumonia (PJP), CMV reactivation as well as fungal infections. Autoimmune toxicities and increased risk of infection have been reported with other PI3K delta inhibitors duvelisib and umbralisib although reports from clinical trials with the latter appear to show decreased risk of autoimmune events, possibly related to the additional inhibition of casein kinase 1 epsilon (CK1ε).[33,34]

Copanlisib, because of its actions PIK3 alpha, has a distinct pattern of adverse events. Hyperglycemia is an on-target effect related to PIK3alpha inhibition on insulin receptor signaling, and has been observed in studies of other pan-PI3K inhibitors (buparlisib, pictilisib).[29] In addition to hyperglycemia, subjects treated with copanlisib experienced infusion-related hypertension in approximately 40% of cases.[35] Both hyperglycemia and hypertension were infusion-related, reversible, and could be managed with medical interventions. Other adverse events observed with copanlisib likely are secondary to its actions on PIK3 delta, including diarrhea in 37% of cases (grade 3 in less than 5% of cases), as well as neutropenia in approximately 25% of cases. Other inflammatory autoimmune events such as pneumonitis are rare.

All three currently FDA-approved PI3K inhibitors (idelalisib, duvelisib, and copanlisib) are metabolized by CYP3A. Interactions with strong inhibitors and inducers as well as substrates of this system need to be considered when prescribing these agents. Dose modification guidelines are available. Umbralisib is not metabolized through CYP3A and reportedly has limited medication interactions.

Idelalisib is currently approved as a single agent for relapsed follicular lymphoma and in combination with rituximab for CLL patients. The approved dosing is 150 mg PO twice daily. In the randomized trial in relapsed CLL patients, comparing rituximab plus idelalisib vs. rituximab plus placebo, the addition of idelalisib resulted in longer progression-free survival (median 19.4 months vs. 6.5 months), with response rate of 83.6% vs. 15.5%.[36] All responses were partial. As single agent in relapsed follicular lymphoma, idelalisib was evaluated in a single-arm phase II study and resulted in a response rate of 57% (6% complete responses), with median progression-free survival of 11 months.[37]

Duvelisib is currently approved as single agent for treatment of relapsed CLL, SLL, or FL after two prior lines of therapy. Duvelisib was compared in a randomized trial with ofatumumab including relapsed CLL/SLL subjects with two or more prior lines of therapy but excluding prior BTK or PI3K inhibitor therapy. Overall response was 74% (all partial response [PR]) versus 45% with ofatumumab (all PR), while median progression free survival was 13.3 months vs. 9.9 months (HR 0.52, $P<.0001$).[38] A non-randomized phase II trial of duvelisib was conducted in patients with refractory indolent lymphoma treated with at least two previous treatment regimens, but excluding previous treatment with BTK or PI3K inhibitors. In the follicular lymphoma subgroup ($n = 83$), duvelisib resulted in an ORR of 42% (1.2% complete response), and median progression free survival for the whole cohort ($n = 129$) of patients with follicular, marginal, and small lymphocytic lymphoma was 9.5 months.[39] Copanlisib received accelerated approval for patients with follicular lymphoma treated with two prior systemic therapies. The CHRONOS-1 trial was a single-arm phase II trial that included 141 subjects with relapsed/refractory indolent NHL. The response rate among follicular lymphoma ($n = 104$) was 58.7% (14.4% complete response), with median duration of response in follicular lymphoma of 12.2 months. Progression free survival for the complete trial cohort including other indolent lymphomas was 11.2 months.[40]

AKT Inhibitors

The frequent presence of AKT abnormalities in human neoplasms makes this enzyme an attractive target for potential novel treatment strategies. Several drugs have been developed using dephosphorylation of the active enzyme, allosteric enzyme inhibition, and ATP competition as strategies for targeting AKT. Allosteric inhibitors bind the lipid-binding domain of AKT, resulting in a change in conformation that prevents localization to the plasma membrane and subsequent activation. The allosteric inhibitor perifostine had modest clinical activity as a single agent in patients with Waldenström macroglobulinemia and in patients with myeloma alone or in combination with bortezomib. Phase III studies failed to demonstrate clinical benefit. MK2206 is another oral allosteric inhibitor with minimal single-agent activity against solid tumors and hematologic malignancies.

Early ATP-competitive AKT inhibitors had significant off-target effects. More recently, ipatasertib (GDC-0068), an oral pan AKT inhibitor, has been observed to have significant selectivity for AKT. Clinical development has focused on solid tumors. Afuresertib (GSK 2110183) is a reversible ATP-competitive AKT inhibitor with in vitro activity against ALL, CLL, lymphoma, and myeloma. A phase I study of single-agent afuresertib showed activity in MM, with a maximum tolerated dose of 125 mg PO once daily.[41] Subsequent studies have demonstrated activity of afuresertib when used in combination with bortezomib and dexamethasone for the treatment of myeloma, and with ofatumumab for the treatment of CLL. Frequent adverse events include gastrointestinal complaints (diarrhea, nausea, dyspepsia, gastrointestinal reflux, and anorexia) and fatigue. Severe adverse events include rash, fatigue, elevations in liver function tests, and thrombocytopenia.

Inhibitors of the Mammalian Target of Rapamycin

The first mTOR inhibitor discovered was the naturally occurring macrolide rapamycin (sirolimus), widely used as an immunosuppressant (see Chapter 108). The importance of the mTOR pathway in cancer suggested this agent would have antineoplastic activity. Improvements in solubility and pharmacokinetic properties led to development of rapamycin analogs (rapalogs), of which everolimus and temsirolimus are available as antineoplastic agents.[42] The mechanism of rapamycin and its analogs is similar: after complexing with the small protein FKBP12, they bind irreversibly to the FKBP12-rapamycin binding site on the mTOR protein. Acute rapamycin treatment only affects mTORC1 because the FKBP12-rapamycin is occluded in mTORC2. Prolonged rapalog exposure may result in decreased mTOR availability and therefore indirectly decreased mTORC2 activity through limited mTORC2 complex formation. It is well recognized that growth factor signaling initiated through the RTKs or caused by the activity of cytosolic tyrosine kinases (TKs), such as BCR-ABL, results in activation of PI3K/AKT signaling. AKT has been shown to phosphorylate and inactivate tuberous sclerosis (TSC)2 (also known as tuberin), thereby disrupting its interaction with TSC1 (or hamartin; see Fig. 58.7). Inhibition of the TSC1–TSC2 complex derepresses RHEB, which is a small G protein that activates mTOR. When RHEB is in an active GTP-bound state, its localization to the membrane stimulates mTOR-mediated phosphorylation of the downstream eukaryotic initiation 4E-BP and ribosomal protein S6K1 (see Fig. 58.7). However, the association of mTOR with the 150-kDa Raptor (regulatory-associated protein of mTOR) is necessary for the phosphorylation of 4E-BP and S6K1. mTOR-mediated phosphorylation and activation of S6K1 results in the phosphorylation of the ribosomal S6 protein and eIF4B (see Fig. 58.7). AKT has also been shown to directly activate S6K1. S6K1 activity is involved in regulating the translation of a group of mRNAs that have a highly structured 5′ -UTR (untranslated region), including mRNAs that have a 5′-TOP (terminal oligopyrimidines; a stretch of 4 to 14 pyrimidines).[43]

The rapalogs temsirolimus and everolimus have been tested in lymphoid malignancies, and as single agents they have demonstrated activity, although modest, against a variety of lymphomas (see Chapter 82). In the initial phase II study in patients with MCL, temsirolimus was administered at a dose of 250 mg based on a phase II study done in renal cell carcinoma patients. A modest response rate was noted (ORR: 38%), but the majority of patients required a dose reduction because of myelosuppression, particularly thrombocytopenia. A second trial in relapsed refractory MCL patients was conducted to determine if a lower dose of temsirolimus could be used. In a follow-up phase II study, temsirolimus was given at a dose of 25 mg IV weekly and was found to be as effective as the 250-mg IV dose, with a modest improvement in the toxicity profile and dose reductions. This dose and schedule were also noted to be efficacious in nonmantle cell NHL, with thrombocytopenia being the main dose-limiting toxicity. A recent phase III study in relapsed refractory MCL patients evaluated two different dosing regimens of temsirolimus; 175 mg weekly for 3 weeks followed by 75 mg weekly versus 175 mg weekly for 3 weeks followed by 25 mg weekly versus the investigator's choice.[44] At the conclusion of this study, it was determined that the temsirolimus regimen with 175/75 mg dosing had a significant improvement in progression-free survival (PFS) and objective response rate compared with the investigator's choice. Everolimus, given orally at a daily dose of 10 mg has single-agent activity against Hodgkin lymphoma (PMI, Waldenström macroglobulinemia, diffuse large B-cell lymphoma [DLBCL], CLL, and other relapsed lymphomas).

The most common side effect of rapalogs is myelosuppression; other common side effects include fatigue, oral ulcers, and dermatologic abnormalities. Metabolic abnormalities are common, including hyperglycemia, hypercholesterolemia, and hypertriglyceridemia. An uncommon pulmonary toxicity manifested as interstitial lung disease has also been observed with rapalogs.

Anaplastic Lymphoma Kinase Inhibitors

Anaplastic lymphoma kinase (ALK) encodes for a 210 kDa receptor tyrosine kinase, member of the insulin receptor superfamily, closely related to leukocyte tyrosine kinase. While ALK has a normal role in nervous system development, translocations involving ALK have been described in a variety of malignancies, including anaplastic large cell lymphoma (NPM-ALK, TFG-ALK, ATIC-ALK and CLTC-ALK translocations) [45] diffuse large B-cell lymphoma (NPM-ALK, CLTC-ALK, SQSTM1-ALK, SEC31A-ALK), as well as non-small cell lung cancer (NSLCL) (EML4-ALK translocation and others)[46] and inflammatory myofibroblastic tumors in children.[47] These translocations result in ALK chimeras with fusion of the intracytoplasmic domain of ALK with partner proteins that provide a dimerization domain that results in ALK-mediated autophosphorylation and constitutive activation. Subsequent signaling promotes cellular proliferation, survival, and growth via phospholipase Cγ, RAS/MAPK, PI3K, and c-Src. ALK inhibitors are currently approved for treatment of non-small cell lung cancer (NSCLC), including crizotinib, alectinib (CH5424802), and ceritinib.

Crizotinib is a dual ALK/c-MET inhibitor with additional inhibitory activity against the kinase ROS1. It inhibits kinase activation through binding to the kinase domain and displacing the kinase activation loop, interfering with ATP and substrate binding. Crizotinib was shown to be 20-fold more selective for ALK and MET than other kinases, and inhibited cell proliferation and induced apoptosis in NPL-ALK-dependent cell lines. Alectinib is a dual ALK/RET inhibitor that binds to the ATP site of ALK, but can maintain the interaction with the ATP binding site in presence of the common gatekeeper mutation L1196M, overcoming this mechanism of resistance.[48]

The most common adverse events of crizotinib include gastrointestinal symptoms (nausea, vomiting, diarrhea), visual impairment, asthenia, cough, and myelosuppression (neutropenia, lymphopenia) as well as elevations of hepatic function tests. Alectinib has been primarily tested in NSCLC subjects, and its adverse events include fatigue, constipation, edema, and myalgia. Less commonly, alectinib is associated with hepatotoxicity, pneumonitis or interstitial lung disease, and bradycardia as well as increases in creatine phosphokinase.

Crizotinib is metabolized by CYP3A system, with known interactions with strong inhibitors or strong inducers of this system. Alectinib is also metabolized by CYP3A4 into its metabolite M4, but no interactions were seen when coadministered with strong inducers or inhibitors of CYP3A.

The initial clinical studies done in patients with NSCLC showed the maximum tolerated dose was 250 mg orally twice daily. Although initially tested as a c-MET inhibitor in these patients, ALK translocations were reported to be associated with marked responses in patients treated with crizotinib. Subsequent studies in ALK-rearranged NSCLC confirmed the activity of crizotinib in NSCLC with ALK translocations. In 2011, the FDA granted approval for crizotinib in this patient population. Subsequent studies conducted in relapsed and refractory ALK-positive anaplastic large-cell lymphoma showed high rates of response to single-agent crizotinib. Additional trials testing crizotinib for ALK positive lymphomas are ongoing. Studies with alectinib in treatment of ALCL are ongoing in countries with high prevalence of these diseases,[49] and published experience in this disease is limited to case reports and series.[50]

Inhibitors of the RAF1/MEK/ERK Pathway

The MAPK (mitogen-activated protein kinase) pathways consist of three parallel serine-threonine kinase modules that are intimately involved in the control of cell survival, proliferation, and differentiation: JNK (c-Jun N-terminal kinase), p38 MAPK, and ERK (extracellular signal-regulated kinase). Although exceptions exist, JNK and p38 MAPK primarily exert proapoptotic functions, but ERK activation is generally associated with cell survival. The only well-defined activator of ERK is the serine-threonine kinase mitogen-activated protein kinase 1/2 (MEK1/2), but numerous ERK targets have been identified, including ELK-1, CREB, BCL2, Bad, FRAP1 (also known as mTOR), and caspase 9, among numerous others. The activating effects of MEK1/2 on ERK are opposed by phosphatases that dephosphorylate and inactivate the enzyme (e.g., MAP kinase phosphatase 1/2).[51]

The major activator of MEK1/2 is the serine-threonine kinase RAF, of which three forms exist: RAF1, B-RAF, and A-RAF. RAF can be activated by Ras (discussed earlier), as well as through various RAS-independent pathways, including PKC (protein kinase C), KSR (kinase suppressor of Ras), as well as the Src and JAK family of kinases, among others. The activation of RAF involves several processes, including recruitment to the plasma membrane, phosphorylation on serine and threonine residues, and dimerization. Interference with any of these processes can lead to inhibition of RAF activation as well as downstream targets.[52]

Dysregulation of the RAF/MEK/ERK pathway has been observed in most hematopoietic malignancies, including acute leukemia, CLL, MM, and lymphomas. Consequently, there has been considerable interest in the development of pharmacologic inhibitors of the RAF/MEK/ERK pathway in these disorders. In addition to their potential intrinsic activity against malignant hematopoietic cells, evidence indicates that such agents might also enhance the activity of conventional cytotoxic drugs. Nevertheless, translation of RAF/MEK/ERK inhibitors into the treatment of hematologic malignancies has significantly impacted the treatment of certain malignancies.

Vemurafenib and Dabrafenib

Vemurafenib is a selective inhibitor of mutant B-RAF, and was developed with a scaffold-based drug design approach and was able to achieve serum concentrations in excess of the IC50.[53] Although originally approved for metastatic melanoma harboring the B-RAF V600E mutation, it was the first MAPK pathway targeting medication to be approved for the treatment of hematologic malignancy, specifically for hairy cell leukemia (HCL) and Erdheim-Chester disease (ECD). B-RAF V600E was identified as a key genetic lesion in HCL in the early 2000s, and nearly universally mutated in this condition and inhibition with vemurafenib induces responses in over 95% of relapsed and refractory cases (Chapter 77).[54,55] Although ECD was formerly felt to be an inflammatory disorder, the identification of recurrent activating mutations in the RAF/MEK/ERK pathway led to its reclassification as a hematologic malignancy. Similarly, another histiocytic disorder, Langerhans cell histiocytosis (LCH), was identified as a clonal disease through genetic analyses. Both ECD and LCH were found to have a high prevalence (38% to 57%) of mutations at the V600 residue of B-RAF.[56,57] The efficacy of vemurafenib in these diseases was evaluated as part of the histology independent VE-BASKET study, and found an ORR over 60% for these diseases. [58] Vemurafenib was approved by the FDA for the treatment of B-RAF V600E mutant ECD in 2017.

Dabrafenib is a competitive ATP binding site inhibitor for B-RAF, with lower IC^{50} concentrations for mutant B-RAF than wildtype. Notably, dabrafenib has reported activity in CNS lesions for patients with V600E mutant malignancies. Early reports have suggested that it may play a role in the treatment of ECD, with reported high response rates, including in patients with vemurafenib resistance or progression of lesions in the CNS.[59]

Inhibitors of *fms*-like Tyrosine Kinase 3 (FLT3)

The FLT3 is a surface receptor within class III receptor tyrosine kinase family and is also known as CD135.[60] It is transmembrane protein and expressed on normal CD34+ hematopoietic stem cells and immature progenitors of both B-lymphoid and myeloid progenitors. When bound to FLT3 ligand in a dimeric form, it phosphorylates downstream targets, particularly simultaneous activation of non-overlapping pathways of the PI3K/AKT pathway and the RAS/RAF/MEK pathway. Signal transduction leads to transcription of genes important for proliferation and anti-apoptotic pathway. FLT3 is highly implicated in hematologic malignancies, particularly AML. Wild-type FLT3 is usually expressed at a high level in AML. Most crucial has been the identification of activating mutations in over 30% of AML patients. The most common mutations are internal tandem duplications of the transmembrane domain, which have been consistently associated with more adverse outcomes. Point mutations of the tyrosine kinase binding domain (TKD), particularly at the D835 residue, can also be activating and potentially sensitive to inhibition. TKD mutations have not consistently been associated with more adverse outcomes.

Inhibitors of FLT3 may be classified as type I or type II. Type I inhibitors bind to the gatekeeper domain near the ATP binding pocket in both the active and inactive conformations of the protein. Type II inhibitors bind to a hydrophobic region directly adjacent to the ATP binding site when the protein is in the inactive conformation. Type II inhibitors do not inhibit FLT3 with TKD mutations, as these mutations favor the active conformation of the protein.

Sorafenib

Although sorafenib has not found a role as a MAPK pathway inhibitor in solid tumors, it has found a niche as a FLT3 inhibitor in AML. Sorafenib was original developed as an inhibitor of RAF, but early on was found to have broad activity across numerous kinase families including VEGFR, PDGFRβ, c-KIT, and FLT3.[61,62] Early evaluation of sorafenib in AML noted modest single-agent activity, and it was subsequently combined with multiagent chemotherapy in the upfront setting.[63] Response rates and disease-free survival in phase II settings were encouraging, and evaluation of FLT-ITD mutant subsets suggested that the inclusion of sorafenib with initial chemotherapy and subsequent maintenance may have improved the outcomes of this adverse mutation. As a type II inhibitor, correspondingly, analyses were not suggested of improvements in patients with TKD mutations.[64] Studies with sorafenib paved the way for other FLT3 and *multi-kinase inhibitors in AML.*

Midostaurin

Midostaurin is a multikinase inhibitor that is a derivative of the naturally occurring staurosporine, and was originally developed as an inhibitor of protein kinase C. In vitro, it has broad activity, and further characterization of the compound found it capable of inhibiting numerous serine and tyrosine kinases.[65] Its broad activity includes PDGFR, VEGFR, Syk, Src, and c-kit. Midostaurin undergoes metabolism in the cytochrome p450 pathway into at least 2-major metabolites, which also appear to have kinase inhibitory activity. Midostaurin's potential as a FLT3 inhibitor was identified through broad screening of compounds to induce apoptosis in FLT3-ITD expressing cells. Further characterization of midostaurin demonstrated that it is a type I inhibitor of FLT3 and active in both FLT3-ITD and FLT3-TKD, but has a clear affinity for mutant protein, with a ten-fold lower inhibitory concentration of wildtype FLT3.[66] Although only modest activity of midostaurin was identified in single agent studies, it was moved into treatment in combination with front line therapy, and the phase III RATIFY study demonstrated a clear overall survival advantage in FLT3 mutant AML when combined with traditional 7+3 therapy, and was approved for combination therapy in 2017.[67]

The c-KIT inhibitor effects of midostaurin are also clinically important. Midostaurin inhibits c-KIT D816V mutation, which is found in 80% of patients with systemic mastocytosis and confers upfront resistance to inhibition with imatinib. Systemic mastocytosis patients have high response rates to midostaurin, with 50% to 71% of patients with aggressive forms of the disease responding to single-agent therapy. However, inhibition of KIT may lead to myelosuppression that has been observed secondary to midostaurin.[66] Common side effects of midostaurin include elevated liver enzymes, nausea, myelosuppression, edema, and prolonged QTc (requiring monitoring) (see Chapter 60).

Gilteritinib

Gilteritinib is a pyrazine carboxamide derivative and was specifically synthesized to be a potent inhibitor of FLT3. It does target other kinases, such as AXL, but has a very high affinity for mutant FLT3 with an IC_{50} of 1 nM. This compares favorably to the wildtype form, of 5 nM as well as to other kinases, such as AXL with an IC_{50} of 41 nM. Clinical studies with gilteritinib have demonstrated a lower rate of myelosuppression compared to other FLT3 inhibitors. This is often attributed to the fact that gilteritinib does not inhibit c-kit, unlike many of its related compounds. Clinically, single-agent gilteritinib had activity even at low levels in early studies, and in relapsed and refractory disease, 24% of patient achieved a CR with incomplete recovery of counts. The phase III ADMIRAL study compared gilteritinib to other standard forms of salvage therapy in AML patients after failure of frontline intensive therapy, and demonstrated a median OS benefit of 9.3 months versus 5.6 months, as well as an advantage of patients proceeding to allogeneic stem cell transplant. Results of the ADMIRAL study resulted in FDA approval of gilteritinib in 2018.[68] Common side effects of gilteritinib include arthralgias, myalgias, fatigue, and edema (see Chapter 60).

Quizartinib

Quizartinib is a small molecule inhibitor developed specifically as a FLT3 inhibitor, with kinase inhibitor active of c-kit and PDGFR as well. It is a type II inhibitor and does not affect TKD mutations. Nevertheless, preclinical and early clinical data suggested potent antileukemia effects in FLT3-ITD models and patients. IC_{50} values in vitro were 1.1 nM for inhibition of FLT3 autophosphorylation and 0.56 nM for inhibition of FLT-ITD cell models. Early phase trials found in relapsed/refractory AML, high rates of blast clearance including reported remissions over 30% in multiple early trials.[69,70] The phase III QuANTUM-R trial evaluated the efficacy of quizartinib versus high-intensity salvage chemotherapy in adult patients with relapsed FLT3-ITD with less than six months remission, and demonstrated a median OS benefit of 6.2 versus 4.7 months.[71] Based on these outcomes, quizartinib has been approved for relapsed/refractory AML in Japan. In the United States, approval was withheld due to concerns about the quality of remission and persistence of severe cytopenias is a major toxicity. Most FLT3 inhibitors have some concerns of either being an inhibitor of potassium channels, or having a high level of interaction with other medications that inhibitor these channels and associated prolongation of the QTc interval. In the QuANTUM-R study. Common side effects of quizartinib include neutropenia, anemia, thrombocytopenia, and nausea (see Chapter 60).

Crenolanib

Crenolanib, a benzamidine quinolone analog originally developed as an inhibitor of PDGFR, was found to be a type I inhibitor of FLT3 potent effects against both FLT3-TKD and ITD mutations with IC_{50} as low as 1.2 nM. Similar to gilteritinib, it has selective activity against c-kit and appears in early studies to have less myelosuppression. Phase II trials with crenolanib have suggested rates of CR and CRi of 15% to 37% in relapsed/refractory FLT3 mutated AML patients.[72] Crenolanib development is ongoing.

Janus Kinase 2 Inhibitors

JAK2 is a non-RTK that plays a central role in the transduction of differentiation and proliferation signals in hematopoietic progenitor cells. Ligand binding to surface receptors for hematopoietic growth factors leads to phosphorylation of JAK2 with subsequent activation of transcription factors in the JAK/signal transducer and activator of transcription (STAT) pathway, including STAT3 and STAT5 (see Chapters 68 to 70). Identification of the JAKV617F mutation in patients with myeloproliferative neoplasms, including polycythemia vera, essential thrombocythemia, and primary myelofibrosis, represented a fundamental step in understanding the pathophysiology of these disorders. The genetic abnormality corresponds to a point mutation in nucleotide 1849 of the molecule, where guanine replaces thiamine, resulting in substitution of a valine for phenylalanine in the JH2 pseudokinase autoinhibitory domain of the molecule. The result is either hypersensitivity to cytokine signals or constitutive activation of the kinase. Development of JAK2 inhibitors followed as a rational, targeted therapeutic strategy for these neoplasms (see Chapters 70 to 72).

Ruxolitinib

Ruxolitinib (INCB018424, Jakafi) is a small-molecule inhibitor of JAK1 and JAK2, and the first-in-class JAK inhibitor to receive FDA approval for treatment of intermediate- and high-risk myelofibrosis (see Chapter 70).[73,74] It exerts its inhibitory activity through competitive inhibition of the kinase's ATP-binding catalytic site. In preclinical studies, JAK1/2 inhibition with ruxolitinib decreased STAT3/5 signaling both in wild-type cells and those carrying *JAKV617F*. Two large phase III studies of ruxolitinib have evaluated the efficacy of ruxolitinib compared to best alternative care in intermediate-2 and high-risk myelofibrosis, where the primary endpoint was reduction in splenomegaly: COMFORT-I and COMFORT-II. Responses were observed in patients both with the *JAKV617F* mutation as well as those with wild-type *JAK2*, and clearly favored ruxolitinib. Importantly, the majority of patients experienced a decrease in constitutional symptoms and improved exercise tolerance and performance status, as well as weight gain. Additionally, long-term follow-up suggests an overall survival benefit, and ruxolitinib is a standard of care for this population. Nevertheless, the medication was not effective in reversing histologic, cytogenetic, or molecular abnormalities in peripheral blood or BM, suggesting that ruxolitinib is not curative.[75] More recent clinical trials suggest that ruxolitinib in combination therapies, such as hypomethylating agents, may play a role in reversing fibrosis. Ruxolitinib has also been evaluated in polycythemia vera. The phase III RESPONSE study enrolled patients refractory or intolerant to hydroxyurea and demonstrated improvement in spleen size and hematologic response. Rapid redevelopment of splenomegaly and symptom exacerbation can occur after abrupt interruption or discontinuation of ruxolitinib. Common side effects of ruxolitinib include myelosuppression, primarily anemia, and thrombocytopenia requiring dose modifications as expected with inhibition of the JAK:STAT pathway; increased risk of infections and herpes zoster; gastrointestinal symptoms (abdominal pain, diarrhea), fatigue, and headache.

Fedratinib

Fedratinib is a pyrimidine-based JAK2 inhibitor specifically developed to be selective for JAK2 without cross-inhibition of other kinases in the same class, including JAK1, JAK3, and TYK2. In vitro IC_{50} for JAK2 is 3 nM, but over 100 nM for the related kinases, whereas ruxolitinib inhibits JAK1 with an IC_{50} 3.3 nM. Large phase III studies evaluated fedratinib in JAK inhibitor naïve and previously treated patients (JAKARATA and JAKARTA-2) and identified significant improvement in splenic volume and quality of life. Development was halted when multiple cases of an ill-defined encephalopathy were reported, and there was suspicion that fedratinib may cause Wernicke encephalopathy. However, review of the data strongly suggested that all afflicted patients had severe cachexia and developed Wernicke encephalopathy and these events were probably not directly related to fedratinib, but instead due to nutritional deficiencies exacerbated by gastrointestinal toxicities. Fedratinib was subsequently approved with warning to supplement thiamine and immediately cease dosing in the event of encephalopathy[76] (see Chapter 72).

Other JAK2 Inhibitors

Several other inhibitors with activity against JAK2 remain under investigation. Pacritinib is a JAK2 inhibitor with activity against the wild-type kinase as well as the JAKV617F-mutated kinase, and has activity against FLT3. It achieves high rates of reduction in spleen volume and in early phase studies did not appear to be associated with high rates of thrombocytopenia. The phase III PERSIST-1 trial evaluated patients with higher-risk primary myelofibrosis without regard for anemia or thrombocytopenia. Primary endpoint of spleen volume reduction by 35% or more was achieved by 19% of patients.[77] Further studies are examining the efficacy specifically in myelofibrosis patients with severe thrombocytopenia. The main side effects are gastrointestinal, predominantly diarrhea, nausea, vomiting, and abdominal pain, while hematologic adverse events are modest.

Momelotinib (CYT387) is an oral multikinase inhibitor affecting JAK1/2, TYK2, TBK1, PRKD1, ROCK2, PRKCN, MAPK8, and CDK2/cyclin A. Early trials in myelofibrosis patients resulted in decreased splenomegaly and improvement in symptoms in the majority of patients treated and appeared to be effective in patients refractory to ruxolitinib. The phase III SIMPLIFY-1 trial compared momelotinib to ruxolitinib with a noninferiority design. Although there was demonstrable activity, it did not meet criteria for non-inferiority compared to ruxolitinib, which remains a standard of care. Nevertheless, development of momelotinib is continuing to evaluate efficacy in the second-line setting. The most common side effects included myelosuppression, primarily thrombocytopenia. Nonhematologic side effects included headache, QTc prolongation, neuropathy, and abnormal liver test results. The maximum tolerated dose has been established at 300 mg/day given continuously in 28-day cycles.

Cyclin-Dependent Kinase Inhibitors

Orderly progression through the cell cycle is regulated by the coordinated expression of a variety of genes and proteins, and effected by the interactions between cyclins, CDKs 1 to 9 and endogenous CDK inhibitors (e.g., $p21^{CIP1}$, $p27^{KIP1}$, and $p57^{KIP2}$; see Fig. 58.1). CDK1, in association with cyclins A and B, is involved in G_2M progression; CDK2, CDK4, and CDK6, in association with cyclins A, D, and E, are involved in G_1S progression. Activation of CDKs results in phosphorylation of the pRb, which leads to its dissociation from the E2F transcription factor. Once freed, E2F triggers the transcription of diverse genes involved in cell cycle progression (thymidylate synthase and DHFR, among numerous others). Endogenous small-molecule CDK inhibitors such as $P21^{CIP1}$ and $P27^{KIP1}$ bind stoichiometrically to CDKs and inhibit their activity. CDK activity can also be regulated through inhibitory or activating phosphorylation. Interference with the activation of CDKs results in dephosphorylation of pRb, leading in turn to binding and inactivation of E2F and inhibition of cell cycle progression.

Cell cycle dysregulation is a cardinal characteristic of cancer. A classic example of this phenomenon is the association of increased expression of cyclin D_1 in MCL. Regulation of the cell cycle has been found to be closely related to apoptosis, and disruption of normal cell cycle transit has been shown to be a potent cell death stimulus. A corollary of this observation is that agents that interfere with the cell cycle, in addition to blocking cell cycle progression, can be potent inducers of programmed cell death. Cell cycle inhibitors can be subdivided into several categories. For example, they can act directly, as in the case of CDK inhibitors, or indirectly, as in the case of histone deacetylase inhibitors (HDIs), compounds that block cell cycle progression by inducing endogenous cell cycle inhibitors such as $P21^{CIP1}$. The latter agents are discussed later in this chapter. CDK inhibitors can also be classified as specific (i.e., directed against a particular CDK, such as CDK2) or those that nonspecifically inhibit most CDKs (e.g., flavopiridol).

Flavopiridol

Flavopiridol (L86-8275) is a semisynthetic flavonoid derived from the Indian plant *rohitukine*. It was the first CDK inhibitor to enter clinical trials in humans. Flavopiridol binds to the ATP-binding site of CDKs, resulting in reversible, competitive enzyme inhibition at concentrations of less than 100 nM. As noted earlier, flavopiridol is a relatively nonspecific CDK inhibitor and inhibits all CDKs, although it is less effective against CDK7. Flavopiridol induces G_1S or G_2M arrest, presumably a consequence of inhibition of CDK1 and CDK2. Flavopiridol may also act to block cell cycle progression by downregulating cyclin D_1 levels, inhibiting the CDK-activating complex (CDK7), or both.

In addition to blocking cell cycle progression, flavopiridol has been shown to be a potent inducer of apoptosis in malignant hematopoietic cells (e.g., acute and chronic leukemia) at low concentrations (e.g., <100 nM). Moreover, flavopiridol has shown activity against MM cells in vitro. The proapoptotic actions of flavopiridol have been attributed to its capacity to inhibit the positive transcription elongation factor-β (PTEF-β), cyclin T/CDK9 complex by inhibiting phosphorylation of the C-terminal domain of RNA polymerase II. This leads to downregulation of several antiapoptotic proteins, including BIRC4, P_{21}^{CIP1}, and, in the case of MM cells, Mcl-1. Flavopiridol has also recently been shown to block the antiapoptotic actions of the IAP family member survivin.

In clinical studies, flavopiridol was initially administered as a 72-hour continuous infusion every 2 weeks, with a maximally tolerated dose of 40 mg/m^2. Steady-state plasma levels in excess of those necessary to inhibit CDKs and induce apoptosis in leukemia cells (e.g., 350 nM) were achieved. Dose-limiting toxicities were fatigue, diarrhea, nausea, and myelosuppression. However, the occurrence of thromboembolic phenomena and the general lack of single-agent activity have limited enthusiasm for administering flavopiridol by this schedule. Flavopiridol has also been administered as a daily IV bolus for 1, 3, or 5 days every 3 weeks with manageable toxicity, and other schedules are being examined, including a hybrid schedule with half the dose administered as an IV bolus and the other half as a more prolonged infusion. When administered as a daily bolus infusion for 3 days every 3 weeks, flavopiridol exhibited modest activity in patients with MCL. A novel pharmacologically directed schedule of flavopiridol has been developed in which half of the dose (e.g., 30 mg/m^2) is administered as a 30-minute bolus-loading infusion and 30 mg/m^2 as a 4-hour infusion. In a phase I study, objective response rates of 45% were obtained with this schedule in patients with progressive CLL, including some with high-risk disease.[78] Because of the rapidity of response, particularly in patients with high white blood cell counts, aggressive measures designed to avoid tumor lysis syndrome (TLS) (e.g., hydration, alkalinization of the urine, administration of rasburicase) are advisable. Efforts are now underway to use this novel flavopiridol schedule in combination with other agents and in other hematologic malignancies.

Because of limited single-agent activity, combination regimens involving flavopiridol are being explored in hematologic malignancies. On the basis of preclinical evidence of synergism with the antimetabolite ara-C, a regimen combining flavopiridol on a daily IV bolus schedule followed by high-dose ara-C has been initiated in patients with AML and has shown some activity. In a phase II study, flavopiridol was administered as a 1-hour bolus infusion of 50 mg/m^2 daily for 3 days before administration of high-dose ara-C (day 6) and mitoxantrone (day 9). CR rates of 67% were obtained in patients with high-risk AML and more than half were durable. More recently, evidence of synergism between flavopiridol and other signal transduction modulators has become the focus of considerable attention. For example, the observation that flavopiridol interacts synergistically with imatinib mesylate against CML cells, including some that are imatinib mesylate resistant, has prompted the initiation of a phase I trial of flavopiridol and imatinib mesylate in patients with progressive BCR-ABL$^+$ hematologic malignancies. Four out of 21 patients responded. Evidence that flavopiridol interacts synergistically with HDAC and proteasome inhibitors in human leukemia cells has appeared, and clinical trials combining flavopiridol with the HDI vorinostat or the proteasome inhibitor bortezomib in patients with refractory AML/MDS and MM/indolent NHL are currently underway.

Targeting Apoptosis Signaling in Hematologic Malignancies

The processes of cell division and cell death are tightly coupled so that a net increase in cell numbers does not occur. Alterations in the expression or function of the genes controlling cell division and cell death can upset this delicate balance and are hallmarks of cancer. Although conventional anticancer drugs cause cell cycle perturbation or DNA damage, they do not directly interact with the intracellular machinery involved in apoptosis. Tumor selectivity of conventional agents is largely caused by the increased sensitivity to apoptosis of tumor cells after DNA damage or cell cycle perturbation. Novel therapeutic agents or strategies that target critical regulators or effectors of apoptosis are under development and clinical testing, and these agents or strategies have the potential to exert selective cytotoxicity against cancer cells.

Caspases are the “executioners” for apoptosis. They are proteases that exist as inactive zymogens and are activated by proteolytic cleavage of their proforms in response to a variety of death stimuli. This processing occurs at conserved aspartic acid residues, thus generating the enzymatically active caspases. Caspase activation is organized as a cascade, with an upstream initiator and downstream effector caspase. Upstream initiator caspases contain large prodomains that interact with specific proteins involved in triggering the cascade. The downstream caspases, which function as the ultimate effectors of apoptosis, possess small prodomains and are activated predominantly by proteolytic cleavage by upstream caspases. The irreversible cleavage of specific protein death substrates by the downstream effector caspases directly or indirectly accounts for the biochemical and morphologic changes that are recognized as apoptosis.

At least three pathways of caspase activation leading to apoptosis have been identified (Fig. 58.8): (1) the receptor-initiated apoptosis pathway, where the TNF family of cytokine receptors activate initiator caspases such as caspase 8; (2) the mitochondria-initiated apoptosis pathway, where cytochrome c and other prodeath effectors are released from mitochondria into the cytosol that results in activation of caspase 9; and (3) a pathway of caspase activation, which involves a serine protease, granzyme B, that directly cleaves and activates several caspases, including procaspase 3.

Proapoptotic Targets of Anticancer Agents

Most cancer cells have active antiapoptotic pathways that prevent cell death in response to growth, checkpoint, DNA damage, and metabolic stimuli. A number of current anticancer agents in development target these pathways and are designed to be effective alone or in combination with other agents that disrupt the cell cycle, DNA synthesis, invoke DNA damage, and so on.

Death Receptor–Initiated Apoptotic Signaling

Several TNF family receptors are known to transduce signals that result in apoptosis. These include TNFRSF1A (also known as CD120a and previously designated tumor necrosis factor receptor-1 [TNFR1]), TNFRSF6 (also known as CD95, APO-1, or FAS), TNFRSF25 (also designated TRAMP and known as DR3 or APO3), TNFRSF10A (also known as DR4 or TRAIL-R1), and TNFRSF10B (also known as DR5 or TRAIL-R2). These receptors, also called *death receptors*, are characterized by the presence of a death domain within their cytoplasmic region, and have been shown to trigger apoptosis upon binding to their cognate ligands or specific agonist antibody. The activating ligands for these death receptors are structurally related molecules that also belong to the TNF gene superfamily such as TNFSF6 (also known as Fas ligand), TNF, and TRAIL.

Ligation of death receptors produces receptor trimerization and formation of a death-inducing signaling complex (DISC). This is composed of TNFRSF6, Fas (TNFRSF6)-associated via death domain (FADD), and procaspase 8, an apical signaling complex that mediates receptor-induced apoptosis. FADD binds directly to FasR, TNFRSF10A, or TNFRSF10B and indirectly to TNFRSF1A via TNFRSF1A-associated via death domain protein (TRADD). FADD is essential for cell death signaling from all three receptors. FADD interacts through its C-terminal death domain to cross-link TNFRSF6, TNFRSF10A, or TNFRSF10B receptors and recruits procaspase 8 and procaspase 10, or TRADD, through its N-terminal death effector domain (DED) to the DISC (see Fig. 58.8). Oligomerization of caspase 8 within the DISC results in a high local concentration of the zymogen. The induced proximity under these crowded conditions generates low levels of intrinsic proteolytic activity of caspase 8, enough to allow the various proenzymatic molecules to mutually cleave each other. Processing of caspase 8 removes the DED-containing prodomain, thus releasing the activated protease into the cytosol, where it can cleave and activate other downstream procaspases. In certain types of cells (type I), enough caspase 8 is activated by the activation of the death receptor to cause apoptosis. In other cell types, such as hepatocytes (type II), a sufficient level of caspase 8 activation is not achieved and the apoptotic signal is amplified by the mitochondrial pathway. The active caspase 8 cleaves the cytosolic p22 Bid into a BH3-only domain-containing, proapoptotic,

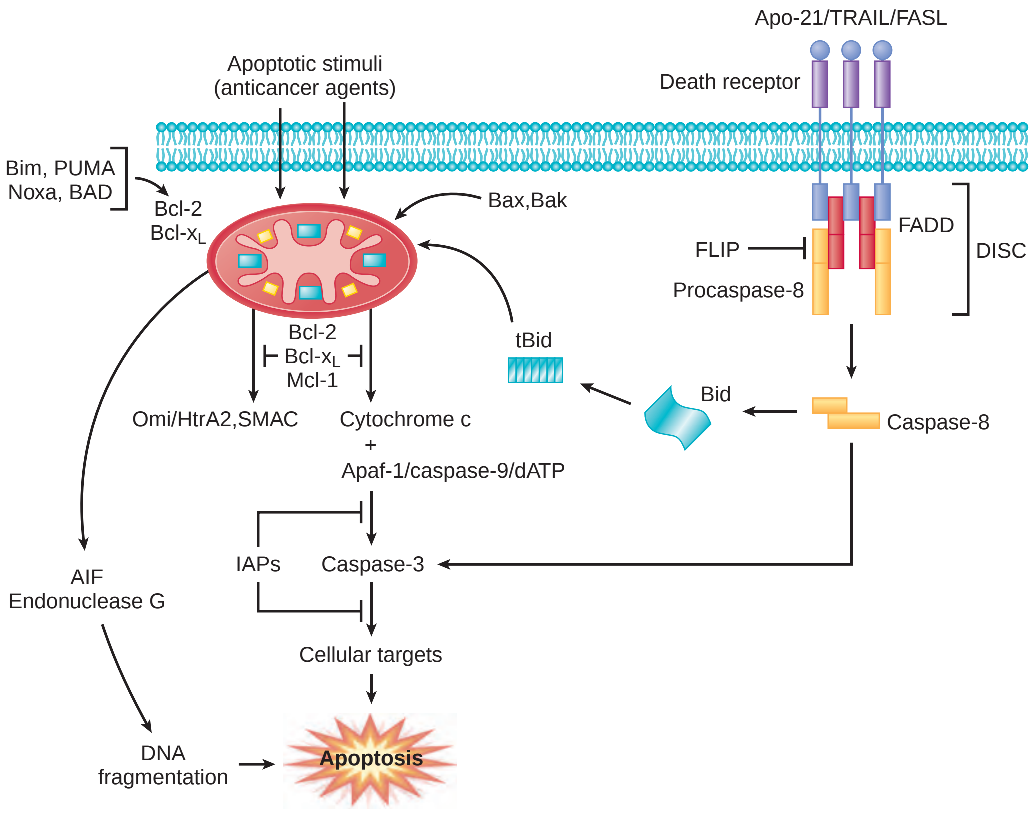

Figure 58.8 SCHEMATIC REPRESENTATION OF APOPTOTIC PATHWAYS.

truncated p15 tBid fragment, which translocates to the mitochondria and triggers the release of cyt c into the cytosol. Cleavage by caspase 8 has been shown to cause exposure of a glycine residue on p15 Bid that is myristoylated, thereby targeting p15 Bid to the mitochondria. Thus, N-myristoylation acts as an activating switch that enhances tBid-induced release of cyt c and apoptosis. The ability to cleave Bid may not be limited to caspase 8. Other caspases, such as caspase 3, as well other proteases, such as granzyme B and lysosomal proteases, have been shown to activate Bid. This indicates that Bid probably serves to amplify the caspase cascade rather than to initiate it (see Fig. 58.8).

Fas ligation has also been shown to initiate an alternative pathway leading to apoptosis, involving activation of JNK/SAPK. After ligation, Fas recruits an adaptor protein called Daxx that interacts with the apoptosis signal-regulating kinase 1 (ASK1), activating the transcription factors AP-1 and ATF-2. After activation, ASK-1 launches a phosphorylation cascade that culminates in the activation of JNK. Activated JNK phosphorylates substrates such as c-Jun, p53, and a pro-death Bcl-2 member Bim. This, in turn, has been shown to trigger mitochondrial or death receptor-initiated apoptotic signaling.

Mitochondria-Initiated Apoptotic Signaling

Mitochondria sequester a potent cocktail of proapoptotic proteins. These proteins promote apoptosis by activating caspases (e.g., by cyt c), by inducing DNA fragmentation (e.g., by endonuclease G or apoptosis-inducing factor [AIF]), or by neutralizing cytosolic inhibitors of apoptosis (IAPs; e.g., by SMAC or Omi/HtrA2). On induction of apoptosis, unlike other proapoptotic proteins, mitochondrial AIF translocates to the nucleus to induce DNA fragmentation and apoptosis. cytochrome c is a well-known component of the mitochondrial electron transfer chain. cytochrome c is released from the mitochondria during apoptosis. After release into the cytosol, cytochrome c binds to apoptosis-activating factor (Apaf-1), a cytosolic adapter protein that contains a caspase recruitment domain (CARD), a nucleotide-binding domain, and multiple WD-40 repeats. Binding of cytochrome c to Apaf-1 increases its affinity for dATP or ATP by approximately 10-fold. It also triggers the oligomerization of Apaf-1 into a multimeric Apaf-1– cytochrome c complex, also called the *apoptosome*. This exposes the CARD domain of Apaf-1, which recruits several molecules of procaspase 9, inducing their autoactivation. Only the caspase 9 bound to the apoptosome is able to efficiently cleave and activate a downstream executioner caspase, caspase 3.

SMAC/DIABLO is a 25-kDa mitochondrial protein that is released by mitochondria into the cytosol during apoptosis. SMAC contains a mitochondria-targeting sequence at its N-terminus. This sequence is removed on import into the mitochondria, generating the mature SMAC protein. In the mitochondria-initiated and common effector pathways of apoptosis, the processing and proteolytic activity of caspase 9 followed by caspases 3 and 7 are inhibited by the IAP family of proteins. IAP family members include XIAP, cIAP1, cIAP2, and survivin. All IAPs contain at least one baculovirus repeat (BIR) domain, although some contain three. Another region, the RING domain, has ubiquitin ligase activity and promotes the self-degradation of IAPs through proteasomes in response to some apoptotic stimuli. Furthermore, during Fas death receptor-mediated apoptosis, XIAP is cleaved by activated caspase 3 into the N-terminal BIR1 and 2 and BIR3-RING finger fragments. The BIR3 domain binds and sequesters the monomeric and inactive caspase 9, thereby inhibiting its activation. Overexpression of XIAP inhibits anticancer drug (including ara-C)–induced caspase activity and apoptosis. In contrast, downregulation of XIAP sensitizes cancer cells to apoptosis induced by chemotherapeutic drugs. The antiapoptotic activity of NFκB has also been shown to be mediated by the induction of IAPs. The first four amino acids of the mature SMAC, Ala-Val-Pro-Ile (AVPI), bind to the BIR domain of IAP proteins. The four amino acids (AVPI) of SMAC that bind to the BIR3 domain of XIAP are similar to the XIAP-binding sequence of active caspase 9. In addition, SMAC has been shown to form a stable complex with the BIR2 domain of XIAP. SMAC binds to the linker-BIR2 domain and presumably disrupts its inhibition of the active caspase 3 and caspase 7 by steric hindrance. On induction of apoptosis, another mitochondrial protein, Omi/HtrA2 (a serine protease), is released from mitochondria and can induce caspase-independent cell death. Additionally, like SMAC, the mature Omi protein contains a conserved IAP-binding motif (AVPS) at its N-terminus. Omi complexes with XIAP at high stoichiometry and promotes apoptosis by neutralizing the caspase-inhibitory effect of XIAP. Recently, Omi has also been shown to process XIAP and promote its proteasomal degradation.

The Bcl-2 family of proteins is divided into three subfamilies. Members of the subfamily that include Bcl-2, Bcl-x_L, and Mcl-1 inhibit apoptosis (see Fig. 58.8). The Bax subfamily members that promote apoptosis, including Bax and Bak, share with Bcl-2 three of the four Bcl-2 homology domains, BH1–BH3. A C-terminus hydrophobic tail is responsible for the localization of these proteins to the outer membranes of the mitochondria and ER. The third BH3-only subfamily of proteins that includes Bid, Bim, and Bad also promotes apoptosis by binding and inactivating prosurvival Bcl-2 family members. The prosurvival Bcl-2 family members, to a variable degree, are bound to the membranes of the mitochondria, the ER, and the nuclear envelope. In the event of an apoptotic stimulus, BH3-only proteins require Bax and Bak to trigger mitochondrial apoptotic signaling. For example, the exposed BH3 domain of tBid oligomerizes with Bak and Bax, causing their mitochondrial membrane insertion and cytochrome c release. In response to apoptotic stimuli, Bax and Bak undergo conformational change and form membrane-associated homo-oligomers, disrupting the outer membrane of the mitochondria and ER and releasing the pro-death molecules into the cytosol. Besides tBid, Humanin peptide has been shown to activate Bax. Bcl-2 can block these events involving Bax activation by titrating tBid or Bim and/or heterodimerization with Bax and preventing mitochondrial permeabilization.

Induction of $P53^{wt}$ in cells triggers apoptosis by transcriptional activation of prodeath effectors, including Bax, Noxa, Puma, Apaf-1, and DR5, and by transcriptional repression of Bcl-2 and IAPs. p53-dependent apoptosis has also been shown to occur in the absence of any gene transcription or translation. In response to apoptotic stimulus such as irradiation, p53 translocates to the mitochondria, where it directly induces permeabilization of the outer membrane by forming complexes with the protective Bcl-2, resulting in the release of cytochrome c into the cytosol. The E2F transcription factor, normally restrained by the Rb tumor suppressor to inhibit cell proliferation, has been shown to induce apoptosis though p53-dependent and p53-independent mechanisms. These mechanisms include transcriptional activation of ARF (the alternate reading frame product of the INK4a/ARF tumor suppressor locus) or p73 (a member of the p53 family), repression of Mcl-1, and inducing the levels of caspase proenzymes.

Selective Antiapoptotic Agents or Strategies

BCL2 Family of Proteins as Targets for Anticancer Drug Design

The antiapoptotic protein BCL2 was originally identified during the process of the discovery of the t(14;18) in human follicular lymphoma. Overexpression of BCL2 has been reported in both hematologic and solid malignancies and to mediate resistance to traditional chemotherapeutic agents, radiation, and other antitumor treatments.

BH3 Peptide/Mimetics or Bcl-2/Bcl-XL Small-Molecule Antagonists

Another strategy to create Bcl-2 inhibitors has focused on developing small molecules that mimic the action of the endogenous Bcl-2-binding death agonists. Compounds that mimic the BH3-only class of death agonists such as Bad inhibit the survival proteins Bcl-2 and

Bcl-x_L but do not appear to have independent proapoptotic activity. Two classes of novel small-molecule cell-permeable inhibitors of the Bcl-x_L-BH3 domain (BH3I) have been identified. Studies have demonstrated that BH3Is induce apoptosis by preventing BH3 domain-mediated interaction between proapoptotic and antiapoptotic members of the Bcl-2 family. Two natural products have been suggested to antagonize the antiapoptotic function of Bcl-2 or Bcl-x_L. Tetrocarcin A was reported to inhibit mitochondrial functions of Bcl-2 and suppress its antiapoptotic activity. In another report, Antimycin-A was shown to mimic activity of BH3 peptides and selectively induce apoptosis in cell lines overexpressing Bcl-x_L. Certain green tea catechins and black tea theaflavins were identified as potent inhibitors (K_i in the nanomolar range) of the antiapoptotic Bcl-2 family of proteins. On the basis of the high-resolution three-dimensional structure of the target receptor, small organic molecules that bind to this interface have been designed. ABT-737 is a BH3 mimetic that binds to Bcl-2, Bcl-xL, and Bcl-w with high affinity (K_i <1 nM) but not to Mcl-1. Preclinical data demonstrate cytotoxic activity in B lymphoid tumor cell lines, human follicular lymphoma, myeloma, and CLL cells, as well as synergism with other chemotherapeutic agents. However, the clinical utility of ABT-737 is limited, as it undergoes rapid metabolism and is not orally bioavailable. Targeted modifications of ABT-737 led to synthesis of navitoclax (ABT-263), an orally bioavailable BH3 mimetic. In the initial phase I trial[79] more than half of patients had a decrease in their lymphocytosis, with 35% achieving partial remission. The main toxicity was dose-dependent thrombocytopenia, which occurred early in the treatment cycle (days 2 to 5 of a 21-day cycle). Neutropenia occurred at higher dose levels. Other adverse events included gastrointestinal side effects and fatigue. The remarkable activity of this agent in early trials validated Bcl-2 as a target for the treatment of CLL. The clinical development of navitoclax was suspended because of thrombocytopenia, which is an off-target effect due to inhibition of Bcl-XL.

Venetoclax (Abt-199) was subsequently developed to replace navitoclax as a highly selective, orally available small-molecule Bcl-2 family protein inhibitor that binds with high affinity (K_i <0.10 nM) to Bcl-2 and with lower affinity to other Bcl-2 family proteins Bcl-XL and Bcl-w (>480-fold and >2000-fold lower affinity than to Bcl-2, respectively). Thrombocytopenia is less frequent with venetoclax due to its lower affinity to Bcl-XL. Early clinical experience with venetoclax is very promising, with remarkable efficacy in a patient population with relapsed or refractory CLL with high ORR (75% to 79%) and impressive CR rates (22% to 29%) and clearance of measurable residual disease (MRD) even in the high-risk subsets of patients with the adverse-risk del(17p) chromosomal abnormality associated with p53 mutation/dysfunction, an unmutated immunoglobulin heavy chain gene (IGHV), and those with disease refractory to fludarabine in a phase I trial. The early clinical trials of venetoclax were suspended initially because patients presented TLS, which led to two deaths. That led to modification of the clinical protocol with a gradual dose escalation of venetoclax over 4 weeks from 20 to 400 mg daily with stringent monitoring and aggressive prophylaxis and management of TLS. These preventive measures have decreased the incidence of TLS with venetoclax. In the MURANO phase III trial, the combination of venetoclax and rituximab was compared with bendamustine and rituximab for treatment of relapsed CLL, demonstrating the venetoclax combination achieved superior PFS and OS,[80] with the potential for treatment discontinuation in patients who achieved MRD-negative disease. Frontline treatment in a sequence—combination with obinutuzumab was done in the CLL14 trial, which included untreated CLL patients with significant comorbidities,[81] with chlorambucil and obinutuzumab used to treat patients in the control arm. Pretreatment with obinutuzumab for three weeks significantly decreased the incidence of TLS, and the venetoclax combination resulted in significant PFS benefit (3-year PFS of 81.9% vs. 49.5%). Based on the studies, venetoclax is currently approved by regulatory agencies for previously untreated CLL patients and for patients with relapsed disease.

BCL-2 dependence is not limited to lymphoid malignancies or overexpression of the target protein. In vitro profiling of mitochondrial out membrane permeabilization by exposure to BH3 peptides in AML cell lines has found that many are dependent on the anti-apoptotic signaling of BCL-2 for survival. These same cell lines are exquisitely sensitive to BCL-2 inhibition by many BH3 mimetics, including navitoclax and venetoclax.[82] The potential for BH3 profiling as a potential biomarker for AML sensitivity to venetoclax was explored in a phase II clinical trial. Single agent venetoclax was given at a dose of 800 mg per day in a population of heavily pretreated, high-risk AML patients. Nineteen percent of patients had an objective response, including 6% of patients achieving a CR or CRi. Patients with BH3 profiles predictive of venetoclax sensitivity were more likely to respond and remain on study. Two landmark phase I studies evaluated both the safety and preliminary efficacy of venetoclax in combination with low-dose cytarabine and hypomethylating agents respectively. Complete response rates of 54% and 61% were reported, both much higher than historical experiences.[83,84] DiNardo et al. further evaluated the pharmacokinetics of venetoclax in combination with CYP34A substrates, and thus established appropriate dose adjustments with antifungal prophylaxis. Due to the outcomes, the FDA granted venetoclax accelerated approval in November of 2018. A phase III study of azacytidine and venetoclax versus azacytidine and placebo reported an overall survival advantage for venetoclax of 14.7 versus 9.6 months and established this combination as a current standard of care for AML patients unfit for more intensive therapies. The CR rate was 36.7% versus 17.9%. Additionally, the response rate for AML patients with IDH1 and IDH2 mutated AML was also confirmed to be significantly higher in the venetoclax arm with 75.4% versus 10.7% entering a CR. Numerous clinical trials evaluating venetoclax in other combinations are ongoing as well as upfront and in relapse settings.

Agents Targeting Complex Multicomponent Cellular Processes

Proteasome Inhibitors

In eukaryotic cells, the lysosomal pathway degrades extracellular proteins imported into the cell through endocytosis or pinocytosis and the ubiquitin proteasome pathway controls the degradation of intracellular proteins. Numerous studies have demonstrated that the ubiquitin–proteasome system controls basic cellular functions such as cell cycle progression, signal transduction, programmed cell death, DNA repair, and antigen presentation.[85] Ubiquitin is a highly conserved 76-amino–acid polypeptide that is expressed in all eukaryotic cells. Under the sequential action of E1 (ubiquitin-activating enzyme), E2 (ubiquitin-conjugating enzyme), and E3 (ubiquitin ligase), ubiquitin is activated and covalently conjugated to potential proteasome substrates via an isopeptide bond between the C-terminal glycine residue of ubiquitin and the ε-amino group of internal lysine residues in target proteins. The same set of enzymes also catalyzes the formation of the isopeptide bond between G76 and the lysine residue (K48) of previously conjugated ubiquitin, leading to formation of a polyubiquitin chain. Polyubiquitinated substrates are usually targeted for proteasomal degradation.

The 26S proteasome is a large (2000-kDa) threonine protease present in the nucleus and cytoplasm of all eukaryotic cells. This ATP-dependent, multicatalytic protease eliminates damaged or misfolded proteins and regulates cyclins and CDK inhibitor cell cycle regulatory proteins as well as other proteins that govern the transcription factor activation, apoptosis, and cell trafficking. Its structure consists of two parts: the 20S core and the 19S cap regulatory particle (Fig. 58.9). The 19S cap is involved in the recognition, binding, and unfolding of ubiquitinated proteins and in the regulation of the opening of the 20S core. The 20S core is a cylinder composed of four stacked heptameric rings, each containing seven different α or β subunits (α7β7β7α7; Figs. 58.9 and 58.10). Three different active sites are located inside the cylindrical core within the β-subunit rings. Proteasome inhibitors target the 20S subunit of the proteasome. At least three distinct proteolytic sites present in the 20s subunit are named after enzymes with similar proteolytic activity[85]: chymotrypsin-like (β5), trypsin-like

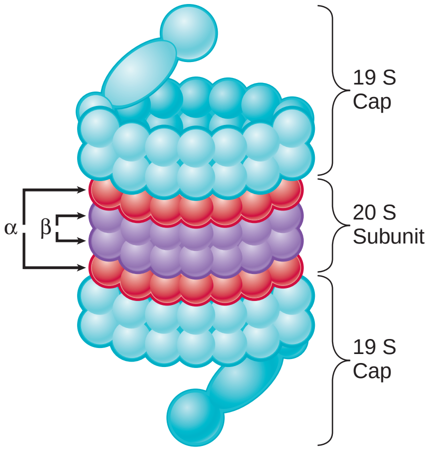

Figure 58.9 26 S PROTEASOME.

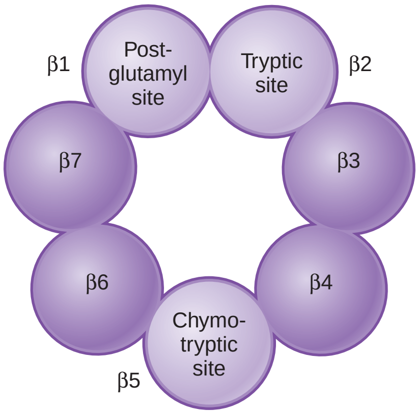

Figure 58.10 CROSS-SECTION OF THE BETA RING OF THE 20 S CORE OF THE 26 S PROTEASOME.

(β2), and caspase-like (post-glutamyl peptide hydrolyzing-like)(β1). After release from the substrate, the polyubiquitin chain is hydrolyzed into single ubiquitin moieties, and tagged proteins are degraded to small peptides. Both the assembly of the 26S proteasome and the degradation of protein substrates are ATP dependent.

Abnormal function of UPP can contribute to oncogenesis through increased or decreased degradation of proteins,[86] including down regulation of tumor suppressor proteins p53 and p27 or decreased degradation of NF-κB. The mechanisms leading to cell death after proteasome inhibition are not fully understood, but it is hypothesized that accumulation of incompatible regulatory proteins within the cell, accumulation of mis-folded proteins from the endoplasmic reticulum (ER) ("ER stress") causing suspension of protein synthesis, and interference with degradation of the NF-κB inhibitor IκB, preventing NF-κB action by blocking its nuclear translocation.

First-Generation Proteasome Inhibitors

Bortezomib. Bortezomib (pyrazylcarbonyl-Phe-Leu-boronate), the first in this class of agents to enter clinical trials, is a dipeptidyl boronic acid that is a specific and selective inhibitor of the 26S proteasome. The boron atom interacts reversibly with the catalytic threonine residue of the proteasome, primarily inhibiting its chymotrypsin-like activity. The inhibition of the ubiquitin–proteasome pathway with bortezomib was demonstrated to arrest the growth of malignant cells (breast, colon, prostate tumor cell lines, Burkitt lymphoma, adult T-cell leukemia, Lewis lung carcinoma, CLL, and myeloma cell lines) and sensitize them to chemotherapeutic agents (5-FU, cisplatin, Taxol, doxorubicin, CPT-11, and gemcitabine). Bortezomib mediates these effects through multiple mechanisms by regulating the expression of proteins involved in cell cycle progression ($P21^{cip1}$, $P27^{Kip1}$), oncogenesis (P53, IκB), apoptosis (BCL2, BIRC2, BIRC3, BIRC4, Bax), and, more recently, DNA repair (DNA-PKcs, ATM). Loss of IκB destabilizes NFκB, reducing expression of a critical plasma cell cytokine stimulatory molecule, interleukin (IL)-6 (see Chapters 86 and p1). The process of cell death appears to be p53-independent and to result in mitotic catastrophe, although the classical caspase 8-dependent apoptosis pathway has also been implicated. A recent study found a strong correlation between immunoglobulin production and apoptotic sensitivity to bortezomib, suggesting that the active requirement for protein folding in the ER provides a direct target and explains sensitivity to proteasome inhibition.[87,88]

Bortezomib is primarily metabolized through cytochrome P450 (CYP) and not via phase II pathways (e.g., glucuronidation and sulfation). In vitro studies indicated that the primary metabolic pathway was deboronation mediated by CYP3A4. Bortezomib was also metabolized by CYP2D6, but the rate of metabolism was slower than that observed with CYP3A4. The deboronated metabolites have been shown to be inactive in the 20S proteasome assay. Bortezomib rapidly exits the plasma compartment, with more than 90% cleared within 15 minutes of IV administration. In whole-body autoradiography of [^{14}C] bortezomib-treated rats, the CNS, testes, and eyes appeared to be protected from bortezomib. Bortezomib specifically and selectively inhibits proteasome function by binding tightly (dissociation constant [K_i] >0.6 nM) and reversibly to the enzyme's chymotrypsin-like site. In ex vivo 20S proteasome activity bioassays, the proteasome was inhibited within 1 hour of bortezomib administration, and baseline proteasome activity was restored within 48 to 72 hours. An intermittent but high level of inhibition (>70%) of proteasome activity was better tolerated than sustained inhibition. Thus, a twice-weekly clinical dosing regimen is better tolerated. Nonetheless, this dose schedule is often associated with significant myelosuppression and the onset of peripheral neuropathy. Reducing the dose schedule to a weekly regimen ameliorates these toxicities and appears to increase patient tolerance without jeopardizing clinical efficacy.

Bortezomib showed significant single-agent clinical activity in phase I and phase II clinical trials in relapsed/refractory MM. In the SUMMIT study of 202 patients with relapsed MM, 27% of patients achieved a PR or complete response (CR), and median TTP was 7 months.[89] The FDA approved the drug for use in relapsed/refractory MM in 2003 on the basis of this study. In 2008, the VISTA trial presented evidence demonstrating the superiority of bortezomib plus melphalan and prednisone (VMP) compared to MP alone for patients with newly diagnosed MM, which led to FDA approval for the use of bortezomib combinations as front-line therapy. In the VISTA trial, the median TTP was 24 months for VMP versus 16.6 months with MP. After initial treatment, many patients remain sensitive to bortezomib and can be retreated upon relapse; 63% of patients who responded to initial treatment with bortezomib respond to retreatment, with a median TTP of 9.3 months.

Second-Generation Proteasome Inhibitors

Carfilzomib. Carfilzomib is a second-generation proteasome inhibitor. It is an epoxy-ketone that selectively inhibits the chymotrypsin-like activity of the proteasome through irreversible binding of N-terminal threonines, resulting in more prolonged proteasome inhibition.[90]

Carfilzomib is active in patients with bortezomib resistant MM. Carfilzomib was approved in 2012 for the treatment of patients with myeloma who have received at least two prior therapies. As a monotherapy in phase II studies, carfilzomib induced an ORR of 20% in patients refractory to bortezomib. In a large, randomized phase III trial, comparison of carfilzomib + dexamethasone (KD) vs. bortezomib + dexamethasone (VD) in relapsed MM, KD was found to be superior to VD (PFS 18.7 months vs. 9.4 months, $P<.0001$). Of note, studies of initial therapy have not shown superiority of carfilzomib- vs. bortezomib-containing regimens.

Ixazomib. Like bortezomib, ixazomib is a boronic acid-containing peptide with chymotrypsin- and caspase-like proteasome inhibitory activity, formulated for oral administration.

Toxicities of Proteasome Inhibitors

Given their broad application, prolonged exposure, and use in combination with other agents with similar toxicities (especially vinca alkaloids and IMiDs), there has been a considerable effort to characterize and mitigate the side effects of proteasome inhibitors. One of the major motivations for the development of the second-generation agents has been to reduce the occurrence of neuropathy. Unlike IMiDs, proteasome inhibitors, as a class, do not appear to induce chromosomal abnormalities and therefore are not associated with an increased risk for secondary malignancies. Proteasome inhibitors may therefore be safer for long-term use/maintenance therapy than other agents.[91]

Peripheral Neuropathy. Bortezomib and ixazomib are more frequently associated with peripheral neuropathy than carfilzomib. The peripheral neuropathy associated with proteasome inhibitors is typically a sensory neuropathy affecting the hands and feet in a "stocking and glove" distribution and is frequently painful. Grade ≥ 3 PN occurs in 5% to 15% of patients but is reversible in most cases (in the phase III VISTA trial, 60% of instances of neuropathy showed complete resolution within a median of 5.7 months). The mechanism of peripheral neuropathy is unknown but is hypothesized to be due to aggresome formation and cytoskeletal collapse in dorsal root ganglion sensory neuron axons, alterations in mitochondrial function, or other off-target effects. It is possible that the boron moiety is implicated in the peripheral neuropathy since carfilzomib (which does not contain a boron atom) is much less likely to cause neuropathy than bortezomib. The incidence of peripheral neuropathy with bortezomib is reduced by SC administration and weekly dosing. The lower incidence of neuropathy of SC vs. IV administration of bortezomib has been attributed to IV dosing achieving peak serum levels of bortezomib that exceed the threshold that causes peripheral neuropathy, whereas the slower pharmacokinetics of SC administration deliver an effective antimyeloma dose without exceeding the neuropathy threshold.

Hematologic Toxicity. Hematologic adverse events appear to be a class effect associated with proteasome inhibitors; all agents tested so far are associated with thrombocytopenia, neutropenia, anemia, and lymphopenia. Differences in the tendency of the different agents to cause hematologic toxicity remain to be established as newer agents undergo further testing in clinical trials (there is hope that second-generation drugs may have lower rates of hematologic toxicity). Bortezomib, carfilzomib, and ixazomib cause transient, cyclical thrombocytopenia, with platelet counts dropping and then returning to baseline prior to the next cycle of treatment. The exact mechanism of bortezomib-induced thrombocytopenia remains to be fully elucidated. Bortezomib does not appear to adversely affect stem cell function. One hypothesis is that proteasome inhibition with bortezomib prevents the activation of NFκB, which leads to impairment of platelet budding from megakaryocytes.

Herpes Zoster Reactivation. Bortezomib has been associated with a significantly increased rate of herpes zoster reactivation. In the phase III study of bortezomib VMP versus MP alone, zoster reactivation was observed in 13% of patients in the VMP group versus 4% in the MP group. In the subgroup of patients in the VMP group who were receiving antiviral prophylaxis, the rate of zoster reactivation was reduced to 3%. The increased susceptibility to herpes zoster reactivation in patients treated with bortezomib may be due to the effect of bortezomib treatment on the number and function of specific lymphocyte subsets.

Other Toxicities. Infusion reactions (chills, fever, and dyspnea) have been observed with carfilzomib. Therefore, it is recommended that dexamethasone (4 mg PO or IV) be administered prior to each dose during cycle 1 and prior to the first of the higher doses during cycle 2. Carfilzomib has been associated with pulmonary complications, renal toxicity, and cardiac events (including congestive heart failure and cardiac arrest) in up to 7% of treated patients. Chest pain and acute congestive heart failure may have been related to prehydration with normal saline. Ixazomib may cause transient rash.

Hypomethylating Agents

Promoter methylation within CpG islands regulates gene expression in all cells. Disruption of normal gene expression profiles accompanies malignant transformation, giving rise to complex patterns of gene expression. As a consequence, promoters of many genes have an altered pattern of methylation, resulting in either gene activation or gene repression. The link between these concepts and the interest in agents that alter promoter methylation began with the realization that azacitidine, an agent used sparingly for treating myeloid leukemias, had efficacy when given at low doses either IV or SC for extended periods of time, and that in these cases, altered gene expression accompanied responses. The primary mechanism of action for both 5-azacytidine (azacitidine) and 5-aza-2-deoxycytidine (decitabine) act by irreversible inhibition of the DNA methyltransferase-1 (DNMT1) responsible for methylation of the cytidine in CpG islands. Inhibition of DNMT1 requires azacitidine and decitabine to be converted into 5-aza-2-deoxycytidine triphosphate and subsequently incorporated into DNA. Thus, both agents are S-phase-dependent requiring active DNA synthesis for activity. Wijermans et al.[92] first described the efficacy of decitabine when given as a continuous infusion to elderly patients with high-risk MDS, with a 54% ORR. The mechanism of action included both a direct change in promoter methylation and independent changes, with up to 70% genome-wide demethylation, suggesting either that genes with altered expression either up- or downregulated a second set of genes through altered pathways such as induction of WAFp21, p15, and p16, or in a more direct fashion through altered transcription factor expression. Additional studies have identified activity of these agents in other myeloid malignancies, particularly AML. Most often, PRs or short-lived CRs are seen in AML, with CRs more common in MDS. Recent studies also describe a number of extended therapy regimens. Kantarjian et al.[93] reported a comparison of 20 mg/m^2 decitabine IV for 5 days with 20 mg/m^2 SC daily for 5 days and 10 mg/m^2 IV for 10 days. The 5-day IV dose schedule was judged superior on the basis of clinical outcome with 39% CR, a higher proportion of reactivation of p15, and achievement of a hypomethylation state as well as clinical tolerance. For MDS, a course of 7 days of azacitidine at 75 mg/m^2 has been established as a standard of care for high-risk MDS with an overall survival benefit compared to supportive care in a phase III study.[94]

Both azacitidine and decitabine have also been given for AML in remission as "maintenance therapies," and have been associated with both leukemia free and disease-free survival. Both decitabine and azacitidine have demonstrated disease free survival benefits in large randomized controlled trials for AML in first complete remission. An oral formulation of azacitidine administered at a high dose has demonstrated overall survival benefit as maintenance therapy for AML patients in first remission who are not candidates for allogeneic stem cell transplant and was approved by the FDA for this population.[95] Even after stem cell transplant, safety and signals of efficacy of maintenance hypomethylating agents has been demonstrated, though lower doses are required to limit toxicity. De Lima et al.[96] established the MTD of azacitidine after transplant as 32 mg/m^2 for 5 days. Posttransplant azacitidine may also augment graft-versus-leukemia effect and attenuate GVHD after transplant through expansion of T-regulatory cells.

One goal of drug development has been oral formulations of both available hypomethylating agents, as this would ease the burden of drug delivery and potentially further permit extended drug exposure during S-phase of cancer cells. A major barrier to oral azacitidine has been high first pass metabolism by cytidine deaminase (CDA), which is highly expressed in gastrointestinal tissues. The high CDA expression also contributes to a different toxicity profile, as oral azacitidine also has a higher rate of gastrointestinal toxicities than IV or SC administration. Co-administration with CDA inhibitors may permit a higher absorption of the active drug. Tetrahydropyridine in combination with azacitidine and decitabine has been showed to improve the pharmacokinetics of oral administration. Cedazuridine is a novel CDA inhibitor designed to have increased stability compared to tetrahydropyridine and was approved by the FDA in combination with an oral formation of decitabine after phase II and III pharmacokinetic studies demonstrated equivalent area-under-the-curve and hypomethylation patterns to intravenously administered decitabine.[97]

Pretreatment with hypomethylating agents has also been postulated to improve malignant cell sensitivity to standard agents by re-expression of tumor suppressor genes. Several early phase studies have suggested that this “epigenetic priming” can restore chemosensitivity. In DLBCL cells in vitro and in clinical samples from patients azacitidine “priming” decreased SMAD1 methylation, and increased SMAD1 mRNA, in DLBCL cells obtained from patients. SMAD1 is the major downstream effector of TGF-β. TGF-β exerts an antiproliferative effect in most NHLs, and loss of antiproliferative response to TGF-β has been demonstrated in the majority of NHLs. SMAD1 hypomethylation has been associated with an abundance of SMAD1 mRNA and restoration of chemosensitivity in DLBCL cells after azacitidine “priming.” In leukemia, priming can demonstrably result in increased hypomethylation in constitutively hypermethylated regions of the genome (HIST1H2AA and LINE1 repetitive elements).[98] Unfortunately, examination of priming in larger-scale studies has yet to suggest a clear role for azacitidine and decitabine prior to standard chemotherapy. Epigenetic priming is still being explored as a method to increase the efficacy of immune checkpoint inhibition. High rates of CR have been observed in relapsed and refractory Hodgkin lymphoma patients with prior exposure to hypomethylating agents.[99]

Histone Deacetylase Inhibitors

Histone acetyl transferases (HATs) and HDAC are two classes of enzymes that mediate the acetylation and deacetylation of histones, respectively, at evolutionarily conserved N-terminal lysine residues. Acetylated histones are negatively charged and do not bind as tightly to negatively charged DNA, thereby facilitating gene transcription. In contrast, deacetylated histones bind closely to DNA, preventing transcription. The acetylation status of chromatin and hence gene transcription is dictated by the balance of the actions of HATs and HDACs. Acetylation of core histone bases has also been implicated in chromatin assembly, DNA repair, and replication timing of specific genomic regions. Crosstalk also exists between acetylation and ubiquitination. Thus, HDACs can decrease the half-lives of substrates by exposing the lysine residue for ubiquitination.

Poorly regulated balance between HATs and HDACs can lead to perturbed gene expression, facilitating the development of malignant cell phenotypes. Eckschlager and colleagues enumerated the possible effects of changes in HAT/HDAC activity[100]: (1) modified gene expression profile resulting in changes in intracellular signaling pathways; (2) Changes in proteasomal degradation; (3) Changes in DNA methylation status; and (4) Modify protein kinase C activity.

Classes of Histone Deacetylase Inhibitors

HDAC inhibitors (HDIs) may act on a specific HDAC subtype or may affect all types (pan-HDIs). Several structurally diverse classes of naturally occurring and synthetic compounds have been investigated for their ability to inhibit HDAC activity (Table 58.6). These include hydroxamic acid derivatives (e.g., vorinostat, Panobinostat, short-chain fatty acids (e.g., valproic acid [VPA]), synthetic benzamides (e.g., entinostat), cyclic tetrapeptides (e.g., romidepsin), and sirtuin inhibitors. HDAC inhibitors of all classes have undergone clinical evaluation.

TABLE 58.6 **Histone Deacetylase Inhibitors[a]**

Name	Type of Compound	Cell Culture (Activity)	Animal Tumor Models	Clinical Trial
Butyrates	Short-chain fatty acids	Yes (μM)	Yes	Phase I/II
Valproic acid	Short-chain fatty acid	Yes	Yes	Phase I/II
Trichostatin A	Hydroxamic acid	Yes (nM)	Yes	–
Pyroxamide	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
Oxamflatin	Hydroxamic acid derivative	Yes (μM)	Yes	–
SAHA	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I/II
TPX-HA analog (CHAP)	Hydroxamic acid derivative	Yes (nM)	Yes	–
LAQ824	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
MS-275	Benzamide derivative	Yes (μM)	Yes	–
CI-994 (*N*-acetyl dinaline)	Benzamide derivative	Yes	Yes	Phase I
Depsipeptide (FR901228, FK-228)	Cyclic tetrapeptides	Yes (nM)	Yes	Phase I/II
Trapoxin	Cyclic tetrapeptides	Yes (nM)	–	–
Apicidin	Cyclic tetrapeptides	Yes (nM)	Yes	–

SAHA, Suberoylanilide hydroxamic acid.

[a] Activity reported as “Yes” indicates that the compound has been shown to inhibit histone deacetylase (HDAC) activity, that is, growth of transformed cells in culture and in vivo tumor growth in animal studies. (–) indicates no data reported. CI-994 is reported to inhibit histone deacetylation but does not directly inhibit HDAC.

Vorinostat and Other Hydroxamic Acid Derivative Histone Deacetylase Inhibitors. Members of this class are some of the most potent HDIs. They contain a functional group that interacts with the critical zinc atom at the base of the catalytic pocket of the class I and II HDACs. These HDIs also possess a hydrophobic cap and an aliphatic side chain that interacts with the edge and fits into the hydrophobic catalytic pocket of HDAC, respectively, of the HDACs. Members of this class inhibit both class I and II HDACs. Vorinostat (suberoylanilide hydroxamic acid [SAHA], Zolinza) is a second-generation polar–planar compound that induces in vitro growth arrest, differentiation, or apoptosis of a variety of cancer, leukemia, and MM cells by restoring function of aberrantly silenced genes, among other effects. Most clinically relevant responses have been observed in patients with cutaneous T-cell lymphoma, where an overall response of approximately 30% resulted in regulatory approval.[101] Belinostat is another hydroxamic acid HDI that was recently FDA approved for the treatment of relapsed and refractory peripheral T-cell lymphoma (PTCL) based on a multicenter, single-arm BELIEF trial of 120 evaluable patients with PTCL that was refractory or had relapsed after prior treatment. Among patients with histologically confirmed PTCL ($n = 120$), the ORR was 25.8%. Similar to other

FDA-approved HDIs, belinostat was also tested in phase I and II clinical trials for both solid and hematological cancers. Panobinostat is a second-generation hydroxamic acid-based hybrid polar HDI tested both in in vitro and in vivo tumor models, and in clinical trials. Panobinostat induces apoptosis in a dose-dependent manner on human CML blast crisis K562 cells and acute leukemia MV4-11 cells with the activating length mutation of *FLT-3*. Exposure to panobinostat is associated with hyperacetylation of H3, H4, and Hsp90; increase in p21; and induction of cell cycle G_1 phase accumulation. Panobinostat influences the ubiquitin-proteasome system through hyperacetylation of α-tubulin and uncoupling of HDAC6 and dynein (i.e., involved with lysosomal degradation of misfolded proteins or autophagy) leading to higher levels of ubiquitinated protein and apoptosis.[102,103] This explains the synergistic effect of panobinostat with bortezomib.[102] HDAC6 inhibition augments the anti-myeloma immunity.[104]

Short-Chain Fatty Acid Histone Deacetylase Inhibitors. Sodium butyrate, a well-studied member of this class of compounds, induces in vitro growth arrest and differentiation of human leukemia cells at millimolar concentrations. Its clinical development has been hampered by its short half-life and difficulty in achieving millimolar levels in vivo. Phenylbutyrate, another derivative of butyric acid, induces in vitro growth arrest and differentiation of leukemia cells at clinically achievable submillimolar concentrations. Importantly, at these levels, phenylbutyrate synergizes with retinoids in inducing cell cycle arrest, differentiation, and apoptosis of myeloid leukemia cells, and with ara-C in myeloid leukemias. VPA, a well-tolerated antiepileptic, was shown to be as effective as an HDI at levels ranging between 0.5 and 2.5 mM.

Two phase I trials have examined the therapeutic effects of phenylbutyrate in patients with AML and MDS. No responses were noted in either study, with neurotoxicity being the dose-limiting toxicity. Several studies have used VPA as monotherapy or in combination with other agents in hematologic malignancies. As monotherapy in MDS, response rates have been as high as 16% using the IWG criteria. Neurotoxicity has been the major side effect. Other side effects of VPA include thrombocytopenia, weight gain, asthenia, and rarely hepatic failure and pancreatitis. Given the low response rate, emphasis has shifted to newer HDIs.

Synthetic Benzamide Derivative Histone Deacetylase Inhibitors. Benzamide-containing HDIs are another class of compounds that showed both in vitro and in vivo anticancer activities. Among them, and entinostat is an HDAC Class I selective inhibitor currently approved for treatment of solid tumors. A phase I trial tested entinostat in patients with refractory solid tumors and lymphomas. Prolonged disease stabilization was seen in some patients, and the drug was well tolerated and demonstrated antitumor activity.

Cyclic Tetrapeptide Histone Deacetylase Inhibitors. The principal members of this class of agents are depsipeptide (romidepsin). Romidepsin has been approved by the FDA as an agent for the treatment of patients with relapsed or refractory CTCL. It is a potent HDI that exerts in vitro antitumor effects at nanomolar levels against several cancer cell types. It also induces apoptosis of human acute leukemia and CLL cells. Romidepsin is a natural product derived from *Chromobacterium violaceum*, a bacterium isolated from Japanese soil samples. Additionally, romidepsin was shown to exert antiangiogenic effects by modulating the expression of genes involved in angiogenesis. FDA approval for romidepsin in relapsed/refractory CTCL is based on two large phase II studies: a multi-institutional study based at the NCI in the United States (71 patients), and an international study (96 patients). The treatment schedule was identical across both studies and the ORR was 34% in both studies.[105,106] Romidepsin also induced complete and durable responses in patients with relapsed or refractory PTCL across all major PTCL subtypes, regardless of the number or types of prior therapies, with an objective response rate of 25%, which led to the approval of single-agent romidepsin for the treatment of relapsed or refractory PTCL in the United States.

Toxicity of Histone Deacetylase Inhibitors in Clinical Trials

The most common grade 3 and 4 adverse events observed with the use of HDIs were thrombocytopenia, neutropenia, anemia, fatigue, and diarrhea. In some cases, HDI-induced thrombocytopenia can be rapidly reversible upon withdrawal of the drug. Nausea, vomiting, anorexia, constipation, and dehydration were also seen in patients receiving HDIs. Deaths have been reported in clinical studies involving HDIs. For example, when mocetinostat was tested in patients with relapsed Hodgkin lymphoma four patients died, of which two were treatment-related deaths. Similarly, deaths were also reported in clinical trials involving vorinostat, givinostat, and many other HDIs.

Combinations of Histone Deacetylase Inhibitors With Other Agents

With an increased understanding of the function of HDIs, rational combinations of chemotherapeutic agents and HDI inhibitors have been investigated. The acceptable toxicity profile associated with HDI treatment permits a broad integration into currently approved chemotherapy regimens. A variety of HDIs synergistically enhance the growth inhibition and apoptosis of DNA-damaging agents and irradiation. This occurs, in part, through an HDI-mediated increase in chromatin accessibility and downregulation of DNA repair. A small phase I study examined the MTD of vorinostat with standard-dose CHOP chemotherapy in 14 patients with untreated PTCL. The MTD of vorinostat was 300 mg daily. The combination was tolerated, with diarrhea being the most common toxicity observed, and with a 2-year PFS and OS of 79/70% and 81/75% in the two dosing schedules tested, respectively. Synergy between HDI and proteasome inhibitors has been demonstrated in preclinical and clinical studies in myeloma. The most well-characterized model of synergy between proteasome inhibitors and HDIs are the dual inhibition of the proteasome and aggresomal pathways. Targeting both the proteasome with bortezomib and the aggresome with HDAC6 inhibitors in tumor cells induces greater accumulation of polyubiquitinated proteins, resulting in increased cellular stress and apoptosis. More specifically, proteasome inhibition drives the formation of aggresomes, which are dependent on the interaction of HDAC6 with tubulin and dynein complex. Moreover, the proteasome inhibitor (bortezomib) and HDAC6 inhibitors (tubacin or panobinostat) lead to increased hyperacetylation of tubulin and generation of polyubiquitinated proteins, thus increasing cellular stress response (i.e., c-Jun N-terminal protein kinase activation) and leading to apoptosis, which is, in part, dependent on caspase activity. The addition of panobinostat to bortezomib improved PFS by about 3 months in a recent randomized phase III trial of 768 patients with relapsed/refractory myeloma that led to FDA approval.[107] Clinical trials are ongoing to test the combinations of HDI with hypomethylating agents, mTOR inhibitors, and other proteasome inhibitors.

EZH2 Inhibitors

Enhancer of zeste homolog 2 (EZH2) is the catalytic subunit of the Polycomb repressive complex 2 (PRC2). The polycomb group proteins have well characterized roles in cancer, acting as epigenetic regulators.[108] The PRC2 is a multimer that includes one of the catalytic subunits EZH1 or EZH2 and includes other core components, including SUZ12, RBAP46 or RBAP48, JARID2, and AEBP2. This complex catalyzes mono-, di-, and trimethylation of lysine 27 of histone H3(H2K27), with the physiologic role of PRC2 thought to be maintenance of transcriptional silencing rather than its initiation.[108]

The ubiquitous role of PRC2 in epigenetic regulation has led to consideration of the role of EZH2 as both an oncogene and a tumor suppressor gene. Hyperactivating mutations of EZH2 occur in several subtypes of NHLs of germinal center origin,[109] including DLBCL and follicular lymphoma, where EZH2 may occur in up to 27% of cases and represent an early event in the pathogenesis of disease.[110] Several gain of function mutations have been identified in lymphomas,[111] including point mutation at tyrosine 641 (Y641X) within the EZH2 catalytic SET domain, affecting the substrate specificity of the enzyme and enhancing histone trymethylation in the presence of residual wild-type EXH2, which is more efficient at mono and di-methylation.[112] Other activating point mutations within the SET domain of EZH2 have been identified in follicular and diffuse large B-cell lymphoma. In contrast, in myeloid malignancies, EZH2 appears to act as a tumor suppressor gene, and abnormalities are characterized by loss of function mutations.

Tazemetostat (EPZ-6438) is the first EZH2 inhibitor to receive regulatory approval. Tazemetostat is a competitive inhibitor of the s-adenosyl-methionine pocket of the SET domain of EZH2. In preclinical models, tazemetostat inhibited methylation of H3K27 in both EZH2 mutated and wild-type lymphoma cells, with increased cell death in those with EZH2 catalytic point mutations.[113] Animal model studies with lymphoma-bearing mice showed that tazemetostat treatment decreases histone methylation and was capable of tumor control in EZH2-mutant lymphoma xenografts.

The initial phase I trial conducted by Italiano and colleagues[114] included 64 patients with lymphomas and solid tumors. The most frequent all-grade adverse events included asthenia (53%), muscle spasms (22%), gastrointestinal complaints (nausea [20%], vomiting [19%], constipation [17%], abdominal pain [16%]), hematologic toxicities (anemia[17%], thrombocytopenia [11%]), and, although rare, neutropenia (3%). Among grade 3 to 4 adverse events, asthenia (33%) and nausea (20%) were the most common. A subsequent phase II study included EZH2 mutated and wild-type follicular lymphoma ($n = 99$), treated with tazemetostat 800 mg orally twice a day. Fatigue was the most common all-grade adverse event (36%), followed by gastrointestinal complaints (nausea [24%], abdominal pain [20%], diarrhea [18%], vomiting [12%]). Treatment-related grade 3 or worse adverse events included thrombocytopenia (3%), neutropenia (3%), and anemia (2%).

Pharmacokinetic studies done in phase I showed tazemetostat is rapidly absorbed after oral administration, with median t_{max} of 1 to 2 hours, and half- life of 3 to 4 hours. Repeated administration of tazemetostat resulted in decreased AUC, indicating autoinduction of CYP3A4 metabolism. Drug interactions are a result of tazemetostat metabolism by CYP3A4, and co-administration with strong or moderate inhibitors should be avoided or require decreased tazemetostat dosing. Strong CYP3A4 inducers can decrease tazemetostat plasma concentrations and should be avoided. Given that tazemetostat is an inducer of CYP3A, it can decrease the concentrations of its substrates.

In phase I, ORR for relapsed/refractory B-cell lymphoma was 38%, with a median time to response of 3.5 months, and a median duration of response of 12.4 months. Follicular lymphoma patients enrolled in a multi-arm phase II trial presented different response rates according to their EZH2 mutation status, with EZH2-mutated patients presenting an overall response of 74% ((95% CI 57.9% to 87%) versus 34% in EZH2 wild-type follicular lymphoma. Complete response rates were 64% and 28%, respectively. Median duration of response was 40 weeks for EZH2-mutated patients and 56 weeks for those with wild-type EZH2.[115] Based on these results, tazemetostat has received approval as a third-line agent for follicular lymphoma patients with mutations of EZH2 as well as for patients without EZH2 mutations who do not have available effective therapies. Tazemetostat appears to have efficacy in DLBCL, with 17% ORR both in patients with mutated and wild-type EZH2.

Protein Translation Inhibitors

The increased proliferation and cell survival of cancer cells imposes a requirement for increased levels of short-lived proteins involved in cell division and survival. As a result, protein translation is markedly upregulated in cancer cells, making ribosomal function and protein synthesis a potential therapeutic target.

Protein translation is divided into three phases: initiation, elongation, and termination. As discussed in earlier sections of this chapter, mTOR inhibitors disrupt the initiation phase by preventing assembly of the eIF4F complex, responsible for ribosomal recruitment. Other agents aimed at impeding translation by directly targeting the function of eIF4F have not yet had successful clinical applications.

Omacetaxine

Omacetaxine mepesuccinate (homoharringtonine, HHT, Synribo), is a semisynthetic, highly purified compound derived from a plant alkaloid discovered more than 40 years ago. Omacetaxine prevents peptide elongation by binding the A site in the peptidyl cleft of the large ribosomal subunit, thus blocking correct positioning of the amino-acid side chains of tRNAs. The clinical activity of omacetaxine has been correlated with its capacity to decrease translation of short-lived proteins such as c-Myc, MCL-1, and Cyclin D1. The initial clinical studies of omacetaxine in CML were done with IV administration, before the introduction of BCR-ABL inhibitors, and were focused on patients who had failed IFN-α. Interest decreased after approval of imatinib for CML, but subsequent studies focused on the use of SC omacetaxine in patients who developed resistance to TK inhibitors and those carrying the T315I mutation. The maximum tolerated dose was 1.25 mg/m^2 subcutaneously twice daily. Subsequent studies demonstrated omacetaxine was capable of achieving major cytogenetic response in 23% of chronic-phase CML patients carrying the T315I mutation. Omacetaxine dosing was 1.25 mg/m^2 twice daily for 14 days every 28 days until achievement of a hematologic response, after which maintenance was given at the same dose for 7 days every 28 days. Hematologic toxicity was frequent (neutropenia 44%, anemia 39%, and thrombocytopenia 76%), particularly in the initial stages of treatment, and was managed by reducing the number of days of drug administration.[116] The most common nonhematologic toxicities were infections, diarrhea, nausea, and fever. Severe nonhematologic toxicities included infection (10%), fatigue (5%), and increased alanine aminotransferase (3%). Omacetaxine received FDA approval in 2012 for the treatment of CML patients who have failed two or more TKI treatments.

Isocitrate Dehydrogenase Inhibitors

Isocitrate dehydrogenases (IDH) are key enzymes in the citric acid cycle, converting isocitrate to α-ketoglutarate (αKG) and vice versa. IDH1 is typically restricted to the cytoplasm and IDH2 and IDH3 found intramitochondrial space. Somatic mutations at the active site of the enzymes results in aberrant conversion of isocitrate into 2-hydroglutarate (2HG). 2HG is considered an oncometabolite, as high concentrations inhibit histone and DNA demethylases which are usually dependent on αKG. As such, these tumors generally exhibit a high level of DNA hypermethylation and a clear block in terminal differentiation.[117]

IDH1 and IDH2 mutations conferring this altered activity are found in up to 20% of AML and 5% of MDS.[118,119] These activating mutations are well defined with mutations occurring at residues at R132 in IDH1, and at R140 and R172 in IDH2. Inhibition of these mutated enzymes *in vitro* can demonstrably reduce 2HG levels and subsequently change DNA and histone methylation patterns. Moreover, human-derived AML blasts will express surface markers indicative of terminal differentiation.[120]

Two IDH inhibitors have been granted acerated approval by the FDA based on early evidence of clinical efficacy. Enasidenib, an IDH2 inhibitor, was approved for relapsed and refractory IDH2 mutant AML based on outcomes of a phase I/II study of 239 patients with relapsed or refractory AML and a documented R140 or R172 IDH mutation. 23% of patients achieved a CR or CRh and remained in remission for a median of 8 months. Toxicities overall were modest, but included nausea, vomiting, and elevated bilirubin. Hyperbilirubinemia was predominantly indirect bilirubin, and reduced activity of UGT1A1, similar to Gilbert syndrome, was suspected, and little direct liver toxicity was noted.[121] Ivosidenib has been approved both as a single agent for relapsed and refractory IDH1 mutant AML, and in combination with azacitidine for newly diagnosed IDH1 mutant AML. A phase I/II study of 258 relapsed and refractory patients found a CR rate of 21.6% and an ORR of 41.6% with a median response time exceeding 8 months. In patients with de novo AML unfit for more intensive therapy, azacitidine and ivosidenib was studied in 23 patients and demonstrated a CR rate of 56.5% and an ORR of 78.6%. Treatment emergent toxicity that appeared related to ivosidenib in both studies included nausea, diarrhea, and prolonged QTc requiring monitoring.[122]

A unique toxicity of IDH inhibition appears to be a modest, but real risk of differentiation syndrome. Previously well described as a potential adverse event with all-trans retinoic acid in acute promyelocytic leukemia, differentiation syndrome is characterized by fever, weight gain, edema, pulmonary edema, and effusions. Management of differentiation syndrome requires urgent recognition and the start of high-dose steroids. Though correlation with response has yet to be clearly observed, this is felt to be a natural effect of the *in vivo* differentiation of the malignant cells.[123]

Hedgehog Pathway Inhibitors

The Hedgehog (Hh) signaling pathway was originally described as a critical intracellular system in embryonic development, controlling maintenance and differentiation. In the canonical pathway, hedgehog ligands interact with two cell surface receptors, a negative regulator named Patched (PTCH1) and a positive regulator named Smoothened (SMO). When ligands bind to PTCH, SMO is depressed. In the active form, SMO promotes transduction of GLI proteins, which in turn lead to expression of numerous genes, including c-MYC and BCL-2. In some myeloid malignancies including AML and CML, aberrant activation of the Hh pathway appears to result in selective survival of the malignant stem cell. In CML, inhibition of SMO can reduce the cell renewal capacity that the BCR-ABL fusion protein induces.[124] AML cell lines with overexpression of Hh pathway proteins appear to have increased drug resistance in addition to uncontrolled self-renewal. Inhibition of SMO appears to restore sensitivity to traditional cytotoxic medications.[125]

To date, clinically relevant pharmacologic agents targeting the Hh pathway have all been inhibitors of SMO. Indeed, several agents are approved for basal cell cancer and nevoid basal cell cancer syndrome, which are uniquely dependent on the Hh pathway. In vitro, both vismodegib and sonidegib have single agent activity against AML, and clinical trials are ongoing. Despite these agents being available, a different SMO inhibitor, glasdegib, has translated into clinical practice for the treatment of AML. Early phase studies have suggested a favorable toxicity profile with dysgeusia and muscle spasms as common events, and little additional toxicity when added to low-dose citarabine.[126] A phase II study of low-dose cytarabine with glasdegib versus placebo demonstrated an improved OS benefit, and this led to a breakthrough designation and approval for glasdegib by the FDA.[127]

Immunomodulatory Agents and Cereblon E3 Ligase Modulation Drugs

Immunomodulatory drugs (IMiDs), thalidomide, lenalidomide, and pomalidomide, are oral agents derived from glutarimide with high anti-tumor activity against plasma cell dyscrasias and lymphoid malignancies. Despite the established use in the last 15 years, particularly in management of plasma cell malignancies, only recently the target of IMiDs has been described. These agents bind to Cereblon, a critical E3 ligase enzyme part of the ubiquitination system, resulting in enhanced degradation of tumor promoting agents. Of note, Cereblon is the primary target of thalidomide-induced teratogenicity.[128] This finding led to advent of a new generation of compounds, called Cereblon E3 ligase modulation drugs (CELMoDs), which have been tested in later-stage clinical trials.[129]

IMiD-based combination induction therapy is considered as standard-of-care modality for newly diagnosed MM regardless of transplant eligibility as well as single-agent post-transplant maintenance therapy. IMiDs also have noticeable activity when combined with monoclonal anti-CD38, such as (daratumumab),[130] or anti-SLAMF7 (elotuzumab) [131] antibodies, most likely due to enhanced antibody dependent cell-mediated cytotoxicity and NK cell activity with these combinations.

IMiDs have mostly similar chemical structures, however, it is clear that subtle differences in their structures can lead to significant difference in the anti-tumor activity.

Lenalidomide

Lenalidomide was identified as an analog of thalidomide with more potent immunomodulatory functions but less neuropathy. The immunomodulatory effects include modifications in T-cell function which can enhance their function,[132] including enhanced ADCC (antibody-dependent cellular cytotoxicity). Lenalidomide also has antiangiogenic properties and increases the anti-inflammatory cytokine IL-10 while decreasing pro-inflammatory IL-6, IL-1b, IL-2, and TNF-alpha production. Decreases in NFκB and IκB levels are also observed in cells. In addition, lenalidomide induces caspase 8-mediated apoptosis and mitochondrial-mediated cell death. T-cell activation and increased natural killer (NK) activity are observed, thus increasing the anticancer immune response.[133]

Lenalidomide can cause significant myelosuppression, which can be dose limiting. The risk of thrombosis is also increased and the administration of lenalidomide should be accompanied by antithrombotic prophylaxis. Hypersensitivity rash occurs in up to 10% of patients. In trials of CLL and lymphoma, initial treatment with lenalidomide can result in tumor flare, characterized by fever, rash, and painful lymphadenopathy; lower initial doses should be considered in patients with high tumor burden and CLL.

A variety of dosing schedules provides a flexible therapeutic approach and a high response rate in front-line and relapsed myeloma patients, including maintenance therapy after autologous stem cell transplant.[134] In 5q-MDS patients, response in over 40% of patients was observed, indicating more based on the achievement of transfusion independence (see Chapter 60). The activity of lenalidomide has been observed in several lymphoid malignancies, including relapsed mantle cell lymphoma, follicular lymphoma, and diffuse large B-cell lymphoma, all in combination with monoclonal antibodies targeting CD20 or CD19.[133]

Pomalidomide

Pomalidomide is a third-generation IMiDs class. In addition to its immunomodulatory and antiangiogenic activity, pomalidomide has direct activity against myeloma cells, affecting gene expression, and promoting apoptosis and cell cycle arrest. Pomalidomide upregulates expression of p21WAF and downregulates interferon (IFN) regulatory factor 4. p21WAFinhibits CDK2, which in turn results in phosphorylation of the retinoblastoma (Rb) protein and cell cycle arrest at G_1. Apoptosis is also induced via activation of caspase 8. In vitro studies showed that pomalidomide was active in cell lines resistant to thalidomide and lenalidomide.[135]

The most common severe adverse events are myelosuppression (anemia, neutropenia, and thrombocytopenia), infections, and fatigue. Venous thromboembolic events were observed in early-phase studies and subsequent trials have required thromboprophylaxis, under which the rate of VTE with pomalidomide is less than 5%.

Phase I studies established that the maximum tolerated dose of pomalidomide was 4 mg given PO on days 1 to 21 of 28-day cycles, which corresponds to the currently approved starting dose. Results of a phase II study combining pomalidomide with dexamethasone in patients with relapsed myeloma showed an encouraging ORR of 63% (PR or better), including 60% of patients who were refractory to bortezomib and 40% of patients who were refractory to lenalidomide.

CELMoDs

CELMoD CC-885, CC-122, and C-220 are emerging as potent antimyeloma agents. CC-885 has a potent antitumor activity through binding to Cereblon and mediating the ubiquitination and degradation of the translation termination factor, GSPT1.[136] CC-122 is another CELMoDs that includes the glutarimide moiety that is present in IMiDs and is currently being evaluated in diffuse large B-cell lymphoma and a number of other malignancies.[137] CC-220 has a higher affinity than either lenalidomide or pomalidomide for CRBN and more potently degrades IKZF1 and IKZF3. Importantly, core structure of this compound is similar to the IMiDs with additional phenyl and morpholino moieties that seem to increase its binding capacity to Cereblon.[138]

Denileukin Diftitox

Denileukin diftitox (DD) or DAB389IL-2 (Ontak) is a fusion protein in which the receptor binding domain of diphtheria toxin has been exchanged for that of the IL-2 molecule. Because of the specificity of the IL-2 domain, the DT-mediated cytotoxic activity will predominately affect cells that express the IL-2 receptor (IL-2R). The IL-2R is selectively expressed on activated T-lymphocytes, B cells, and NK cells. It has been shown that IL-2 fusion toxin is cytotoxic against in vitro T-cell lines. It has been estimated that approximately 50% of CTCL cases express the IL-2R (CD25), as demonstrated by immunohistochemical staining. DD was approved by the FDA for the treatment of relapsed or persistent $CD25^+$ CTCL based on demonstrated efficacy in a placebo-controlled multinational dose-ranging study that enrolled 144 patients with $CD25^+$ stages Ia–III CTCL. Patients who had three or fewer prior therapies were randomly assigned to receive an IV infusion of either DD at 0.018 mg/kg or 0.009 mg/kg on days 1 to 5 of a 21-day cycle (maximum eight cycles) or saline placebo. The ORR for patients receiving the 0.018 mg/kg dose was 46%, with a median response duration of 220 days. The ORR for patients receiving the 0.009 mg/kg dose was 37%, with a median response duration of 277 days. Patients receiving the saline placebo had an ORR of 16% and median response duration of 81 days. Significant improvements of PFS at both doses of DD was noted (hazard ratio: 0.27 comparing 0.018 mg/kg vs. placebo, $P = .0002$; hazard ratio: 0.42 comparing the 0.009 mg/kg vs. placebo, $P = .02$). Treatment-emergent adverse events that occurred in at least 20% of patients in the 0.018 mg/kg group, and more frequently than in the placebo arm, were fever, nausea, rigors, fatigue, vomiting, headache, peripheral edema, diarrhea, anorexia, rash, and myalgia. Serious adverse events in patients receiving DD included infusion reactions, capillary leak syndrome, and loss of visual acuity, including loss of color vision. Laboratory abnormalities reported included hypoalbuminemia and hepatic transaminitis. Both bexarotene and alitretinoin were shown to increase the expression of CD25 in the CTCL cell line. Cells that were subsequently exposed to DD showed a 50% to 70% decrease in protein synthesis. This observation suggests that increases in expression of components of the IL-2R can be achieved by retinoids and rexinoids, which may enhance the cytotoxicity of DD. A phase I trial investigating the use of bexarotene in conjunction with DD in patients with relapsed or refractory CTCL was undertaken, and eight out of 12 treated patients showed a greater than 50% increase in CD25 expression after treatment with bexarotene. A phase II trial of DD demonstrated an ORR of 48% in relapsed/refractory PTCL (excluding CTCL) with median PFS of 6 months. Higher responses (61%) were seen in $CD25^+$ tumors. In a phase II trial in patients with relapsed/refractory NHL, the ORR was 25%, with similar responses in $CD25^+$ and $CD25^-$ tumors. DD has also demonstrated promising activity in 30 patients with steroid-refractory acute GVHD, with 71% of patients responding with either complete (50%) or partial resolution (21%) of GVHD. Hepatic transaminase elevation was the dose-limiting toxicity.

DRUG RESISTANCE TO CHEMOTHERAPEUTIC AGENTS OR MULTIDRUG RESISTANCE

Leukemia Stem Cells

Clonal Evolution

Although many hematologic malignancies develop resistance to a specific class of chemotherapeutic agents, or to targeted therapeutics. The basis for resistance includes overexpression of anti-apoptotic proteins, preexisting and acquired drug-specific resistance mechanisms often at the active site of the target protein, emerging mutations as part of clonal evolution, DNA repair gene expression-mediated resistance, and overexpression of the ATP-binding cassette (ABC) transporters such as MDR-1 for drug efflux. In general, genomic instability and clonal evolution of hematologic malignancies, the existence and selective regrowth of sub-clone populations, especially leukemic stem cells, and more specific error prone DNA repair provide a background for a high mutational frequency that under selective survival pressure due to both cytotoxic and targeted therapies give rise to an exceptional environment for rapid evolution of resistance phenotypes.

P-Glycoprotein (ABC-B1 Transporter)

Structure and Function

The ABC superfamily of membrane transporters mediates the cross-membrane flux of xenobiotics, naturally occurring toxic compounds, drugs, peptides, and ions. The ABC family has a profound impact on homeostasis and is critically important to proliferation and differentiation signals in normal progenitor cells. It also mediates drug sensitivity. This phosphorylated glycoprotein has a molecular mass of approximately 170 kDa and is localized to the plasma membrane, where it functions as a drug efflux pump (Table 58.7). The family of drug-transporting proteins has been more carefully characterized, leading to the use of the term *ATP-binding cassette transporters*. The observation of double-minute chromosomes and homogeneously staining regions in several MDR cell lines suggested that gene amplification is involved in PGP-mediated MDR. These double minute amplifications[139] contain not only drug resistance genes but also oncogenic drivers on episomes that replicate with the tumor cell. The human *MDR1* gene, which codes for PGP and is involved in antitumor drug resistance, and the human *MDR2* gene (the product of which is expressed by hepatocytes) are located very near each other on human chromosome 7q21.1. PGP is a member of the ABC superfamily, which includes, among more than 100 others, the MRP; the *pfmdr* pump in *Plasmodium falciparum*, which results in chloroquine resistance; STE6, the transporter of the "a" peptide mating factor in yeast; the cystic fibrosis transmembrane conductance regulator (CFTR); and the TAP-1 and TAP-2 proteins that transport antigenic peptides for association with class I molecules and surface antigen presentation.

PGP has a broad specificity for hydrophobic compounds and can both reduce the influx of drugs into the cytosol and increase efflux from the cytosol. To accomplish the former, this "hydrophobic vacuum cleaner" must detect drugs and expel them while they are still in the plasma membrane. Drugs are thought to be effluxed from the cytosol through a single barrel of the PGP transporter, although an exact mechanism has been lacking. PGP is monomeric, with the shape of a cylinder 10 nm in diameter with a maximum height (in the plane of the membrane) of 8 nm (Fig. 58.11). Approximately half of the PGP molecule is within the membrane because the lipid bilayer is approximately 4 nm in depth. When viewed from the extracellular surface of the membrane, PGP is pteroidal with a large central pore 5 nm in diameter. Thus, this large pore has a "gate" on the cytoplasmic side of the membrane that can regulate the transport of different-sized substrates.

TABLE 58.7 **Characteristics of Three Mechanisms of Multidrug Resistance That Result From Overexpression of P-glycoprotein, Multidrug Resistance-Associated Protein, or Lung Resistance-Related Protein**

	PGP	MRP	LRP
Gene on chromosome	7q21.1	16p13.1	16p11.2
Protein			
Molecular mass	170 kDa	190 kDa	110 kDa
Cellular location	Plasma membrane	Plasma membrane	Cytoplasm ≫ nuclear membrane
Function	Efflux pump, chloride channel	Drug transporter	Major vault protein (nucleocytoplasmic transport?)
Energy source	ATP	ATP	
Posttranslational modifications	*N*-glycosylation, phosphorylation	*N*-glycosylation, phosphorylation	No *N*- or *O*-glycosylation

Substrates of PGP include (see Table 58.7) anthracyclines (doxorubicin, daunorubicin, epirubicin, and idarubicin), anthracenediones (mitoxantrone), aminoacridines (amsacrine), taxanes (Taxol and Taxotere), epipodophyllotoxins (VP-16 and VM-26), vinca alkaloids (vincristine, vinblastine, and vinorelbine), bortezomib, and actinomycin D. Mitomycin C and one of the topoisomerase I inhibitors (topotecan) are both weak substrates for PGP. Several drugs reverse the resistance mediated by PGP overexpression and sensitize cells to the cytotoxic effects of antineoplastic agents. These drugs compete with antitumor agents for efflux from the cell, effectively increasing the intracellular concentration of the cytotoxic drug, and include immunosuppressants (cyclosporin A [CSA], FK 506, rapamycin, PSC 833), calcium channel blockers (verapamil, nifedipine), antiarrhythmics (quinidine), and other miscellaneous agents. Several of these MDR-modulating agents have been used in clinical trials in an effort to sensitize resistant tumor cells (see later).

P-Glycoprotein Expression in Human Malignancies

Increased expression of PGP has been observed in several human tumors, especially those malignancies that arise in tissues that normally have high levels of PGP expression. An analysis of 61 human tumor cell lines (from leukemia, CNS tumors, melanoma, breast cancer, ovarian cancer, colon cancer, lung cancer, and kidney cancer) that were not selected for resistance to antitumor agents demonstrated co-expression of two or three of the MDR proteins (PGP, LRP, or MRP) in 64% of the cell lines. PGP and LRP were overexpressed in 3% of the tumors; MRP and LRP in 43%; and PGP, LRP, and MRP in 18%. The cell lines with the highest levels of drug resistance were found to overexpress all three proteins. Whether this is true in primary human tumors awaits further investigations.

Acute Myeloid Leukemia

An analysis of 96 untreated patients with AML showed that PGP expression predicted induction failure ($P < .0001$) and decreased OS ($P < .001$), as did unfavorable cytogenetics. PGP expression was not detected in patients with favorable cytogenetic abnormalities [t(15;17), inv(16), t(8;21)], was found in 29% of those samples with a normal karyotype, and was expressed in 62% of patients with an unfavorable cytogenetic abnormality. PGP was also detected in 63% of those with secondary AML compared with 25% of those with de novo disease. PGP analysis with the MRK16 antibody in 211 elderly patients (older than 55 years) with untreated AML again showed that PGP expression is significantly associated with a decreased CR rate and resistant disease. Patients in this report with de novo PGP-negative AML with favorable cytogenetics have a CR rate of 81% compared with 12% for those with secondary AML, which is PGP positive and has unfavorable cytogenetics.

Clinical Studies With Modulators of P-Glycoprotein

The clinical trials that have used various modulators of PGP have been reviewed by several investigators. An early study in VAD (vincristine-Adriamycin-dexamethasone)-refractory MM resulted in short-lived PRs to VAD plus racemic verapamil in five out of 22 patients. Four of the five responders overexpressed PGP; however, cardiac side effects

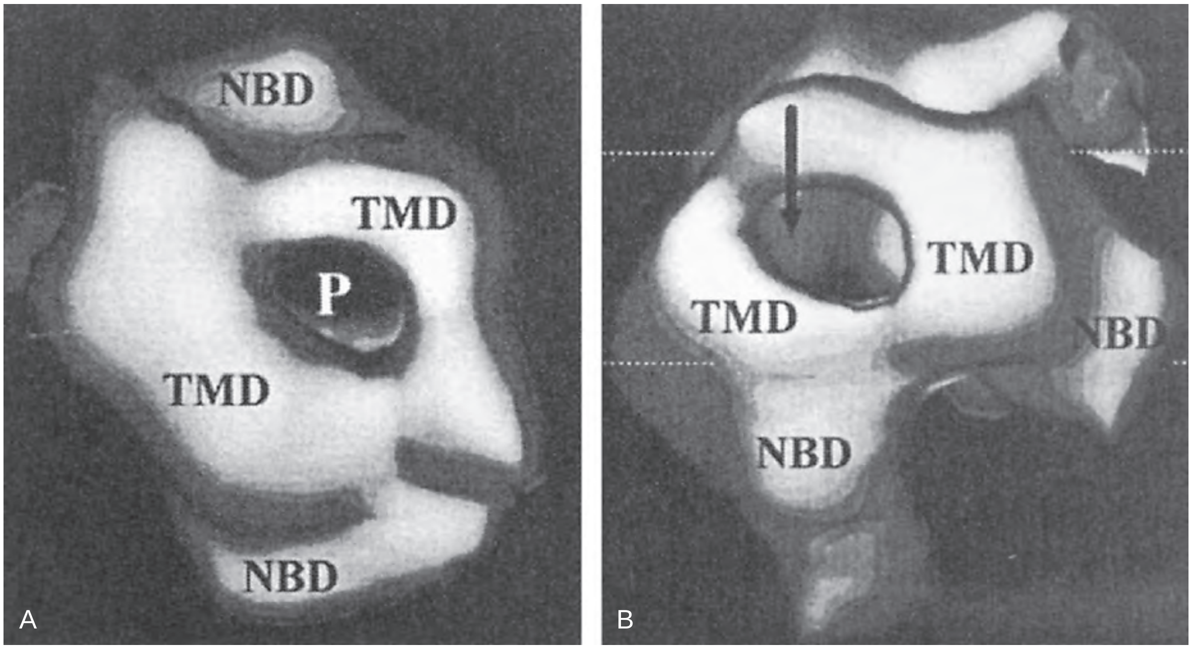

Figure 58.11 STRUCTURE OF P-GLYCOPROTEIN DETERMINED BY ELECTRON MICROSCOPY. A computer graphic representation of the three-dimensional reconstruction is shown as a shaded surface representation of the structure. The *straight arrow* shows the putative adenosine triphosphate binding domains. *P* represents the aqueous pore open at the extracellular face of the membrane. *TMD*, two thumbs, each of which probably corresponds to one of the two transmembrane domains. *NBD*, 3-nm lobes projecting from the structure at the cytoplasmic face of the membrane, probably corresponding to the two nucleotide-binding domains. (A) View perpendicular to the extracellular surface of the lipid bilayer; (B) side view of P-glycoprotein in which the approximate position of the lipid bilayer is indicated by the two horizontal *dashed lines*. *Arrow* indicates asymmetric opening providing access from the lipid phase to the aqueous core of the protein. *(Reproduced with permission from Rosenberg MF, Callaghan R, Ford RC, et al. precluded further dose escalation of IV *R*,*S*-verapamil. Continuous IV infusion of CSA with VAD in VAD-resistant myeloma patients resulted in seven out of 15 responses, which were more common in those who overexpressed PGP. A randomized SWOG phase III study of VAD and PO verapamil in 120 patients with refractory myeloma demonstrated a 41% and 36% response in the VAD and VAD/verapamil arms, respectively, with median survival times of 10 and 13 months, respectively. Continuous-infusion CSA has been dose escalated in combination with daunorubicin and ara-C. A CR was seen in 26 out of 42 patients; however, the MDR phenotype was not found to influence the response. A study of PSC833 in patients with acute leukemia treated with cytarabine, daunorubicin, and etoposide showed a modest benefit in patients younger than 45 years of age. The future role of modulation of PGP in leukemia management remains ill defined.

Multidrug Resistance-Associated Protein (ABC G2 Transporter)

Structure and Function

The MRP was first described in 1992 in the doxorubicin-selected small-cell lung cancer cell line, and its biochemical characteristics and biologic properties have been reviewed.[140] It has now been classified within the larger context of ABC transporters, termed *ABC G2 transporters* (Fig. 58.12).

The overexpression of MRP has been shown in vitro to result in different levels of drug resistance to several classes of antineoplastic agents, represented by actinomycin D, chlorambucil, melphalan, cisplatin (CDDP), daunomycin, doxorubicin, epirubicin, teniposide (VM-26), etoposide (VP-16), and vincristine. Compounds reported to modulate MRP-mediated drug resistance in vitro include the calcium channel blocker verapamil nicardipine; the protein kinase C inhibitor GF109203X; the cyclosporin analog PSC833; the TKI

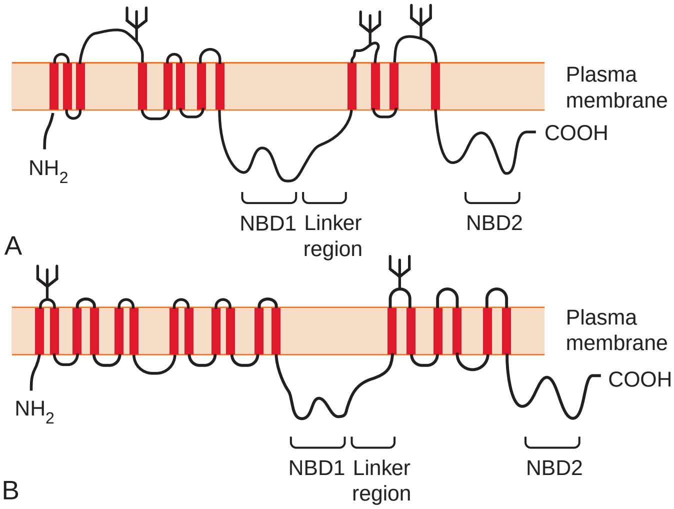

Figure 58.12 MODELS OF MULTIDRUG-RESISTANCE PROTEIN MEMBRANE TOPOLOGY. Multidrug-resistance protein (MRP) possesses features common to all members of the adenosine triphosphate binding cassette (ABC) cassette transporter superfamily in that each half of the protein is predicted to consist of several transmembrane domains followed by a cytosolic nucleotide-binding domain (MBD). The first model (A) is based on computer-assisted hydropathy analyses of the human MRP amino acid sequence and predicts that MRP is composed of 12 transmembrane domains *(solid bars)*, eight of which are within the NH_2-proximal half of the protein. The second model (B), based on a comparison of human and murine MRP with other ABC transporters, suggests that there are up to four additional transmembrane domains in the NH_2-proximal half of the protein. *(Adapted from Loe DW, Deley RG, Cole SPC. Biology of the multidrug resistance-associated protein, MRP. Eur J Cancer. 1996;32A[6]:945.)*

genistein; the gyrase-inhibiting antibiotic difloxacin; and amiodarone VX-710. Amiodarone VX-710, a nonmacrocyclic ligand of the FK506-binding protein FKBP12 and a potent modulator of PGP-mediated MDR, has been found to restore sensitivity of MRP-expressing HL60/ADR cells to the cytotoxic action of doxorubicin, VP-16, and vincristine.

Multidrug-Resistance Protein Expression in Hematologic Malignancies

The expression of MRP mRNA or the level of MRP protein has been assessed in 148 patients with hematopoietic malignancies. MRP mRNA expression was found to be significantly increased in 84% of patients with CLL and in 30% of those with AML. Most patients with ALL, CML, MM, HCL, and NHL were found to have low levels of MRP mRNA expression. MRP protein was assayed using the monoclonal antibody MRPr1, and the results were generally similar with increased expression in most patients with CLL. A study of 40 patients with refractory lymphoma and 16 with newly diagnosed lymphoma suggests a limited role for MRP mRNA expression in drug resistance in NHL because 15 paired samples in the refractory group showed no difference in MRP expression pre- and post-EPOCH treatment. In addition, the untreated patients had MRP mRNA levels that were no different from the pre- or post-EPOCH patient levels. A study of 49 patients with AML and 29 with ALL demonstrated significantly higher expression of MRP in ALL ($P < .007$) and in secondary AML ($P < .016$), but not in de novo AML. Combining overexpression of ABC G2 and FLT3-ITD, an Italian group identified that in adult AML patients, overexpression of ABC G2 was detected in 83 (50%) and FLT3-ITD in 47 (28%) patients. Although the response rate was not affected, the duration of remission was much shorter when these proteins were overexpressed.

The larger family of transporters, the ABC group that includes ABC G2 and ABC B1, is overexpressed in leukemic cells and in many malignant stem cells. In fact, in addition to CD44, high levels of ABC transporters assist in the characterization and isolation of the transplantable subpopulation of malignant stem cells. Brendel and coworkers found that both imatinib and nilotinib used to block the ABL kinase in CML were effectively blocking the ABC transporter in CML cells.[141] This suggested both that these agents might function in part by blocking expression of an important leukemic stem cell protein, and that they would sensitize CML cells to other agents transported by the ABC system.

DNA Repair Pathway Mechanisms of Drug Resistance

O^6-methylguanine-DNA methyltransferase

The nitrosoureas and methylating agents are cytotoxic largely because of formation of DNA adducts at the O^6 position of guanine. The most efficient means of protection from the cytotoxicity of adducts at the O^6 position of guanine is rapid repair by the O^6-MGMT. This protein serves as the stoichiometric acceptor protein for O^6-methylguanine DNA monoadducts, transferring the alkyl group from DNA to the active site of the protein, inactivating the protein, and restoring DNA to normal. However, the $N^1G–N^3C$ DNA cross-link that follows chloroethylation is not a substrate for MGMT. There is a striking correlation between drug resistance and methyltransferase activity. Of interest, high levels of MGMT are found in many leukemias, but low MGMT is observed in normal human CD34 cells, perhaps explaining why nitrosoureas are not used in leukemia management and why nitrosoureas are effective myeloablative agents used in high-dose chemotherapy regimens. A novel inhibitor of MGMT, O^6-benzylguanine (BG) has been used to sensitize human tumors to BCNU. Studies indicate activity of the combination of BG and BCNU in myeloma and in cutaneous lymphomas. Temozolomide has some therapeutic efficacy in leukemia in a manner inversely related to MGGT levels in the tumor cells. A study in five pediatric patients pointed out that response to temozolomide was greater in those with MGMT promoter methylation and no evidence of MMR. This has been tested in a prospective phase II trial of older patients with leukemia. Temozolomide was given in a dosing schedule dependent on MGMT promoter methylation status, with a shorter course of therapy in those with low MGMT expression in the leukemic cells. The ORR in elderly leukemia patients who would otherwise not be candidates for treatment was about 40%, with a median duration of about 29 to 35 weeks.

Mismatch Repair

The spectrum of drug resistance and sensitivity to methylating agents does not end with MGMT. Evidence suggests that methylating agent-induced cell death involves an aborted effort at MMR. Karran and others,[142] in mammalian systems, have shown that the replicative DNA polymerase and the repair polymerase pauses at O^6-mG and preferentially inserts a thymine (T) at the site. The O^6-mG:T base pair is recognized by the MMR system, which initiates (see later). In human cells, the MMR complex consists of at least six proteins involved in the recognition and repair of mismatch lesions: HMLH1, hMSH2, hMSH3, hPMS1, hPMS2, and GTBP (GT-binding protein, also called *MSH6*), all of which appear to be homologs of MMR proteins found in *Escherichia coli* and in yeast. After binding recognition, an endonuclease removes a patch of approximately 100 to 1000 bp containing the T mismatch, DNA polymerase-δ or -γ fills in the patch, with reinsertion of a T opposite the O^6-mG, and a DNA ligase closes the strand break. Because the O^6-mG:T is reformed, cytotoxicity ensues as a result of repetitive efforts at DNA repair and induction of chromosomal breakage, rearrangements, energy depletion, and apoptosis. Drug resistance based on mutation or loss of expression of an MMR protein, owing to mutation within one of the gene coding regions, or promoter methylation leading to loss of gene expression, has been noted in solid tumors and in leukemias and lymphomas. The mutator phenotype was originally described in cells with acquired resistance to methylating agents such as *N*-methyl-*N*-nitroso-*N*-nitrosoguanidine, which were tolerant to G→A point mutations according to the inability to repair O^6-mG and are cross-resistant to 6-TG used in childhood leukemia maintenance regimens, which form the 6-TG:T mismatch.

Major Molecular Response Mutations and Methylating Agent Resistance

MMR defects in humans were initially described in hereditary nonpolyposis colon cancer, which comprises approximately 15% of all colon cancer, lymphomas, and relapsing acute leukemias. The genetic defect results in a high rate of spontaneous mutations within microsatellite DNA, resulting in the RER phenotype arising as the expansion or contraction of mono-, di-, or tri-nucleotide repeats within the microsatellites. In normal hematopoietic stem cells, loss of MMR through promoter methylation of MLH1 in these cells gives rise to microsatellite instability that is age dependent,[143] and may evolve into MDS or acute leukemia.[144] Tumor cells defective in MMR are remarkably resistant to temozolomide regardless of AGT activity or its inhibition by BG, confirming the importance of MMR in sensitivity to methylating agents. Of interest, MMR mutant cells are also two- to threefold resistant to cisplatin, perhaps because the cisplatin DNA adduct is bound by the MMR complex, slowing its recognition and repair by the nucleotide repair pathway and increasing its cytotoxicity. In NHL, loss of MMR results in shorter responses and drug resistance.[145] Such MMR-deficient cells also exhibit microsatellite instability, a measure of genomic instability and the propensity to develop further mutations during therapy, leading to subclones of resistant cells. Loss of PMS2 has been identified in a family of childhood lymphomas, while somatic loss is associated with promoter methylation in acute leukemia.[146] Microsatellite instability is seen in acute leukemias and in T-cell leukemias, suggesting both that these malignancies have lost MMR function and that they are more prone to drug resistance and acquisition of additional mutations that give rise to further drug resistance. Evidence of microsatellite instability and loss of MMR is present in some leukemias but is much more common in treatment-related leukemias, again providing a mechanism of drug resistance.

Base Excision Repair

Methylating agents such as procarbazine and temozolomide form large numbers of N^3-A and N^7-G adducts in addition to O^6-mG (with TMZ, the relative amounts are 72 N^7mG:8 O^6mG:5 N^3mA). Thus, under normal circumstances, cells process many more N^7mG and N^3mA lesions than O^6mG lesions, even though the latter appear much more cytotoxic except in MMR-defective cells. Repair of N^3-A and N^7-G adducts through BER is efficient and normally leads to cell survival rather than cell death. Adducts are recognized by the methylpurine glycosylase with removal of the base, generating an abasic (or AP) site. The AP site is then cleaved by the class II hydrolytic endonuclease (or AP endonuclease) generating a single-strand break with a 5′ PO_4, which becomes the substrate for DNA polymerase-β, and to a lesser extent, polymerases-δ and -γ, followed by DNA ligase.[147] Other compounds induce nucleotide pool imbalance, leading to misincorporation of bases that become substrates for BER. These compounds include folate antagonists such as methotrexate, 5-FdU (floxuridine), and, to a lesser extent, nucleoside analogs such as fludarabine. Misincorporation of uracil alone (after methotrexate) or with 5FU after floxuridine inhibition of thymidylate synthase also leads to BER. Compounds to disrupt BER, such as TRC102, are now being developed and may lead to combination therapy for hematologic malignancies. An initial phase I trial with TRC102 has been completed with fludarabine in CLL[148] and pemetrexed in solid tumors[149]; a trial with temozolomide continues. A third trial using the combination of fludarabine and TRC102 in patients with CLL has found remarkable efficacy in the first cohorts after relapsing from fludarabine (unpublished).

Drug Resistance to Antimetabolites

In addition to their DNA damaging effects and associated resistance patterns, mechanisms of resistance to antimetabolites fall into several broad categories. For example, many antimetabolites are prodrugs in that they must be converted intracellularly into active nucleotide forms to exert their cytotoxic actions. Consequently, events that interfere with cellular accumulation of drug or nucleotide formation will reduce activity. Examples include decreased transport of methotrexate or decreased nucleotide formation of ara-C and 6-TG by reductions in activity of deoxycytidine kinase or hypoxanthine–guanine phosphoribosyltransferase, respectively. Alternatively, enhanced drug catabolism reduces cytotoxicity. Examples include the deamination of ara-C (to inactive ara-U) by cytidine deaminase or catabolism of 6-TG by thiopurine methyltransferase. A third mechanism of resistance stems from the presence of increased intracellular levels of a competing metabolite (e.g., dCTP in the case of ara-C, or hypoxanthine or guanine in the case of 6-TG). Fourth, alterations in the level of activity of a target enzyme or the presence of a mutant form that is a poor target of inhibition will also confer resistance. Examples include increased DHFR activity through gene amplification, most commonly on oncogene-containing episomes termed double minutes DHFR,[150,151] or a mutant form of DHFR (in the case of methotrexate),[152] an altered FLT3-ITD (in the case of ara-C).[153] Finally, cytokinetic factors represent a common theme in the case of most (but not all) antimetabolites, in that a reduction in the S-phase fraction generally leads to reduced drug sensitivity.

Mechanisms of Resistance to Signal Transduction Inhibitors

The introduction of signaling inhibitors to the therapeutic armamentarium represents a significant advance in the treatment of hematologic malignancies. As discussed in the previous sections, these agents can inhibit, with relative selectivity, cellular signaling pathways essential for the survival of neoplastic cells. However, development of resistance has been observed in vitro and in clinical practice.

Genetic Modifications Leading to Resistance to Signal Transduction Inhibitors

Ibrutinib Resistance

Point mutations are the most common mechanism of resistance to TK inhibitors. Emerging ibrutinib resistance due to BTK due to Cys481 mutations occurs in CLL and mantle cell lymphoma, including those with MYD88 mutations.[154] Most often, these BTK^{Cys481} mutations are subclonal and expand over time.[155] While the exact etiology of these mutations is unclear, it is possible that point mutations mediated by BER induced by activation-induced cytidine deamination which is active in B-CLL may be responsible.[156,157]

BCR-ABL Inhibitor Resistance

In CML, the development of multi-generation BCR-ABL inhibitors followed by Src kinase inhibition has provided a plethora of therapeutic options. Resistance to imatinib appears during clonal evolution in a sub population of patients and has the characteristics of a preexisting clone of cells. The T315I BCR-ABL mutation in CML patients is responsible for up to 20% of all clinically observed resistance due to reduced binding to the active site, but may be overcome by addition of interferon.[158] In other patients, a splice variant of BCR-ABL1(35INS) is identified with altered binding to imatinib.[159] While other BCR-ABL inhibitors can be effective for long durations, many other therapeutics to overcome resistance have been identified (see Chapter 69).

Venetoclax Resistance

While very effective, late venetoclax resistance has developed in CLL patients, as noted in those on clinical trials. The novel Gly101Val mutation in BCL2 was identified at progression in 7 of 15 patients with emerging resistance detected after 19 to 42 months of therapy. These mutations were not found at study entry. The point mutation reduces venetoclax affinity of BCL2.[160]

Idelalisib Resistance

The phosphatidylinositol 3-kinase delta (PI3K-δ) inhibitor idelalisib does not have mutational evidence of resistance in CLL but does occur with upregulation of expression of insulin-like growth factor 1 receptor (IGF1R), resulting in enhanced MAPK signaling.[161]

Lenalidomide Resistance

Cereblon, the target for lenalidomide, is often depleted by chromosomal loss or point mutation and results in resistance in myeloma patients. In experimental systems, bromodomain inhibitors can overcome this resistance.

Bortezomib Resistance

Alterations in the proteasome can provide fundamental resistance to proteasome inhibitors in myeloma. High levels of the deubiquitinase USP7, mutations in the proteasome beta-5 subunits, and overexpression of macrophage activating factor (MAF) have been observed.[162–164]

FUTURE DIRECTIONS

Hematologic malignancy research continues to uncover new pathways of pathogenesis, acquired mutations, clonal evolution, drug-induced resistance mutations, and acquired gene activation leading to drug resistance. Artificial intelligence and machine learning are transforming personalized decision making for specific genotypic disorders. Age dependent phenotypes and response rates are emerging as critical in treatment decision making and cell-based therapies and other immune-based therapeutics complement the outlook for patients treated with small molecules.

CHAPTER 59

PATHOBIOLOGY OF ACUTE MYELOID LEUKEMIA

Andrew M. Brunner and Timothy A. Graubert

Acute myeloid leukemia (AML) is a cancer of hematopoietic stem/progenitor cells, characterized by recurrent genetic and epigenetic alterations. Historically, human leukemias were distinguished according to clinical and histological features and subsequently by morphology. Analysis of the AML genome at increasing resolution, from the level of whole chromosomal changes to individual base pairs, together with an appreciation of epigenetic changes and interactions within the bone marrow microenvironment, has furthered the understanding of the biology and clinical behavior of this disease. Characterizing the patient-specific biology of AML is increasingly important both for understanding the origins of disease and also to guide therapeutic decision-making.

PHENOTYPE OF ACUTE MYELOID LEUKEMIA

Normal hematopoiesis is characterized by self-renewal and differentiation of long-term hematopoietic stem cells (HSCs) to short-term HSCs, multipotent progenitors, and common lymphoid and myeloid progenitors (see Chapter 9). These lineage-committed progenitors further differentiate to mature lymphoid or myeloid cells, including erythrocytes, granulocytes, macrophages, and platelets. This process is regulated by lineage-specific transcription factors at key points during normal hematopoiesis. Functional analysis of recurrent chromosomal, molecular, and epigenetic alterations in AML has revealed that many of these lesions corrupt hematopoietic differentiation programs, impacting proliferation, survival, and maturation of myeloid progenitor cells. Consequently, a hallmark of the AML phenotype is an accumulation of immature myeloid precursors. A myeloblast count of 20% or greater distinguishes AML from other myeloid malignancies.

Historically, leukemias were classified according to morphologic criteria using the French-American-British (FAB) classification, first proposed in 1976. This system classifies AML by the extent of maturation and lineage specificity, ranging from M0 (undifferentiated) to M3 (promyelocytic), M4eo (myelomonocytic with eosinophilia), M6 (erythroid), or M7 (megakaryocytic). Certain FAB subtypes were subsequently found to correlate with underlying cytogenetic abnormalities, notably M3 with t(15;17), M4eo with inv(16), and M2 with t(8;21). As greater understanding of recurrent cytogenetic and now molecular and epigenetic aberrations has developed, it has become clear that morphology alone is inadequate to fully describe the disease spectrum of AML.

ETIOLOGY OF ACUTE MYELOID LEUKEMIA

The majority of patients who develop AML lack any recognized antecedent condition, and for these patients their disease is classified as sporadic or de novo. In these cases, AML appears to result from the accumulation of spontaneously acquired somatic mutations in self-renewing hematopoietic cells. In contrast, a diagnosis of secondary AML (sAML) is preceded by a known predisposing condition, including environmental exposure, antecedent hematologic malignancy, or inherited factors.

Toxins and Exposures

A number of environmental, occupational, and iatrogenic exposures have been identified that contribute to sAML via genotoxic damage to hematopoietic cells. Exposure to benzene, an organic component of many commonly used chemicals including plastics, dyes, pesticides, solvents, and petroleum products, has been linked to the subsequent development of AML. This relationship was identified in the 19th century, when bone marrow aplasia and myeloid leukemia were noted among workers exposed to benzene-containing chemicals. Individuals with occupational benzene exposure have an approximately threefold increased relative risk of developing AML. Workplace benzene exposures have decreased significantly since this discovery, but other sources of benzene exposure remain a concern (e.g., through cigarette smoking). Although cytopenias can occur within months of benzene exposure, there is a latency of several years between benzene exposure and the development of leukemia.

Cases of AML arising after chemotherapy or radiation have been historically designated as therapy-related AML (tAML). Two classes of chemotherapy drugs in particular are associated with an increased risk of tAML (Table 59.1); the first class of drugs with clear links to tAML are the topoisomerase II inhibitors. The most commonly used topoisomerase II inhibitors are anthracyclines, such as doxorubicin, idarubicin, and daunorubicin, and the epipodophyllotoxin etoposide, which are critical components of many treatment regimens for both solid tumors and hematologic malignancies. Topoisomerase II is an adenosine triphosphate (ATP)-dependent enzyme that religates deoxyribonucleic acid (DNA) at sites of double-strand breaks to manage supercoils; inhibition of this enzyme increases the number of double-strand breaks. Resolution of these double-strand breaks may occur via error-prone nonhomologous end joining, resulting in accumulation of DNA damage or apoptotic cell death. tAML arising after exposure to topoisomerase II inhibitors typically occurs with a latency of 1 to 3 years and is often characterized by balanced chromosomal translocations, with the majority involving the *KMT2A* (mixed-lineage leukemia [*MLL1*]) locus on chromosome 11q23. Typical lesions are reciprocal translocations such as t(9;11)(p21;q23) and t(11;19)(q23;p13). Other rearrangements that occur in de novo AML also occur in tAML after topoisomerase II inhibitors, including t(15;17), t(8;21), and inv(16). The risk of tAML varies based on the chemotherapy dosing schedule, cumulative dose received, additional cytotoxic agents, and underlying disease characteristics but generally does not exceed 5% of patients treated with topoisomerase II inhibitors.

Alkylating agents are the second class of chemotherapy drugs with a clear role in the pathogenesis of tAML. The first leukemogenic agents identified in this category were nitrogen mustards. Frequently implicated drugs in contemporary clinical practice include cyclophosphamide, ifosfamide, and melphalan; weaker associations have been described with other alkylating agents such as busulfan, thiotepa, and cisplatin. Alkylating agents create adducts in DNA bases, which are variably mutagenic or cytotoxic. Cytogenetic lesions in alkylator-associated tAML are typically unbalanced, including loss of the long arms of chromosomes 5 or 7 [del(5q), del(7q)], or complete loss of these chromosomes (−5, −7). The risk of tAML following alkylator exposure is up to 1% per year but typically has a longer latency (5 to 7 years) compared with topoisomerase II-associated tAML. The risk increases with age and cumulative exposure to these agents. In

TABLE 59.1 Characteristic Features of Therapy-Related Acute Myeloid Leukemia

Class	Examples	Latency	Associated Phenotypes
Topoisomerase II inhibitors	Doxorubicin, idarubicin, daunorubicin, etoposide, mitoxantrone	1–3 years after chemotherapy	Balanced translocations, often with *KMT2A* (*MLL1*), or with t(15;17), inv(16), or t(8;21)
Alkylating agents	Cyclophosphamide, ifosfamide, chlorambucil, busulfan, carmustine, dacarbazine	~5–7 years after chemotherapy	Monosomal karyotype (–7, del5q, –5, etc.), *TP53* mutations are common, underlying dysplastic features
Irradiation	Therapeutic radiation typically involving bone marrow, nuclear accidents, radioiodine	~5–7 years	Often similar to alkylating agents
Immunosuppressive agents	Azathioprine	~8 years	Abnormalities in chromosomes 5 and 7, possibly related to diminished immune surveillance
PARP inhibitors	Olaparib, rucaparib, niraparib, talozoparib	Poorly defined	Limited to date. Possible increased risk in patients with germline *BRCA1/2* mutations

MLL, Mixed-lineage leukemia; *PARP*, poly (ADP-ribose) polymerase.

some cases of tAML, small clonal populations harboring *TP53* mutations antedate chemotherapy exposure. *TP53* deficiency may confer enhanced fitness on these clones, allowing them to expand under the selective pressure of therapy.

Several other therapies have also been implicated as risk factors for tAML, including some immunosuppressive therapies such as azathioprine, while other new associations continue to be investigated—for instance, possible tAML risk associated with poly (ADP-ribose) polymerase (PARP) inhibitors, particularly in patients with germline *BRCA1/2* mutations.

Exposure to ionizing radiation also has been identified as a causative mechanism for tAML. This relationship was identified in the context of occupational exposures during the development of radiography and subsequently in the setting of mass exposures such as the atomic bomb detonations or nuclear power plant disasters, where a time-limited spike in leukemia incidence occurred following the event. Outside of these events, therapeutic radiation therapy represents the most common setting for significant radiation exposure, which is associated with a small but significant increase in tAML risk and likely varies depending on the site and dose of directed radiation therapy. Radiation-associated tAML is characterized by an increased frequency of mutations otherwise implicated in de novo AML pathogenesis—for instance, mutations in *RUNX1*, as well as balanced translocations such as *RUNX1-RUNX1T1* and *DEK-NUP214*—suggesting some selectivity in the patterns of DNA damage.

Prior Hematologic Malignancy

Other myeloid malignancies, including myelodysplastic syndromes (MDSs) and myeloproliferative neoplasms (MPNs), carry a risk of disease evolution to sAML. The risk varies depending upon the underlying disease and may be facilitated by certain exposures, including genotoxic chemotherapy.

Patients with MPNs have an approximately 10% risk of evolution to AML (MPN in blast phase [MPN-BP]) over 10 years, which varies according to the underlying disease. The risk is lowest in essential thrombocythemia and may be as high as 20% for myelofibrosis. There is a clear association between chemotherapies used in treating MPNs, specifically alkylating agents and radioactive phosphorus, and leukemic evolution; treatment with these agents results in a threefold to fourfold increase in progression to MPN-BP. Another mechanism that may contribute to clonal evolution and disease progression may be a chronic inflammatory state related to the underlying MPN. Sequencing of sAML cases developing in the background of an MPN has identified recurrent mutations in *TET2*, *JAK2*, *IDH*, *IKZF1*, and *ASXL1*. Moreover, a number of patients with a *JAK2*-mutated MPN may progress to MPN-BP that is *JAK2* wild-type, thought to arise either from a common pre-*JAK2* founding clone, or due to parallel expansion of a distinct hematopoietic clone. MPN-BP with mutated *JAK2* typically proceeds through an accelerated myelofibrosis phase, whereas MPN-BP that no longer harbors a *JAK2* mutation tends to arise from chronic phase disease and may be associated with the use of cytotoxic therapies (see Chapter 72).

Prior to the introduction of tyrosine kinase inhibitors (TKIs) for chronic myeloid leukemia (CML), patients with CML typically progressed from chronic phase to blast phase within 5 years, at a rate of more than 20% per year (see Chapter 69). Most cases of blast phase CML have a myeloid phenotype, whereas approximately 30% of patients have a lymphoid phenotype. Additional mutations may occur during transformation of CML, and approximately 80% of patients have additional cytogenetic abnormalities, such as duplication of the Philadelphia chromosome, and other trisomies that are recurrent in de novo AML. Up to one third of patients with CML in myeloid blast phase harbor mutations in the tumor suppressor genes *P16* or *TP53*. In addition, *BCR-ABL* signaling upregulates transcription factors implicated in AML pathogenesis, including *HOXA9* and *EVI1*, which may contribute to leukemic transformation. The rate of transformation to blast phase CML in the TKI era has decreased markedly to approximately 1% per year, which underscores the continued requirement for *BCR-ABL1* signaling in CML evolution.

Approximately one-third of patients with MDS progress to sAML, although this varies significantly according to the underlying MDS subtype and disease characteristics, including the percentage of bone marrow blasts, presence of characteristic cytogenetic abnormalities, and cytopenias (see Chapter 61). Progression to leukemia is associated with acquisition of additional somatic mutations as well as epigenetic alterations within the MDS clone. Mutations in transcription factors and cytokine signaling genes, including *RUNX1*, *NRAS*, and *ETV6*, are more common at progression to sAML, compared with the frequency of these mutations at MDS diagnosis. Epigenetic modifications of the MDS genome appear to also play a significant role in AML progression, particularly through DNA methylation–mediated silencing of tumor suppressor genes. These alterations are also enriched in the subtype of AML with myelodysplasia-related changes, even where a prior MDS diagnosis was not known.

Congenital Bone Marrow Failure Syndromes

A number of inherited bone marrow failure syndromes are associated with an increased risk of developing advanced myeloid malignancies (see Chapter 30). This may be due to the proliferative stress imposed by chronic cytopenias or defects in DNA repair that are hallmarks of several of these syndromes. These syndromes are reviewed in detail in Chapter 30.

Fanconi anemia (FA) is the most common inherited bone marrow failure disorder and is caused by germline mutations in factors involved in DNA repair. These disorders have an autosomal recessive inheritance pattern except for *FANCB*, which is X-linked. To date, more than 20 genes have been identified as a part of the *FANC* gene family, and together their protein products are responsible for identifying DNA damage and targeting these sites for repair. The cumulative risk of AML or MDS among FA patients is approximately 10% to 15%, with peak incidence during the teenage years.

Dyskeratosis congenita (DKC) is a bone marrow failure syndrome characterized by inherited mutations in the telomere maintenance pathway. DKC can be inherited in an autosomal dominant (Online Mendelian Inheritance in Man [OMIM] 127550), autosomal recessive (OMIM 224230), or X-linked recessive pattern (OMIM 305000). Mutations in *TERT*, *DKC1*, *TERC*, or *TINF2* account for most cases. These patients will typically develop bone marrow failure by 20 to 30 years of age, although variable penetrance of short telomere syndromes may result in later onset of leukemia—particularly in those with a telomere mutation but without the DKC "triad" phenotype of skin hyperpigmentation, nail dystrophy, and oral leukoplakia. Transformation to AML occurs in approximately 10% of patients and is thought to occur via genomic instability related to shortened telomeres and associated DNA damage, resulting in dysplasia and an increased risk of hematopoietic malignancy.

Shwachman-Diamond syndrome (OMIM 260400) is an autosomal recessive disorder caused by mutations in *SBDS*. AML or MDS occurs in up to a third of patients by 30 years of age and is thought to relate to chromosomal instability and accelerated rates of apoptosis, which may be due to the role of *SBDS* in stabilizing the mitotic spindle during mitosis.

Severe congenital neutropenia or Kostmann syndrome is associated with neutropenia at birth and has been associated with a variety of genetic mutations. The pattern of inheritance can be autosomal dominant (*ELANE* or *GFI1*), autosomal recessive (*HAX1*, *G6PC3*, *VPS45*, or *JAGN1*), or X-linked (*WAS*). Nearly a third of patients develop AML or MDS during adolescence. Transformation into AML is frequently characterized by the acquisition of somatic mutations in *CSF3R*, which encodes the granulocyte colony-stimulating factor (G-CSF) receptor. The causal relationship to chronic G-CSF therapy remains controversial.

Diamond-Blackfan anemia (DBA) (OMIM 105650) is characterized by red cell aplasia and typically spares the leukocyte and platelet lineages. DBA is typically inherited in an autosomal dominant fashion and is associated with mutations in a number of ribosomal proteins. AML can occur in up to 20% of patients and typically occurs after 40 years of age.

Congenital amegakaryocytic thrombocytopenia (CAMT) (OMIM 604498) and thrombocytopenia with absent radii (TAR) (OMIM 274000) syndrome are both characterized by hypoplastic thrombocytopenia. CAMT is inherited in an autosomal recessive manner via mutations in the *MPL* gene, which encodes the receptor for thrombopoietin (TPO). CAMT is associated with an increased incidence of AML, typically in the second decade of life. TAR syndrome has been associated with mutations in *RBM8A*, which is involved in messenger RNA (mRNA) splicing. The thrombocytopenia in TAR syndrome often improves over time; both acute lymphoblastic leukemia and AML have been reported among patients with this rare disorder.

Down syndrome, caused by trisomy 21, is associated with an approximately 10- to 20-fold elevated relative risk of AML and MDS compared with the general population and in particular an increased risk for acute megakaryocytic leukemia, FAB M7 (see Chapters 29 and 30). Infants with Down syndrome may experience transient abnormal myelopoiesis (TAM), where circulating peripheral blood blasts are seen and may be accompanied by hepatic dysfunction, effusions, and rash; this occurs in approximately 10% of these patients. The majority of TAM cases harbor somatic mutations in *GATA1*, resulting in altered function of this transcription factor that plays an important role in hematopoietic cell maturation, particularly in the megakaryocyte lineage. Indeed, up to 30% of persons with TAM will progress to AML, commonly acute megakaryocytic leukemia. The development of AML in patients with Down syndrome likely relates both to acquired somatic mutations, such as *GATA1*, and also the presence of additional copies of genes on chromosome 21 that facilitate leukemogenesis, such as the oncogenes *RUNX1*, *ERG*, and *ETS2*.

Mendelian Acute Myeloid Leukemia Predisposition Syndromes

A number of genes that are targets of recurrent somatic mutation in AML are also mutated in the germline in families with predisposition to myeloid malignancy without a prodrome of bone marrow failure. These include mutations in *RUNX1*, *CEBPA*, *DDX41*, and *GATA2*. Predisposition to AML is also associated with germline variants in *ANKRD26*, *SRP72*, *ETV6*, and *SAMD9*/*SAMD9L*. Because gene panel testing (see box on Molecular Diagnostics in Acute Myeloid Leukemia) of unpaired tumor samples cannot reliably discriminate germline from somatic mutations, detection of a known pathogenic mutation in one of these genes in a bone marrow or peripheral blood sample should prompt referral for genetic counseling and germline testing. Although these familial syndromes are rare, they are important to recognize because affected individuals and asymptomatic carriers require specific clinical management. In particular, asymptomatic carriers require counseling about risks to themselves and their offspring, and they should be deferred as graft donors for allogeneic stem cell transplantation. The prevalence and risk of MDS/AML development has not been defined for most of these syndromes due to ascertainment bias in most of the reported series (Table 59.2).

TABLE 59.2 **Familial Acute Myeloid Leukemia Syndromes**

Gene	Chromosome	Inheritance	Risk of MDS/AML	Associated Phenotypes
RUNX1	21q22.12	AD	~40%	Thrombocytopenia, platelet dysfunction
ANKRD26	10p12.1	AD	Not defined	Thrombocytopenia, platelet dysfunction

SRP72	4q12	AD	Not defined	Cytopenias, sensorineural hearing loss

AD, Autosomal dominant; *AML*, acute myeloid leukemia; *MDS*, myelodysplastic syndrome.

MOLECULAR DIAGNOSTICS IN ACUTE MYELOID LEUKEMIA

The various mutations and dysregulated pathways integral to the pathobiology of acute myeloid leukemia (AML) also act as specific therapeutic targets and offer clear prognostic implications for patients. As such, molecular testing at the time of AML diagnosis has become the standard of care, to assist with subclassification of disease, risk stratification, selection of an induction regimen, and consolidation preferences. Diagnosis of AML requires analysis of a specimen demonstrating excess myeloblasts. For patients with high levels of circulating disease, some studies may be performed with the use of peripheral blood samples; however, assessment of a bone marrow biopsy and aspirate is essential.

Standard Evaluation

The cornerstone of the diagnosis of AML remains morphologic assessment. In the current World Health Organization (WHO) guidelines, at least 20% of the bone marrow cellularity or peripheral blood must be composed of myeloblasts, except in the presence of the t(8;21), t(16;16)/inv(16), or t(15;17) rearrangements, which are sufficient for an AML diagnosis regardless of blast count. In addition, promonocytes in acute monocytic leukemia, megakaryoblasts in acute megakaryocytic leukemia, and abnormal promyelocytes in acute promyelocytic leukemia are added to the blast percentage. Only in pure erythroleukemia are erythroblasts included in the blast count.

Flow cytometry uses multiparametric analysis of single cells to assess cellular granularity and size, cell surface, intracellular antigen expression, and other features. The coexpression of certain cell surface markers may help to confirm myeloid cell origin, identify immature blasts, typically CD34$^+$ and CD117$^+$, and also distinguish an aberrant phenotype of a leukemic blast population. Flow cytometry can enumerate small populations of leukemic cells, below the limit of detection by morphology. For this reason, flow cytometric analysis has been developed as a platform to monitor minimal residual disease (MRD).

A critical element in the initial laboratory assessment of AML is cytogenetic analysis of a bone marrow aspirate specimen. This provides important prognostic data for risk stratification and informs therapeutic strategies. Cells from the aspirate are cultured, mitosis is interrupted, and the paired chromosomes are arranged to identify missing, translocated, or duplicated segments. Fluorescence in situ hybridization uses fluorescently labeled DNA probes and can identify gains and losses of chromosomal material, as well as rearrangements that may be cryptic using conventional banding techniques, and may complement, but not replace, standard karyotyping.

Detection of somatic mutations that are known drivers of AML biology can aid in the initial risk classification of patients with AML, particularly those with intermediate-risk cytogenetics. Current National Comprehensive Cancer Network guidelines recommend testing for recurrent gene mutations (*KIT*, *FLT3, NPM1*, *IDH1, IDH2, TP53*, and *CEBPA*) at diagnosis because their prognostic and therapeutic significance has been validated in large cohorts (level 2 A evidence). Testing for mutations in *RUNX1* and *ASXL1* is recommended for WHO classification. In addition, use of targeted therapies is increasingly dependent on detection of a specific tumor genotype. Multigene panels that test for recurrently mutated genes in AML and other myeloid malignancies are increasingly used for these purposes (later).

Investigational Testing

Given the rapidly expanding number of genes that are recognized targets of recurrent somatic mutation in AML, more comprehensive mutational profiling is increasingly part of routine clinical practice. With increasing numbers of genes to query, next-generation sequencing approaches offer advantages in sensitivity, cost, and efficiency over traditional testing methods (e.g., polymerase chain reaction, Sanger sequencing). Large panels of genes can be tested simultaneously by preenriching for the targets of interest (by automated amplicon generation or hybridization capture). These platforms have also been adapted to monitor MRD for specific known alterations, including *NPM1* and *FLT3*, among others. With further improvements in analytical workflow and cost reduction, whole-genome and transcriptome sequencing could displace some existing diagnostic tools because these platforms can provide simultaneous detection of mutations, gene expression, copy number alteration, and structural variation.

Familial platelet disorder with predisposition to acute myelogenous leukemia (OMIM 601399) is associated with autosomal dominant inheritance of germline mutations in *RUNX1*. Mutation carriers frequently present with easy bruising/bleeding due to quantitative or qualitative platelet dysfunction and have an approximately 40% lifetime risk of developing AML, typically in the third or fourth decade. The most frequently reported mutant alleles in *RUNX1* are loss-of-function nonsense, frameshift, or missense mutations in the DNA-binding domain. The second copy of *RUNX1* is frequently mutated in cases that evolve to MDS/AML.

Germline mutations in *CEBPA* are a rare cause of autosomal dominant familial predisposition to AML (OMIM 116897). The germline mutations are typically truncating at the N-terminus of the protein, whereas somatic acquisition of mutations affecting the C-terminus is a nearly invariant event in the development of AML among these patients. These cases have a relatively favorable prognosis, similar to de novo AML with somatically acquired biallelic *CEBPA* mutations.

Germline mutations in *GATA2* cause a spectrum of disorders with overlapping features, including Emberger syndrome (OMIM 614038) and immunodeficiency 21 (IMD21) (OMIM 614172), also described as monocytopenia with susceptibility to mycobacterial, fungal, and papillomavirus infection and myelodysplasia (MonoMAC syndrome) or dendritic cell, monocyte, B-lymphocyte, and natural killer lymphocyte deficiency (DCML). Patients with IMD21 have decreased monocyte counts and natural killer and B-cell deficiency and are at an increased risk of developing viral and nontuberculous mycobacterial infections. Emberger syndrome patients have a similar presentation but also have deafness and lymphedema and often develop pancytopenia. More than 100 germline *GATA2* mutations have been described, most commonly deletions, nonsense, or missense substitution affecting the C-terminal zinc finger of *GATA2*, in addition to intronic mutations and substitutions at a 5′ enhancer. AML or MDS arises in approximately 70% of carriers and is associated with cooperating genetic events, such as mutations in *ASXL1*, *SETBP1*, *STAG2*, or hemizygous deletions involving chromosome 7.

SAMD9 and *SAMD9L* are paralogous genes on chromosome 7q. Inherited missense mutations in both genes appear to confer gain-of-function growth suppressive activity in hematopoietic cells. A variety of compensatory somatic events have been described that allow cells to escape from this antiproliferative pressure, including acquisition of loss-of-function mutations in cis that abrogate the effects of the germline allele, gene correction by homologous recombination, and loss of the chromosome arm harboring the mutant allele—a phenomenon termed “adaptation by aneuploidy.” The latter is associated with increased risk of MDS/AML development, whereas the former mechanisms are protective. Affected individuals may present with MDS/AML without prior sequelae or may have preceding stigmata of ataxia-pancytopenia (*SAMD9L*; OMIM 159550) or the MIRAGE syndrome (*SAMD9*; OMIM 617053).

Germline mutations in *DDX41* on chromosome 5q are associated with autosomal dominant predisposition to MDS/AML with a long latency (OMIM 616871). Affected individuals may present with cytopenias prior to diagnosis of MDS/AML, but often a family history of hematologic malignancies is the only feature that raises suspicion of an inherited syndrome. Pathogenic germline *DDX41* alleles include deletions, frameshift, nonsense, or missense mutations. Somatic mutations in the remaining *DDX41* allele are acquired in nearly half of individuals who progress to MDS/AML.

Clonal Hematopoiesis

HSCs acquire somatic mutations with age (see Chapter 19). Mutations that confer a fitness advantage create a state of clonal hematopoiesis (CH) in which a clonally derived population of cells can be detected in peripheral blood or bone marrow. CH is nearly ubiquitous in the adult population when very sensitive error-corrected sequencing technologies are used. Using more stringent thresholds typically employed in routine clinical sequencing (i.e., variant allele fraction of 2%), CH is detectable in nearly 10% of apparently healthy individuals older than 65 years of age. This is termed clonal hematopoiesis of indeterminate potential (CHIP) if the affected individual has normal blood counts and no antecedent hematologic malignancy. In contrast, CH in patients with idiopathic cytopenias but without a morphologically apparent hematologic malignancy is referred to as clonal cytopenias of undetermined significance (CCUS). The genes most frequently mutated in CHIP and CCUS encode epigenetic regulators (e.g., *DNMT3A*, *TET2*, *ASXL1*) which are also targets of recurrent mutations in MDS/AML.

Patients with CHIP carry a small but significantly increased risk of progression to overt hematologic malignancy, approximately 0.5% to 1% per year, most often to MDS or AML. The risk of progression to a hematologic malignancy is higher in individuals with CCUS, a large clone size, more than one driver mutation, and mutations in specific genes (particularly, spliceosome components). Patients with CH also have a significantly increased risk of cardiovascular events, typically atherosclerosis-related vascular events, possibly related to altered proinflammatory signaling in clonally derived monocytes, among other mechanisms. Additional epidemiologic study will be required to determine how often CH is a precursor to MDS/AML and whether surveillance and/or early intervention are warranted.

GENETIC AND EPIGENETIC ALTERATIONS IN ACUTE MYELOID LEUKEMIA

AML is characterized by a variety of recurrent cytogenetic, molecular, and epigenetic modifications that illustrate the pathophysiologic role of acquired somatic alterations affecting specific gene products. These mutations have been incorporated into strategies for prognostic stratification and risk-adapted treatment, in addition to providing a framework for targeted therapy. The World Health Organization (WHO) classification now recognizes a number of recurrent genetic abnormalities, including balanced translocations and inversions, as defining features of AML.

Early understanding of the pathogenesis of AML suggested a model in which AML occurred in the setting of acquired mutations in two pathways: mutations that block normal mechanisms of differentiation and mutations that activate cell proliferation and survival pathways. This oversimplified model gained early support from genetically engineered mouse models in which at least two genetic "hits" were required to generate leukemia, such as a mutation activating cytokine signaling and a mutation inactivating a hematopoietic transcription factor. However, this model does not account for the wide spectrum of more recently described somatic alterations, nor do all AML cases carry mutations in these two classes.

Chromosomal Abnormalities

The central role of acquired mutations in AML was first recognized through the identification of recurrent nonrandom cytogenetic alterations in the mid-20th century (see Chapter 57). Recurrent karyotypic lesions are frequent events in AML, present in approximately 50% to 60% of patients at diagnosis, and have distinct prognostic significance that are central to treatment decisions, including the identification of patients for whom HSC transplantation should be considered in first remission, as well as patients likely to achieve a favorable outcome with chemotherapy alone (Fig. 59.1).

Common chromosomal abnormalities include chromosome translocations or inversions, chromosome deletions, and monosomies or trisomies. Patients can be stratified according to karyotype into favorable-, intermediate-, and poor-risk categories. Typically, favorable risk includes patients with t(15;17), t(8;21), or inv(16)/t(16;16), and adverse risk includes inv(3q)/t(3;3), t(6;9), monosomy 7, monosomy 5, loss of 5q, 7q, or 17p, and complex (three or more) chromosomal abnormalities, as well as most translocations involving the *KMT2A* (*MLL1*) locus on chromosome 11q23. In lieu of additional molecular studies, all other karyotypic lesions are generally classified as intermediate risk. This includes patients with a normal karyotype, which comprise approximately 45% of all AML cases.

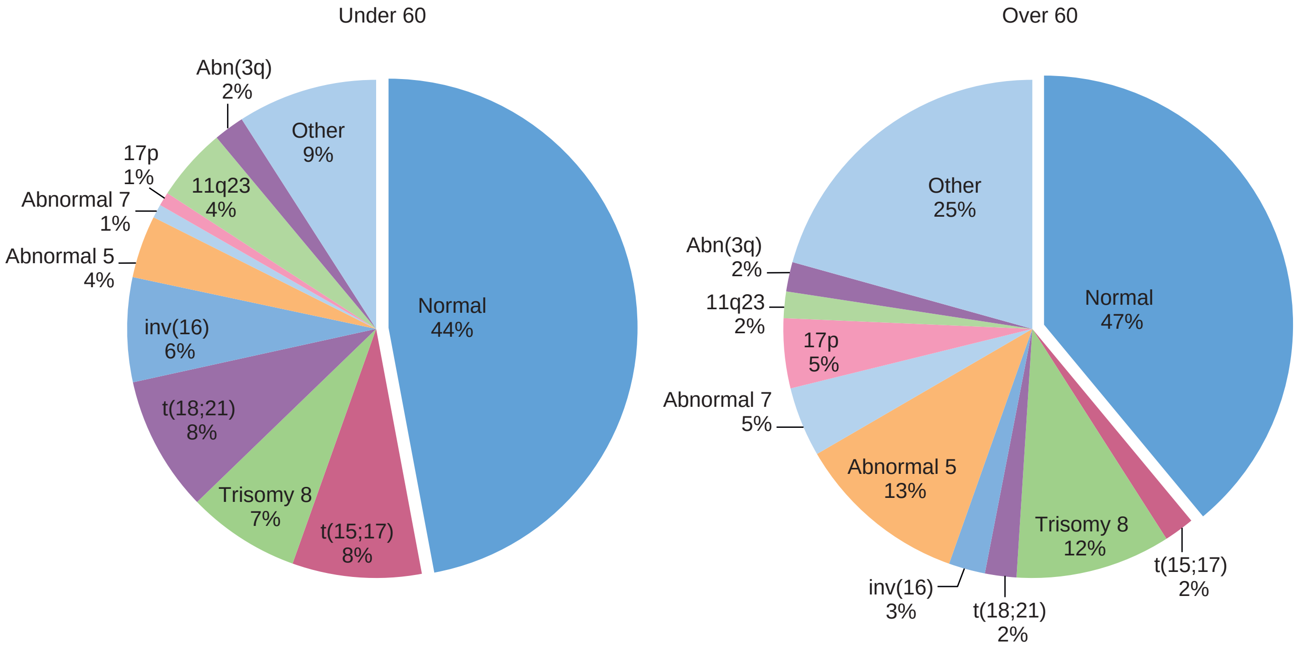

Figure 59.1 FREQUENCY OF CHARACTERISTIC CYTOGENETIC ABNORMALITIES IN ADULT PATIENTS WITH ACUTE MYELOID LEUKEMIA. The proportion of recurrent cytogenetic abnormalities in patients 15 to 60 years old and patients greater than 60 years old at diagnosis is shown. *Abn*, Abnormal; *Inv*, inversion. *(Data derived from previously reported cytogenetic studies by CALGB, MRC, SWOG, ECOG, EBMT, and AMLSG.)*

Retinoic Acid Receptor Rearrangements

A distinct subset of AML, acute promyelocytic leukemia (APL) or FAB M3, comprises approximately 10% of adult AML cases and is defined by the presence of a translocation involving the retinoic acid receptor-α (*RARA*) on chromosome 17q21 (see Chapters 57 and 60). This results in a distinct phenotype characterized by a maturation arrest at the promyelocyte stage. RARs heterodimerize with retinoid X receptors (RXRs) to bind DNA at retinoic acid response elements, where they control gene expression during development and differentiation. In the majority of cases, *RARA* is fused with the *PML* gene on chromosome 15q22 as a consequence of t(15;17)(q22;q21). Other rare fusion partners include PML-like zinc finger (*PLZF*), nucleophosmin (*NPM1*), nuclear mitotic apparatus protein (*NUMA1*), and signal transducer and activator of transcription 5B (*STAT5B*). Each of these fusion partners has a self-association domain, similar to RXRs, and the fusion product interferes with expression of retinoic acid transcriptional targets.

In mouse models, transgenic expression of *PML-RARA* results in APL after a long myeloproliferative phase; the long latency period prior to leukemia development implies that cooperating mutations are typically required for full transformation. Introduction of the *FLT3-ITD* hastens APL onset in mice. Consistent with this finding, more than 35% of human patients with APL have *FLT3-ITD* mutations and nearly 20% have *FLT3-TKD* mutations. *PML-RARA* appears to have a dominant negative effect on RARα transcriptional function, as well as a role in DNA and chromatin modification, resulting in impaired myeloid differentiation. In addition, the fusion protein disrupts the organization of PML nuclear bodies, which are subcellular structures that are involved in a number of cell cycle, metabolic, and apoptotic regulatory pathways.

Core Binding Factor Rearrangements

Rearrangements involving genes encoding components of the core binding factor (CBF) are present in approximately 15% of AML cases (generally, in younger patients). CBF is a heterodimeric transcription factor that is composed of an alpha subunit (encoded by *RUNX1*) that binds to a consensus DNA sequence, and a beta subunit (encoded by *CBFB*) that increases the affinity of the complex for DNA. The t(8;21) is found in up to 10% of AML cases and creates an in-frame fusion of RUNX family transcription factor 1 (*RUNX1*) with RUNX1 partner transcriptional co-repressor 1 (*RUNX1T1*) (encoding CBFA2T1, or ETO). This rearrangement is enriched in the FAB M2 subgroup and composes up to 40% of this patient subgroup. This fusion protein alters the CBF transcription factor complex, allowing it to oligomerize and interact with a nuclear corepressor complex that includes nuclear co-repressor 1 (NCOR1), histone deacetylas 1 (HDAC1), and SIN3 transcription regulator family member a (SIN3A)/HDAC, resulting in reduced RUNX1 target gene expression. The RUNX1-RUNX1T1 fusion protein functions as a dominant negative inhibitor of wild-type CBF and consequently impairs hematopoietic differentiation. The fusion protein also leads to activation of TP53 response genes, which may in part explain the relative chemosensitivity of t(8;21) AML. In addition to t(8;21), *RUNX1* is involved in more than 50 other translocations, including t(16;21)(q24;q22) with myeloid translocation gene on chromosome 16 (*MGT16*), and t(3;21)(q26;q22), with the *MECOM* ("MDS1 and EVI1 complex") locus. RAS pathway mutations (affecting *KIT*, *FLT3*, *N/KRAS, CBL*) are present in more than half of t(8;21) cases and are associated with a higher risk of disease relapse. Frequent co-occurring mutations also include components of the cohesin complex (*SMC1A, SMC3, RAD21*), chromatin modifiers (*ASXL1, ASXL2, EZH2*), and epigenetic regulators (*TET2, IDH1/2*).

Chromosomal alterations involving *CBFB* include inv(16) and t(16;16)(p13;q22), which create an in-frame fusion between *CBFB* and *MYH11*, the gene encoding smooth muscle myosin heavy chain 11. AML with inv(16) or t(16;16) is often associated with the FAB M4eo phenotype. The CBFB-MYH11 gene product exerts a dominant negative effect on RUNX1 and can recruit nuclear corepressors to inhibit transcription of CBF gene targets. Mouse models with a *CBF-MYH11* knock-in mutation require additional mutations to progress to AML. Similar to t(8;21) AML, co-occurring RAS pathway mutations are common in patients with inv(16) AML, but mutations in chromatin modifiers and the cohesin complex are underrepresented in inv(16) AML. Given the clear link between CBF rearrangements, as well as the *PML-RARA* translocation, and the development of AML, the presence of any of these is sufficient for a diagnosis of AML, regardless of the percentage of myeloblasts in the bone marrow or peripheral blood.

Mixed-Lineage Leukemia Gene Rearrangements

Translocations in the *MLL1* gene (also known as *KMT2A*) are seen in up to 10% of patients with AML. *MLL1* rearrangements are common in tAML following exposure to topoisomerase II inhibitors and are enriched in cases with the FAB M5a phenotype. Wild-type MLL1 binds DNA and methylates histone H3K4 via its C-terminal SET domain and regulates expression of target genes, including homeobox (*HOX*) genes. Members of the homeobox A cluster, including *HOXA7* and *HOXA9*, play critical roles in the regulation of hematopoiesis and are normally expressed in early hematopoietic cells.

Rearranged MLL1 retains its N-terminal DNA-binding domain, whereas the C-terminal portion is replaced by a fusion partner. More than 70 unique fusion partners have been identified, including AF4, AF9, AF10, ELL, and ENL; these can interact with and recruit the histone methyltransferase enzyme "disruption of telomeric silencing 1-like" (DOT1L), which methylates H3K79 and results in the expression of *HOXA* genes implicated in leukemic transformation. Expression of the *MLL1-AF9* fusion in mice generates AML with high penetrance and short latency. The oncogenic function of these fusion proteins requires interaction with Menin, a protein encoded by *MEN1* that binds to the N-terminus of MLL1. Inhibition of the Menin/MLL interaction represents a promising new avenue for drug development in AML.

Another mechanism by which *MLL1* plays a role in leukemia is through an in-frame partial tandem duplication (*MLL1-PTD*). Mouse knock-in models with *MLL1-PTD* develop acute leukemias characterized by overexpression of *Hox* genes and an increase in H3/H4 acetylation with associated H3K4 methylation.

Rare Translocations

Less common cytogenetic abnormalities implicated in the pathogenesis of AML include the t(6;9), which fuses the DEK oncogene, encoding a DNA-binding protein involved in transcription regulation and introduction of supercoils, with Nucleoporin 214 (*NUP214* or *CAN*), which encodes a nuclear envelope pore protein that regulates nuclear/cytoplasmic transport. This rearrangement is found in approximately 1% of patients with AML and is associated with a poor prognosis. It typically occurs as a sole chromosomal rearrangement; however, there is a high frequency of concurrent mutations in *FLT3-ITD*. The fusion retains most of the open reading frame from both proteins, but the molecular consequences of the fusion protein are not well understood. Retroviral transduction of long-term HSCs with the *DEK-CAN* fusion generates leukemias after transplantation into mice.

t(3;3)(9q21;q26.2) and inv(3)(q21q26.2) are included in the "acute myeloid leukemia with recurrent cytogenetic abnormalities" category in the WHO classification. Collectively, the inv(3)/t(3;3) rearrangements are present in less than 5% of AML cases and are associated with poor survival. These rearrangements "hijack" an enhancer that normally drives *GATA2* expression, resulting in aberrant activation of *EVI1* and reduced expression of *GATA2*. EVI1 interacts directly with DNA methyltransferase 3 A (DNMT3A) and DNMT3B, which may account for the distinct DNA hypermethylation signature associated with dysregulated EVI1 expression. Patients with this translocation may have a prior MDS, and often the bone marrow morphology shows multilineage dysplasia with atypical megakaryocytes.

t(8;16)(p11;p13) is a rare translocation that occurs in de novo AML and topoisomerase II–associated tAML. The disease typically has an FAB M4 or M5 phenotype, and patients often present with extramedullary disease, coagulopathy, and hemophagocytosis. This translocation fuses two histone acetyltransferases: KAT6A (also known as MOZ or MYST3) and CREB-binding protein. The fusion protein binds to DNA, and the colocalized proteins result in upregulation of the *HOX* genes *HOXA9* and *HOXA10*, as well as their cofactor, *MEIS1*.

The t(1;22) involving one twenty two (*OTT*; or RNA-binding motif protein 15 [*RBM15*]) and megakaryocytic acute leukemia (*MAL* or *MKL1*) is a rare translocation found in infant acute megakaryocytic leukemia. MAL functions as a transcriptional coactivator of DNA-bound serum responsive factors (SRFs) and triggers histone modifications, including acetylation of H3K9. The translocation generates the *OTT-MAL* fusion protein, thus altering MAL function, resulting in SRF-directed expression of *MYL9* and *MMP-9*, which play a role in megakaryocyte development and migration, and may contribute to the phenotype of t(1;22) megakaryocytic leukemia. Mice engineered to express *OTT-MAL* have altered megakaryocyte development and dysregulated NOTCH signaling. With concurrent activating mutations in *MPL*, these mice develop acute megakaryocytic leukemia.

Amplifications and Deletions

Recurrent cytogenetic abnormalities in AML also include somatically acquired chromosome copy or segment gains, chromosomal monosomies, as well as the accumulation of karyotypic abnormalities, classified as complex karyotype, which typically has at least three or more distinct chromosomal abnormalities (see Chapter 57). Common abnormalities include those involving chromosomes 5 and 7, particularly in AML arising out of the background of MDSs, and each of which are seen in approximately 5% to 10% of patients with AML. Enhancer of zeste 2 polycomb repressive complex 2 (PRC2) subunit (EZH2) is a histone methyltransferase that may play a role in leukemogenesis via haploinsufficiency in the setting of loss of material from the long arm of chromosome 7.

Interstitial deletions on the long arm of chromosome 5 at 5q33.1 are associated with the 5q minus syndrome, a subtype of MDS, which has a low risk of progression to sAML but may occur in association with acquired mutations in *TP53* (see Chapter 61). RPS14 and miR145/146a are 5q33.1 genes that have been implicated in the pathogenesis of this syndrome. In contrast, deletions involving a more proximal region at 5q31.2 are associated with higher risk of sAML transformation. Most chromosome 5 deletions in high-risk MDS and AML are large, including most of the long arm or the entire chromosome. Many genes have been implicated in myeloid malignancies associated with these larger deletions, including *APC*, *CTNNA1*, *HSPA9*, *EGR1*, and *NPM1*.

Loss of chromosome 17p, including the *TP53* locus at 17p13, is associated with complex cytogenetics as well as abnormalities in chromosome 5 and 7. Indeed, there appears to be cooperativity between 17p alterations and deletions at chromosome 5q13 at the site of *SSBP4*, another tumor suppressor gene, which may influence the progression to leukemia. Alterations in 17p are enriched in patients with alkylator-associated tAML and sAML arising from an underlying MPN or MDS. In contrast to AML with balanced translocations, leukemias that develop in the context of 17p alterations are characterized by greater genomic instability.

Common examples of trisomy in AML include somatic acquisition of trisomy 8 and trisomy 21, seen in approximately 10% and 3% of patients, respectively. Trisomy 8, the most common chromosomal gain seen in AML, may contribute to leukemogenesis via amplification of *MYC*, which is located at chromosome 8p24 and is implicated in a number of malignancies including AML. Acquired trisomy 21, similar to AML in Down syndrome, appears to progress to AML in association with acquisition of mutations in *RUNX1* or *GATA1*. Unlike Down syndrome, acquired trisomy 21 often occurs in conjunction with other cytogenetic aberrations, in particular with complex cytogenetic rearrangements.

Recurrently Mutated Genes

A recurrent chromosomal abnormality can be detected in a majority of AML patients by either cytogenetic analysis or fluorescence in situ hybridization, using probes for common rearrangements and copy number alterations. However, approximately 45% of AML cases have normal cytogenetics, and this group has historically been categorized as having intermediate prognosis with standard chemotherapy. Molecular testing of this group, as well as patients in other cytogenetic risk groups, has identified a number of recurrent genetic alterations that play critical roles in AML pathogenesis, prognosis, and response to therapy.

On average, AML genomes contain fewer somatic mutations compared with other adult cancers (fewer than 20 mutations in protein-coding genes per case). Despite this relatively low mutation burden, more than 50 genes are recurrently mutated in AML. The large combinatorial matrix of potential co-mutation patterns results in substantial genetic diversity across the AML population (interpatient heterogeneity). This is compounded by clonal diversity (intrapatient heterogeneity), discussed in a later section. AML mutations can be categorized according to the biological pathway involved and the functional impact of the mutation (Fig. 59.2).

Cytokine Signaling

A number of mutations have been identified that result in altered signal transduction, enhancing leukemic cell proliferation and survival. These include mutations in the fms-related tyrosine kinase 3 (*FLT3*) gene, *RAS* genes, and *KIT*, among others.

Mutations in *FLT3* can occur either as an in-frame internal tandem duplication within the juxtamembrane domain of the receptor (*FLT3-ITD*), found in up to 30% of AML patients, or as a mutation in the tyrosine kinase domain (*FLT3-TKD*), the most common being a point mutation resulting in an aspartate to tyrosine substitution at codon 835, detectable in 5% to 10% of AML cases. Both mutations result in constitutive activation of the receptor. *FLT3* signaling activates the PI3K/AKT and RAS/mitogen-activated protein kinase (MAPK) signaling pathways, and mutated *FLT3-ITD* can also activate the STAT5 pathway, which induces the serine-threonine Pim kinases, and results in enhanced cell growth and survival. Murine models that combine *FLT3-ITD* with other mutations, such as *PML-RARA*, *MLL1-ENL*, or *NUP98-HOXD13*, have demonstrated cooperativity between these mutations with respect to latency and penetrance of leukemia, whereas either mutation on its own has low efficiency for disease initiation. The *FLT3-ITD* alteration in particular appears to be associated with increased rates of relapse and worsened patient outcomes; it is less clear whether *FLT3-TKD* mutations have the same impact on outcomes. The *FLT3-ITD* alteration may be present at the time of diagnosis and can be acquired or lost at relapse. Moreover, the length of the duplication, position of the mutation, the allelic fraction, and number of distinct ITDs can vary within a given sample and may have varying prognostic impact. Together, this suggests that the *FLT3-ITD* alteration may be a later event in the development of AML and illustrates the subclonal heterogeneity of AML.

CD117, encoded by *KIT*, is another example of a proto-oncogenic receptor tyrosine kinase implicated in a number of malignancies. KIT is the receptor for stem cell factor and is upregulated in most cases of AML. *KIT* mutations are most frequently seen at codons D816 or N822 in the tyrosine kinase domain or in the extracellular domain; rare ITDs have also been identified in AML. Mutations at D816 or N822 occur in the activating loop of the kinase domain, interrupt autoinhibitory feedback and result in constitutive activation. Mutations in *KIT* occur in less than 10% of patients and are enriched in patients with AML harboring CBF alterations. In mouse models, *KIT* mutations cooperate with *RUNX1-RUNX1T1* and *CBFB-MYH11* to induce AML. *KIT* mutations in patients with CBF AML, particularly with *RUNX1-RUNX1T1*, are associated with increased rates of relapse.

Mutations in the *RAS* proto-oncogenes, most commonly *NRAS* and *KRAS*, are also recurrent events in AML, identified in approximately 10% and 5% of patients, respectively. *RAS* family members are small membrane-associated guanosine triphosphatase signaling proteins that activate the MAPK/extracellular signal-related kinase (ERK) and PI3K

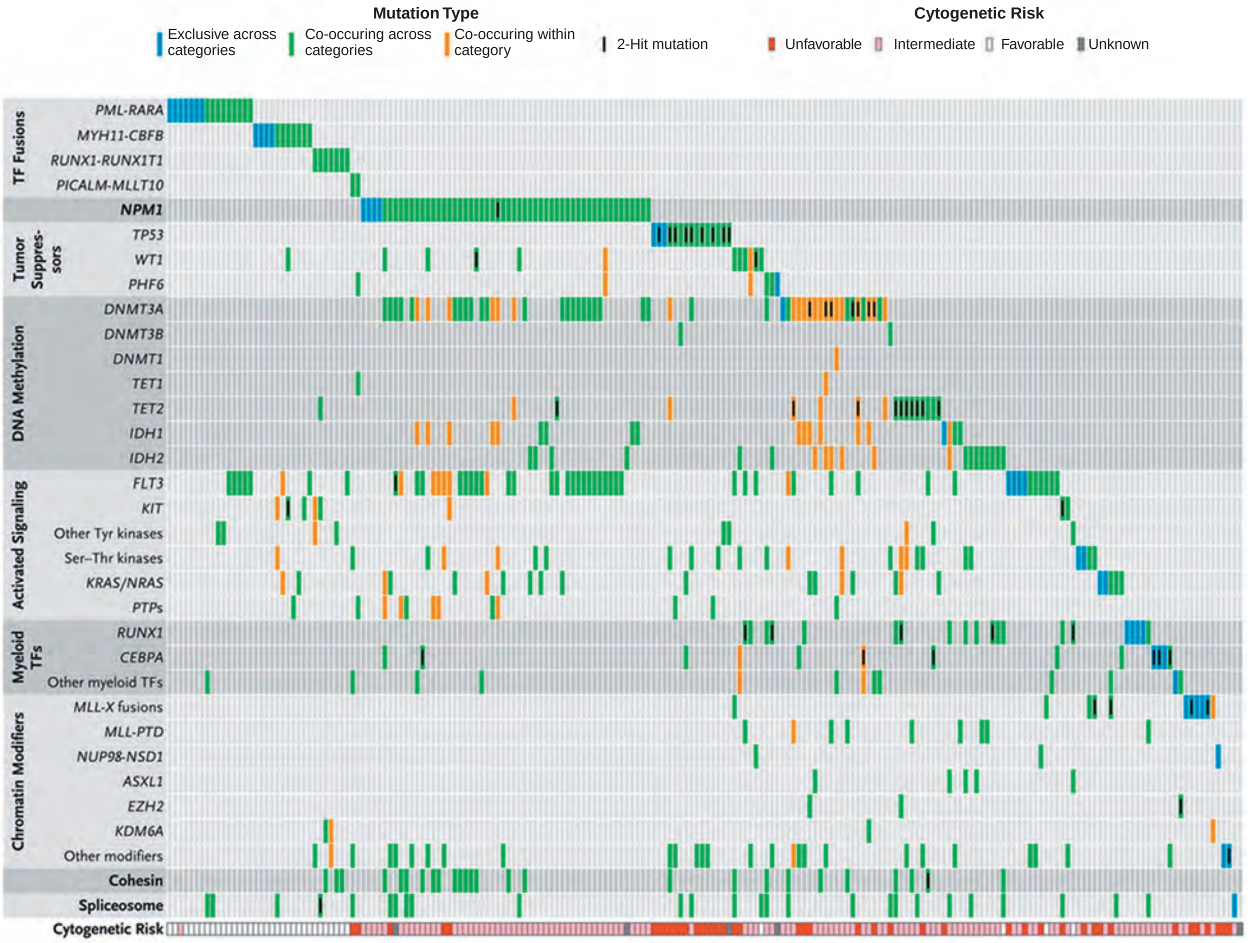

Figure 59.2 CO-OCCURENCE AND MUTUAL EXCLUSIVITY OF SOMATIC MUTATIONS AMONG PATIENTS WITH ACUTE MYELOID LEUKEMIA. A combination of exome, genome, and transcriptome sequencing in 200 patients with de novo acute myeloid leukemia identified a number of mutations which co-occur or are mutually exclusive according to nine categories of biological function: transcription factor fusions, cytokine signaling, transcription factor mutations, tumor suppressor genes, regulators of DNA methylation, polycomb complex, spliceosome, cohesin complex, and nucleophosmin. *TF*, Transcription factor. *(From Ley TJ, Miller C, Ding L, et al. The cancer genome atlas research network. genomic and epigenomic landscapes of adult de novo acute myeloid leukemia. N Engl J Med. 2013;368:2059. Copyright © 2013 Massachusetts Medical Society. Reprinted with permission.)*

pathways, leading to cell growth and survival. The most common mutations in *NRAS* occur at codons 12 and 13 and in *KRAS* at codon 12. These mutations result in a guanosine triphosphate–bound state of the RAS protein, leading to constitutive activation. In murine models, expression of mutant *NRAS* or *KRAS* results in a spectrum of myeloid disease, with variable features of acute leukemia, myeloproliferation, or MDS/MPN overlap. Consistent with this finding, *RAS* is frequently mutated in patients with MPNs and chronic myelomonocytic leukemia (CMML), as well as MDS transforming to AML.

Transcription Factors

In addition to their frequent involvement in chromosomal rearrangements, transcription factors are also recurrently mutated in AML.

RUNX1 mutations occur in approximately 5% to 15% of all patients with AML but are slightly more common in patients with intermediate-risk AML, particularly in association with trisomy 8 or 13. Approximately 80% of *RUNX1* mutations are located in a DNA-binding domain that is homologous to the *Drosophila* runt protein. C-terminal domains of RUNX1 are involved in nuclear matrix localization and recruitment of transcriptional transactivating and repressing factors. Overexpression of mutant *RUNX1* in mice causes AML with dysplastic changes and, in combination with *EVI1* mutations, results in a more rapid AML phenotype.

CEBPA is mutated in almost 10% of AML cases; these mutations are enriched in younger patients and patients with otherwise normal cytogenetics. *CEBPA* encodes the CCAAT/enhancer binding protein-α, a basic leucine zipper transcription factor that is essential for neutrophil development. Mutations may affect the N-terminus (usually frameshift, resulting in preferential expression of a shorter isoform with dominant negative activity) or C-terminus (usually in-frame but also resulting in loss of function). In the majority of CEBPA-mutated AML cases, both alleles are mutated (biallelic, or CEBPA-double mutant). Favorable prognosis is restricted to cases of AML with a normal karyotype and with biallelic *CEBPA* mutations, which is associated with a distinct gene expression signature. When biallelic mutations were engineered in a mouse model, hematopoietic differentiation was impaired and AML developed after a long latency, implying that cooperating mutations were necessary.

Tumor Suppressor Genes

Mutations in tumor suppressor genes facilitate the development of AML. Common examples include the canonical tumor suppressors *TP53* and Wilms tumor 1 (*WT1*).

Mutations in *TP53* are found in fewer than 10% of AML cases overall but are enriched in patients with tAML and patients with a complex karyotype, of whom two-thirds harbor a mutation in *TP53*.

TP53 is a transcription factor that regulates multiple signaling pathways in response to cellular stress, with an output that may culminate in cell cycle arrest, senescence, or apoptosis. Mutations occur throughout the *TP53* gene, usually resulting in loss of function; more than half of cases have concurrent loss of heterozygosity at 17p.

Mutations in *WT1* occur in fewer than 10% of patients with AML, but wild-type *WT1* is frequently overexpressed—such that it has been explored as a way to monitor disease clearance after therapy. WT1 is a zinc finger transcription factor that is required for normal development. Mutations may occur throughout the gene and generally predict loss of function. One mechanism by which loss of WT1 may influence tumorigenesis appears to relate to DNA methylation; mutations in *WT1* result in a DNA methylation pattern similar to that in *TET2* mutated AML, apparently due to a lost interaction between WT1 and wild-type TET2. In addition to loss of function, *WT1* may also have oncogenic effects. In a *RUNX1-RUNX1T1* mouse model of AML, forced overexpression of *WT1* resulted in more rapid progression to AML.

Regulators of Deoxyribonucleic Acid Methylation

Methylation of cytosine residues is an important epigenetic mark that contributes to regulation of gene expression. Genes encoding factors directly or indirectly involved in DNA methylation or demethylation, including *TET2*, *DNMT3A*, and isocitrate dehydrogenase-1 (*IDH1*) or *IDH2*, are recurrently mutated in AML.

DNMT3A encodes a de novo methyltransferase that catalyzes cytosine methylation at CpG dinucleotides. *DNMT3A* mutations are seen in approximately 20% of patients with de novo AML, but nearly 30% of patients with a normal karyotype. Nearly half of all *DNMT3A* mutations are heterozygous missense substitutions at codon R882 (most frequently R882H); the remainder are deletions, frameshifts, and missense substitutions throughout the open reading frame. The unifying mechanism of action appears to be loss of function, through haploinsufficiency or dominant negative activity, resulting in reduced methyltransferase activity. The prognostic significance of *DNMT3A* mutations remains controversial, although most studies have demonstrated an adverse impact on overall and leukemia-free survival.

Mutations in ten-eleven-translocation 2 (*TET2*) have been identified in 10% to 30% of patients with AML and are enriched in patients with prior MDS or MPN. There are three members of the TET gene family, but *TET2* is the most frequently mutated in AML; *TET1* is also rearranged in t(10;11)(p12;q23). TET2 converts 5-methylcytosine to 5-hydroxymethylcytosine, an initial step in the reversion to unmethylated cytosine. Hydroxylation of methylated CpG-rich regions by TET2 activates gene programs important for cellular differentiation, including the homeobox A cluster. By contrast, *TET2* loss-of-function mutations are associated with impaired differentiation. Research in this field has not yet reconciled the opposing biochemical effects of mutant DNMT3A and TET2 (loss and gain of cytosine methylation, respectively) with their shared role in promoting myeloid malignancies. Mice harboring a *TET2*-null allele display enhanced stem cell self-renewal and develop myeloid malignancies with underlying features consistent with CMML or MDS. *TET2* mutations do not have a consistent impact on AML prognosis in multivariate analysis.

Although IDH1 and IDH2 do not directly modify cytosine residues, they impact these epigenetic marks indirectly via their metabolic activity. These enzymes normally decarboxylate isocitrate to form α-ketoglutarate via the reduced form of NADPH, a key reaction in the Krebs cycle. IDH1 is primarily cytosolic, whereas IDH2 localizes to mitochondria. *IDH1/2* mutations are found in approximately 5% to 10% and 15% to 20% of patients with AML, respectively. Mutational hotspots include codon R132 in *IDH1* and codons R140 or R172 in *IDH2*. The mutations are enriched in cases with a normal karyotype and frequently co-occur with *NPM1* mutations. Mutant IDH1/2 catalyzes the conversion of α-ketoglutarate to the oncometabolite 2-hydroxyglutarate (2-HG), which suppresses TET2 activity via competitive inhibition at the α-ketoglutarate binding site. Through this mechanism, excess 2-HG results in a DNA hypermethylation pattern similar to that observed in *TET2*-mutated AML. This interpretation is consistent with the observation that *TET2* mutations are mutually exclusive with *IDH1/2* mutations in AML. Importantly, 2-HG also interferes with other α-ketoglutarate–dependent enzymes, including members of the Jumonji-C domain–containing histone demethylases. Mouse models with *IDH1* mutations in hematopoietic cells develop a disease phenotypically similar to human MDS.

Polycomb-Associated Proteins

The polycomb group proteins play a major role in transcriptional repression of target genes important during development and for maintenance of cell identity in adult organisms. There are two major PRCs in humans: PRC1 and PRC2. EZH2 is the catalytic component of PRC2 and is a target of recurrent loss-of-function mutations in AML.

The additional sex combs-like family includes three members in humans: ASXL1, ASXL2, and ASXL3. These proteins are highly homologous, but only *ASXL1* and *ASXL2* are recurrently mutated in AML. ASXL1 collaborates with the PRC2 complex to repress target genes, including the posterior *HOXA* cluster. ASXL1 also interacts with BAP1 via an N-terminal domain to form a complex that antagonizes PRC1 function. *ASXL1* mutations truncate the protein just upstream of a C-terminal plant homeodomain (PHD) domain that binds methylated H3K4. These mutations were initially interpreted as loss of function, but more recent studies have shown that a truncated protein can be detected by quantitative mass spectrometry and appears to confer gain-of-function activity in transgenic mice. *ASXL1* mutations are more common in older patients with AML and sAML derived from antecedent MDS and are associated with adverse prognosis.

ASXL2 mutations are detectable in more than 20% of patients with t(8;21) AML but are rare in other subtypes of AML. Conversely, *ASXL1* is mutated at a lower frequency in t(8;21) AML and is mutually exclusive with *ASXL2*, implying that these mutations have redundant function or are not tolerated when present in the same cell.

The nuclear receptor binding SET domain protein 1 (*NSD1*) gene encodes a histone methyltransferase, which similarly has a role in normal development; germline mutations result in Sotos syndrome, which is associated with a number of childhood cancers. NSD1 methylates H3K36 and is associated with transcriptional activation. *NSD1* is involved as a fusion partner in the recurrent translocation t(5;11)(q35;p15.5) with *NUP98*, seen in approximately 15% of pediatric AML, but less than 5% of adult AML, and is associated with a poor response to therapy. This fusion protein binds regulatory elements of the polycomb complex and results in *HOX* gene activation.

Spliceosome Complex

The spliceosome is a mega-dalton complex consisting of five small nuclear ribonucleoproteins (snRNPs) and more than 100 auxiliary proteins. The spliceosome functions in a dynamic fashion to define 5′ and 3′ splice junctions, remove intervening introns, and religate exons, resulting in a diversity of mRNA isoforms from each coding gene. Recurrent mutations have been identified in hematologic malignancies in a number of the core splicing components, most often affecting *SF3B1*, *U2AF1*, *SRSF2*, or *ZRSR2*. These mutations are typically heterozygous and tend not to co-occur within patients, suggesting that a second mutation in the pathway confers no additional selective advantage or is not tolerated by hematopoietic cells. Alternative splicing was noted in AML samples prior to the discovery of spliceosome mutations, but the cause and biological consequences were not understood. RNA-seq analysis has demonstrated that *ZRSR2* (X-linked) mutations impair minor (U12) intron excision whereas *SRSF2*, *U2AF1*, and *SF3B1* mutations are "change of function," leading to distinct changes in splice-site preference. Nevertheless, a direct causal connection between alternative splicing and AML pathogenesis has not been established.

Collectively, splicing factor mutations are detectable in approximately 15% of patients with AML. These mutations are frequently

CONTROVERSIES AT THE BOUNDARY BETWEEN MYELODYSPLASTIC SYNDROMES AND ACUTE MYELOID LEUKEMIA

Patients with myelodysplastic syndromes (MDSs) can have a bone marrow myeloblast count up to 19%, but a myeloblast count of 20% or higher defines acute myeloid leukemia (AML). This threshold is useful clinically but does not have a strong biological basis. Based on results from whole-genome sequencing, the majority (>80%) of bone marrow cells are clonally derived in MDSs, even in patients with a normal myeloblast count; this proportion of clonal cells does not significantly increase when patients progress to secondary AML (sAML). This disconnect between morphology and genetics has motivated the search for molecular features that might provide a more robust classifier to define subsets of myeloid malignancies with shared biological and clinical features, particularly at the boundary between MDSs and AML.

Splicing factor mutations have unique biological properties and are common in both MDS (>50% of patients) and AML (~15% of patients). An analysis of a large cohort of MDS and AML cases found that the presence of splicing factor mutations defined a subset of patients with similar molecular (gene expression and DNA methylation) and clinical features. The myeloblast count in splicing factor mutated cases varied widely around the 20% threshold but was lower on average (~30%) compared with AML cases that lacked splicing factor mutations. In another study, the presence of splicing factor mutations (and 4 other MDS-associated mutations) in an otherwise unselected group of AML patients identified a subset with clinical features that closely resembled an independent cohort of patients with rigorously defined MDS-derived sAML. Collectively, these associations suggest that the presence of splicing factor mutations may define a unique clinicopathologic subgroup of MDS/AML cases, independent of myeloblast count.

Erythroleukemia is another diagnostically challenging entity that straddles the boundary between MDS and AML. The original FAB erythroleukemia subtype (M6) was later divided into a group with both elevated erythroid precursors and myeloblasts (M6a) and a group with only increased proerythroblasts (M6b). The World Health Organization (WHO) essentially retained this classification through the 2008 revision, with minor differences in the way blasts were enumerated. This system left open the possibility of classifying cases either as refractory anemia with excess blasts (MDS) or AML (erythroid/myeloid type) based on subtle subjective differences in the percentage of erythroid precursors. The 2016 WHO classification retained only the pure acute erythroleukemia subtype of AML (AEL), requiring at least 80% erythroid precursors of which 30% must be erythroblasts with no excess myeloblasts. The remaining cases (the erythroid/myeloid subtype in the prior classification) were reclassified as MDS (generally, MDS-EB). This led to reclassification of nearly 50% of these cases from AML to MDS.

A comprehensive genomic analysis of adult AEL cases annotated by both the 2008 and 2016 WHO classifications identified four distinct biological groups within this disease subgroup: TP53 mutated, NPM1 mutated, DDX41 mutated, and KMT2A mutated/rearranged. These four groups had distinct clinical outcomes but were randomly distributed across WHO 2016 categories of AML. These data again suggest that classification systems based on molecular features rather than morphology alone may provide more robust prognostic information, particularly in this subset of malignancies at the interface between MDS and AML.

associated with specific subtypes of MDS and MPNs; consequently, AML with splicing factor mutations often have a history of these antecedent disorders (see box on Controversies at the Boundary between MDS and AML). *SF3B1* is the most common mutation in the splicing complex; mutations in this gene are tightly associated with the MDS subtype of single lineage dysplasia with ring sideroblasts. *SRSF2* mutations are common in CMML and are retained when these patients progress to sAML.

Cohesin Complex

The cohesin complex is essential for proper alignment of sister chromatids throughout replication and for organization of topological domains of the genome that are required for coordinated gene expression. The cohesin core complex is comprised of the structural maintenance of chromosomes (SMC) proteins SMC1, SMC3, RAD21 (SCC1), and stromalin antigens STAG1 or STAG2. These core proteins form a ring structure, with a hinge formed by SMC1 and SMC3, and a closed loop formed through the binding of RAD21 with STAG1 or STAG2. Recurrent mutations in the genes for this core complex have been identified in approximately 15% of AML cases, with *STAG2* the most frequently affected. STAG2 loss leads to a reduction in chromatin accessibility, associated with aberrant gene expression and differentiation programs that are not rescued by STAG1. Perturbation of this mechanism may be more relevant to the pathogenesis of AML than sister chromatid cohesion because cohesin mutations have not been associated with increased risk of aneuploidy in AML.

Nucleophosmin

NPM1 is a molecular chaperone with multiple putative functions, including ribosomal protein assembly, the prevention of nucleolar protein aggregation, and regulation of the tumor suppressors TP53 and CDKN2A. *NPM1* mutations are seen in approximately one third of patients with AML and in more than half of patients with normal karyotypes. They occur as insertions in exon 12, most frequently of the four base pairs TCTG (type A), causing a frameshift mutation with an added nuclear export signal motif at the carboxy-terminus and resulting in abnormal cytoplasmic localization (NPM1c). Less common mutations with similar effect include alternate insertions of CATG (type B) or CCTG (type D), among others; there does not appear to be a clinical impact according to the type of mutation. NPM1c mutations without FLT3-ITD constitute a relatively favorable genotype in normal karyotype AML.

The molecular mechanism by which NPM1c contributes to AML remains controversial, but cytoplasmic localization appears essential for maintenance of aberrant *HOXA/B* and *MEIS1* expression and persistence of human AML in xenograft models. NPM1-mutant AML may also be dependent on the MLL1-Menin axis for its survival. Genetically engineered mice harboring the *NPM1* type A mutation have increased megakaryocytes but do not develop AML spontaneously. Consistent with this, mutations in *NPM1* are thought to represent early events in the development of AML and are frequently associated with cooperating mutations in *DNMT3A* and/or *FLT3*. Rarely, *NPM1* is involved in chromosomal translocations, including t(2;5)(p23;q35) with *ALK*, and t(5;17)(q35;q21) with *RARA*, the latter resulting in an uncommon variant of APL.

Epigenetic Alterations in Acute Myeloid Leukemia

AML is characterized by aberrant transcription. As discussed earlier, this is driven in part by somatic mutations in key regulators of DNA methylation, chromatin function, and transcription. In addition, mutations in noncoding regions of the genome can have major effects on gene expression programs that are important for AML pathogenesis.

Methylation of cytosine on DNA at CpG sites, which are enriched at gene promoter regions, is a key regulator of gene expression. The AML genome has increased methylation when compared with normal tissues, and certain genetic subtypes of AML, such as AML with *RUNX1-RUNX1T1* or *PML-RARA* rearrangements, have distinct gene methylation patterns. As discussed earlier, recurrent missense mutations in the de novo DNA methyltransferase, DNMT3A, through haploinsufficiency or dominant negative loss of function lead to focal regions of reduced DNA methylation. TET2 inhibition, either through an acquired loss-of-function mutation or via 2-HG produced preferentially in the setting of *IDH1/2* mutations, results in aberrant hydroxymethylation, particularly at key *HOX* sites, which leads to myeloid expansion and a dysplastic phenotype in mouse models. Causal links between mutations in these regulatory enzymes, cytosine modifications, altered gene expression, and leukemogenesis remain elusive, but it is unlikely that global changes in methylation are sufficient to explain the leukemic phenotype.

DNA methylation and histone modification are often coordinately regulated. For example, EVI1 has DNA methylation activity but also associates with histone deacetylases and methyltransferases. As discussed earlier, PRC2 catalyzes the methylation of histone H3K27, resulting in gene silencing. PRC2 is composed of a noncatalytic subunit, as well as a SET domain with methyltransferase activity via EZH1 or EZH2. Mutations in *EZH2* found in myeloid malignancies are predicted to be loss of function. In mouse models, EZH2 appears to have either tumor suppressor or oncogene characteristics, depending on the timing of the mutation in relation to the stage of disease, and has a role in inhibiting hematopoietic cell differentiation. Similarly, ASXL1 interacts with PRC2, resulting in trimethylation at H3K27; loss-of-function mutations may promote leukemia due to relative activation of PRC2-specific genes. Finally, MLL1 rearrangements bring a diversity of fusion partners to targets normally regulated by MLL1; this interaction depends on the interaction between MLL1 and Menin. Many of these fusion partners interact with DOT1L, a histone H3K79 methyltransferase, which then methylates critical MLL1-dependent regulatory genes, such as *HOXA9*.

In addition to mutations in these *trans*-acting factors, mutations in regulatory regions of the genome can have *cis*-acting effects on gene expression. One example is a super-enhancer downstream of Myc that is required for maintenance of MLL1-AF9 leukemia in mice and is contained within a region of recurrent amplification in human AML. Another example is the *GATA2* enhancer "hijacking" in the case of inv(3) and t(3;3) that was previously discussed.

BIOLOGY OF ACUTE MYELOID LEUKEMIA

The Leukemic Niche

AML arises in hematopoietic cells residing in a bone marrow microenvironment known as the *niche*, where interactions with nonmalignant cells play an important role in leukemia initiation, progression, and response to therapy. Niche cells include endothelial cells, fibroblasts, adipocytes, osteoblasts, osteocytes, mesenchymal stem cells, neurons, and other cell types. There appears to be a reciprocal relationship whereby niche cells can provide signals that promote the development of hematologic malignancies and, conversely, emerging malignant clones can remodel and reprogram niche cells to favor disease progression. Many of the mechanisms that have been implicated derive from observations in animal models and have not been validated in patients. The role of the niche in normal and malignant hematopoiesis is discussed in detail elsewhere (see Chapter 14).

A hallmark of the AML niche is the production of an "inflamed" or proinflammatory microenvironment. This is characterized by aberrant expression of cytokines (e.g., interleukin [IL]-1b, tumor necrosis factor [TNF], IL-6), chemokines (CCL3, CXCL12), and alarmins. These signals are generally growth suppressive for normal hematopoiesis. Leukemic cells are able to evade this hostile microenvironment through poorly understood mechanisms to gain a relative growth advantage. Interactions with niche cells induce prosurvival factors in AML cells (e.g., BCL2, BCLXL, MCL1) through direct cell contact and soluble mediators (e.g., growth arrest specific 6 [GAS6]). Finally, the niche elaborates factors that create an immune-suppressive microenvironment (e.g., indoleamine 2,3-dioxygenase [IDO], arginase) that may facilitate immune evasion by AML cells.

Although it is clear that interactions between leukemic precursors and the bone marrow niche are necessary for leukemogenesis, it is less clear which interaction is most amenable to therapeutic intervention. Early candidates include targeting the interactions between leukemic blasts and existing immune-mediators in the marrow such as T-cell or NK-cell populations, which may be amenable to immunotherapy strategies. Similarly, drug delivery to the niche may concentrate an antileukemic effect; liposomal packaging of chemotherapeutics is based, in part, on this concept. Other strategies have sought to evaluate whether leukemic cells may be more sensitive to chemotherapy if mobilized out of the niche, including inhibiting CXCR4 or mobilizing leukemic blasts with growth factors in combination with chemotherapy.

Clonal Hierarchy of Acute Myeloid Leukemia

The recognition that some mutations may be lost or acquired at relapse (e.g., *FLT3-ITD*), whereas others are present at diagnosis and remain stable (e.g., *NPM1*, *PML-RARA*, and *CBF* rearrangements) suggests that distinct clonal populations can coexist in an individual case of AML. Sequencing of serially obtained samples using bulk and single cell approaches has revealed a clonal hierarchy in AML, beginning with a founding clone that represents the initial population that becomes dominant in the bone marrow. The founding clone spawns subclones that retain founding clone mutations but gain additional mutations that confer a fitness advantage. Initial studies using bulk sequencing approaches suggested that AML evolved largely along a linear trajectory. More recent studies using single cell approaches suggest that more complex branching hierarchies are possible.

The clonal architecture of AML evolves over time as a feature of the natural history of the disease or in response to selective pressure imposed by therapy. Analysis of AML cases that entered morphologic remission after cytotoxic chemotherapy and later relapse revealed that the dominant clone at relapse retains founding clone mutations. These observations raise the hypothesis that therapies directed at eradicating drivers of the founding clone may be more effective than therapies targeting subclones.

Leukemia Stem Cells

Normal human HSCs are characterized by their capacity for self-renewal and multilineage differentiation, properties that can only be assessed in vivo using functional assays such as xenotransplantation into immune-deficient mouse models. The pioneering studies of John Dick and colleagues demonstrated that a similar cellular hierarchy exists in AML, in which rare cells with an immunophenotype similar to normal stem/progenitor cells are enriched for the capacity to initiate leukemia in xenotransplantation models. The stem cell model of AML and other hematologic malignancies is discussed in detail elsewhere (see Chapter 13).

Work from many laboratories has led to the identification of several cell surface antigens that are preferentially expressed on leukemia stem cells (LSCs) compared with normal HSCs, including CD123, CD99, TIM3, and others. No single marker identified to date is sufficient to perfectly discriminate HSCs from LSCs. Combinatorial approaches may improve the ability to identify and selectively target LSCs. LSCs have several biological properties that cause them to resist chemotherapy and create an important reservoir for disease relapse, including expression of drug efflux pumps, resistance to apoptosis, and cell cycle quiescence.

More recently, a "pre-LSC" population has been described. These are cells with an HSC immunophenotype that can be recovered from the bone marrow of patients with AML and are capable of engraftment and multilineage differentiation in vivo in immunodeficient mice. Single cell genotyping has revealed that pre-LSCs often harbor the same class of mutations detected in individuals with CH (e.g., *DNMT3A*, *TET2*) but lack the full complement of mutations found in the bulk AML sample, suggesting that they are ancestral. The contribution of these preleukemic stem cells to chemotherapy resistance and relapse remains to be determined.

Extramedullary Acute Myeloid Leukemia

Typically, AML is characterized by involvement of the bone marrow and peripheral blood, but it may also infiltrate into other tissues, termed extramedullary AML. This may be concurrent with marrow or blood involvement or may be isolated, such as in the case of myeloid sarcoma or chloroma. The pathobiology that results in extramedullary manifestations of AML remains poorly understood. Common sites of extramedullary disease include in the skin, termed leukemia cutis, as well as in soft tissues or the central nervous system (CNS). Certain clinicomorphologic features are associated with extramedullary AML, including monocytic differentiation (notable for mucosal infiltration) and hyperleukocytosis.

Comprehensive or reliable molecular and cytogenetic characterization of extramedullary AML is limited in scope and generally retrospective in nature; however, prior reports suggest an increased frequency of extramedullary disease in CBF-AML—particularly t(8;21)—as well as APL. Other cytogenetic and molecular alterations that appear to be enriched in myeloid sarcoma include trisomy 8, and mutations in *NPM1* or *FLT3-ITD*. There may also be interactions with immune surveillance that lend to extramedullary disease involvement, particularly in disease relapse, including following allogeneic hematopoietic cell transplantation. Some studies have identified T-cell exhaustion as a possible mechanism of extramedullary relapse, with upregulated immune checkpoint expression on biopsy of leukemic infiltrates.

Biology of Relapsed/Refractory Acute Myeloid Leukemia

Treatment failure is the most important cause of mortality in AML. This includes cases that relapse after achieving remission and cases that are refractory to initial therapy. Chemotherapy, targeted therapy, and immunotherapy impose different therapeutic bottlenecks and are associated with different mechanisms of resistance.

Allogeneic stem cell transplantation exerts its principal antileukemic effect by providing cell-mediated immunity against AML cells ("graft-versus-leukemia"). Therefore it is not surprising that the major mechanisms that have been identified in AML patients who relapse after transplant involve adaptations that allow AML cells to evade immune attack. These include loss of mismatched HLA alleles by somatic recombination after haploidentical transplant and downregulation of class II antigens after matched allogeneic transplant.

Resistance to conventional cytotoxic chemotherapy has been associated with mutations in sensors and effectors of the DNA damage response (e.g., TP53) and a metabolic state that is not sufficiently "primed" towards apoptosis in response to DNA damage (e.g. BCL-2 dependence). Using peptides to probe the status of the mitochondrial apoptotic pathway, retrospective studies have demonstrated that cells from AML patients who were refractory to remission induction had a lower level of priming for apoptosis. Finally, cytotoxic chemotherapy is often successful in removing the bulk AML population but leaves behind a residual population capable of seeding relapse (see Leukemia Stem Cells, earlier) with intrinsic properties (including quiescence and expression of drug efflux pumps) that render cells less sensitive to chemotherapy.

Small molecules that target key driver mutations (e.g., FLT3, IDH1/2) have emerged as important therapeutic tools in AML. Predictably, escape from the selective pressure induced by these agents is frequently associated with mutations in the drug target or pathway. With IDH inhibitors, resistance may be conferred by a second site mutation in the drug target (in *cis* or in *trans*) or by emergence of a subclone harboring a mutation in the other isoform (e.g., IDH1 mutations emerging after treatment of IDH2-mutant AML with an IDH2 inhibitor). Resistance to FLT3 inhibitors may be caused by mutations in the ATP-binding pocket that affects drug binding or by nonmutational processes affecting parallel survival pathways. Finally, acquisition of RAS pathway mutations appears to be a relatively common nonspecific escape mechanism that has been associated with resistance to multiple targeted agents.

FUTURE DIRECTIONS

AML comprises a heterogeneous spectrum of disease, which shares a common myeloid phenotype and is characterized by accumulation of abnormal leukemic myeloblasts. The development of AML occurs through the acquisition of somatic mutations, resulting in clonal expansion and genetic evolution of this disease. As our understanding of the genetic underpinnings has grown, it is clear that there are various pathways to the development of AML (Fig. 59.3). Moreover, some mutations appear to be earlier, founding events, whereas other mutations are typically acquired during disease progression. The further identification of the sequence of mutation acquisition, as well as co-occurring and mutually exclusive genetic pathways, will help to better distinguish different subsets of this disease.

A broader understanding of the mutational landscape of AML has provided a basis for development and testing of novel targeted therapies and monitoring of disease. The role of residual disease monitoring may occur through cytogenetic, flow cytometric, and now also molecular assessment. The incorporation of these residual disease markers into clinical practice remains under intense investigation; similar to patients with chronic myeloid leukemia, it may eventually inform treatment duration and maintenance therapies.

CHAPTER 60

CLINICAL MANIFESTATIONS AND TREATMENT OF ACUTE MYELOID LEUKEMIA

Harry P. Erba

Acute myeloid leukemia (AML) is a clonal neoplasm of hematopoietic stem or myeloid progenitor cells characterized by block in differentiation and unregulated proliferation of hematopoietic cells in the marrow, blood, and extramedullary sites. The major consequence of this malignant transformation is bone marrow failure with mortality predominantly due to infectious and hemorrhagic complications of the disease. Knowledge of the pathobiology of AML as it relates to origin of blast cells, their biologic behavior, sensitivity to therapeutic interventions, and their interactions with and interdependence on the microenvironment continues to increase (Chapters 13 and 59). Extensive application of whole-genome sequencing has identified numerous gene mutations and molecular footprints in AML, highlighting the heterogeneity of AML, devising better tools for prognosis, and identifying abnormal cellular and signaling pathways as central to the development of the leukemic phenotype against which novel targeted therapies are increasingly being developed (Chapter 59).

Recent progress in basic and clinical research has altered the decades-old management paradigm. Incorporation of novel drugs into existing chemotherapy backbones, separate approaches to core-binding factor (CBF), *FLT3*-mutated and *IDH*- mutated AML, successful treatment of most patients with acute promyelocytic leukemias (APL) without cytotoxic chemotherapy, and more effective therapy for older, frail patients with AML are highlights of the current treatment algorithms. New drugs allow old concepts such as maintenance therapy to be revisited. Measurements of minimal residual disease (MRD) have emerged as powerful prognostic markers and may be useful to guide therapeutic options. A major challenge for the future lies in the ability to effectively incorporate and utilize the vast amount of generated data in the most effective way to extend to patients with AML the benefit of this basic and translational research.

EPIDEMIOLOGY

In 2019, 21,450 estimated new cases of patients with AML were diagnosed in the United States and an estimated 10,920 patients with AML died from it. The age-adjusted incidence rate of AML is 3.6/100,000 population. However, with a median age at diagnosis of 68 years, incidence rates are as high as greater than 15/100,000 in the older age group, and about 70% of all diagnoses of AML are in patients over 55 years of age. The 5-year survival rate declines with advancing age for many reasons, including declining overall health, higher incidence of poor risk cytogenetic and mutational features, adverse socioeconomic factors such as absence of adequate caregiver support, and inability to tolerate treatments associated with lower risk of relapse, such as high-dose cytarabine consolidation therapy and allogeneic hematopoietic stem cell transplantation (allo HSCT). AML is slightly more frequent in men than women (lifetime risk of acquiring AML: 1 in 227 [male] to 1 in 278 [female]). Based on Surveillance, Epidemiology, and End Results (SEER) data from 2005 to 2009, small differences in frequency also exist by race; AML is more common in whites than other ethnic groups. African Americans have a worse overall survival (OS) than Whites in National Cancer Institute-sponsored cooperative group clinical trials. According to one study of 27,525 patients with AML, based on the SEER database from 1999 to 2008, African Americans and Hispanics had a 12% and 6% increased hazard of death, respectively. This unfavorable hazard rate pertained despite the higher rate in these two ethnic groups of AML with translocations t(8;21) and t(15;17), both associated with a better outcome.

AML has been associated with exposure to benzene, cigarette smoke, chemotherapy, ionizing radiation, and immunosuppressive agents. AML may develop following immunosuppressive therapy for aplastic anemia (Chapters 31 and 32) or evolve from an antecedent myeloid neoplasm (myelodysplastic syndrome [MDS]; Chapter 73), myeloproliferative neoplasms, and myelodysplastic/myeloproliferative neoplasms) (Chapters 70–73). AML may also be due to an inherited germline mutation and indicate a familial cancer syndrome (Chapter 30). AML patients with two or more first- or second-degree relatives with hematologic neoplasms, prolonged cytopenias, or bleeding disorders should be screened for germline mutations which predispose to myeloid neoplasms. AML patients may have physical stigmata associated with known clinical syndromes. For example, mucosal leukoplakia, reticular hyperpigmentation, nail dystrophy, and interstitial lung disease are all suggestive of short telomere syndromes, such as dyskeratosis congenita (Chapter 30). The European Leukemia Network (ELN) 2017 guidelines suggests testing for germline mutations of *RUNX1*, *CEBPA*, *DDX41*, *TERC*, *TERT*, *TP53*, and others, when appropriate. Some of these variants will be detected by NGS panels at the time of AML diagnosis. The patient should be referred for genetic counseling, especially if present at 50% variant allelic frequency at the time of remission. Identification of other affected family members is an important consideration for selection of family members as hematopoietic stem cell donors.

CLINICAL AND LABORATORY MANIFESTATIONS

The initial presentation of patients with AML may vary from the discovery of relatively asymptomatic cytopenias at the time of routine health maintenance exams to life-threatening complications, requiring urgent intervention. Signs and symptoms of AML mostly reflect the effect of cytopenias. Patients typically present with a short history (few weeks to 3 months) of constitutional symptoms (fatigue, lack of energy, malaise, fever, profuse sweats), infections, and/or manifestations of bleeding (e.g., gingival bleeding, bruising, epistaxis, menorrhagia). Fevers should always be presumed to be secondary to infections even in the absence of an identifiable focus and lead to rapid institution of antibiotic therapy. “Tumor fever” due to AML does occur but remains a diagnosis of exclusion. Extramedullary leukemic infiltrates in the gingiva, skin, lymph nodes, or other organs occur occasionally, and are more often associated with monocytic differentiation. Signs and symptoms referable to central nervous system (CNS) involvement (cranial neuropathies and other focal neurologic abnormalities, encephalopathy, seizures) are rare, except for AML with monocytic/monoblastic differentiation or in any AML with considerable leukocytosis (>100,000/μL). The life-threatening complications requiring emergent intervention include clinical leukostasis, spontaneous tumor lysis syndrome (TLS) with renal failure, and DIC with hemorrhagic or occasionally thrombotic complications (see Initial Therapy).

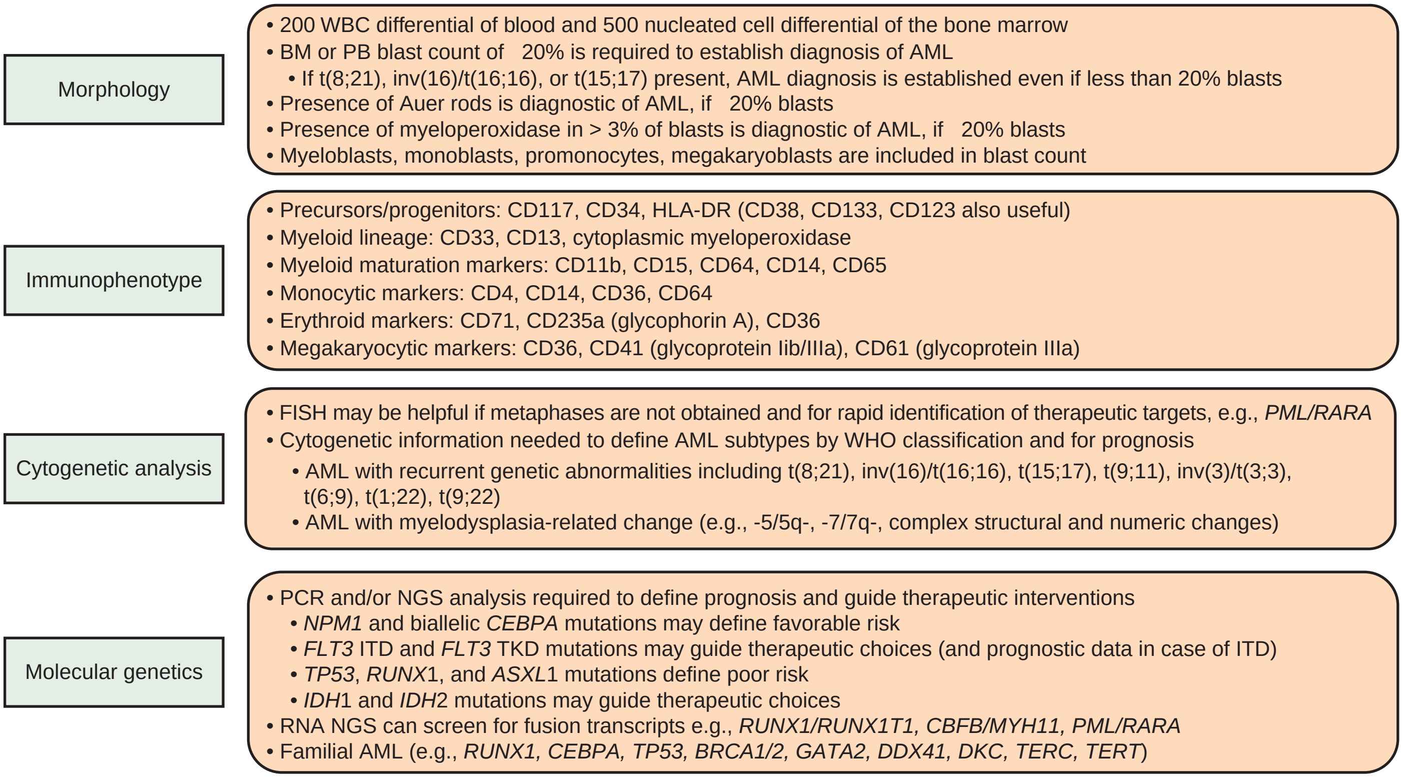
Findings after physical examination are often nonspecific. Patients may demonstrate pallor, tachycardia, oral purpura, ecchymoses, and petechiae due to anemia and thrombocytopenia. There may be signs of extramedullary leukemia such as gingival hypertrophy, enlargement of lymph nodes, cutaneous nodules (leukemia cutis), or hepatosplenomegaly. Examination of the lungs may reveal signs of an infectious process. Many patients with AML have no abnormal findings on physical examination at presentation.

The laboratory evaluation should include blood counts with evaluation of the blood smear, a standard chemistry panel (electrolytes, urea nitrogen, creatinine, total bilirubin, transaminases, uric acid, lactate dehydrogenase [LDH]), and coagulation studies, including prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen levels. Anemia and thrombocytopenia are almost always present. The white blood cell (WBC) count can vary from low to extremely high (>100,000/μL). Spurious hypoxia and hypoglycemia may occur in the setting of hyperleukocytosis due to continued metabolism by the leukemic blasts prior to processing of a blood sample for analysis; spurious hyperkalemia can occur in the setting of hyperleukocytosis due to cell lysis during clot formation in the preparation of serum. On the other hand, hypokalemia is not infrequently observed with monoblastic AML. DIC may be present at diagnosis and is often seen in patients with monocytic AML and APL (Chapter 137). Subclinical DIC, evident by elevated D-dimers, is common in many forms of AML and can worsen with the institution of therapy. Abnormalities of renal and hepatic values may represent infiltration of these organs; renal dysfunction is commonly observed at presentation due to spontaneous TLS or hypoperfusion due to capillary leak syndrome.

Imaging studies are of little help in diagnosis but allow assessment of complications (pneumonia, cerebral hemorrhage). If patients present with any neurologic deficit, the threshold for computed tomography (CT) scan (non-contrast if bleeding is of concern) or any other imaging modality of the brain should be low. Further evaluations should be based on the clinical assessment of the patients.

DIAGNOSIS AND CLASSIFICATION

The diagnosis of AML relies on morphologic evaluation (cytochemical stains), immunophenotyping by flow cytometry, and assessment of karyotype and molecular studies (Fig. 60.1). Blast percentage is best determined by a 500-cell differential of the marrow aspirate. The presence of ≥20% myeloid blasts in the peripheral blood or bone marrow is required for the diagnosis of AML, except in AML with t(8;21), inv(16), or t(15;17), in which case, these specific cytogenetic changes/gene fusions are sufficient for the diagnosis of AML regardless of the blast percentage. Three broad types of myeloblasts are described based on the granular content and nuclear features of the blasts (type 1: agranular basophilic cytoplasm, nucleus with



Morphology

- 200 WBC differential of blood and 500 nucleated cell differential of the bone marrow
- BM or PB blast count of 20% is required to establish diagnosis of AML
  - If t(8;21), inv(16)/t(16;16), or t(15;17) present, AML diagnosis is established even if less than 20% blasts
- Presence of Auer rods is diagnostic of AML, if 20% blasts
- Presence of myeloperoxidase in > 3% of blasts is diagnostic of AML, if 20% blasts
- Myeloblasts, monoblasts, promonocytes, megakaryoblasts are included in blast count

Immunophenotype

- Precursors/progenitors: CD117, CD34, HLA-DR (CD38, CD133, CD123 also useful)
- Myeloid lineage: CD33, CD13, cytoplasmic myeloperoxidase
- Myeloid maturation markers: CD11b, CD15, CD64, CD14, CD65
- Monocytic markers: CD4, CD14, CD36, CD64
- Erythroid markers: CD71, CD235a (glycophorin A), CD36
- Megakaryocytic markers: CD36, CD41 (glycoprotein Iib/IIIa), CD61 (glycoprotein IIIa)

Cytogenetic analysis

- FISH may be helpful if metaphases are not obtained and for rapid identification of therapeutic targets, e.g., *PML/RARA*
- Cytogenetic information needed to define AML subtypes by WHO classification and for prognosis
  - AML with recurrent genetic abnormalities including t(8;21), inv(16)/t(16;16), t(15;17), t(9;11), inv(3)/t(3;3), t(6;9), t(1;22), t(9;22)
  - AML with myelodysplasia-related change (e.g., -5/5q-, -7/7q-, complex structural and numeric changes)

Molecular genetics

- PCR and/or NGS analysis required to define prognosis and guide therapeutic interventions
  - *NPM1* and biallelic *CEBPA* mutations may define favorable risk
  - *FLT3* ITD and *FLT3* TKD mutations may guide therapeutic choices (and prognostic data in case of ITD)
  - *TP53*, *RUNX*1, and *ASXL*1 mutations define poor risk
  - *IDH*1 and *IDH*2 mutations may guide therapeutic choices
- RNA NGS can screen for fusion transcripts e.g., *RUNX1/RUNX1T1, CBFB/MYH11, PML/RARA*
- Familial AML (e.g., *RUNX1, CEBPA, TP53, BRCA1/2, GATA2, DDX41, DKC, TERC, TERT*)

Figure 60.1 WORKUP OF ACUTE MYELOID LEUKEMIA. The diagnostic workup consists of a morphologic assessment, immunophenotyping by flow cytometry, assessment of the karyotype, and a panel of gene mutations. Whereas morphologic assessment by itself is often not sufficient to render a diagnosis, flow cytometry will confirm the lineage assignment (myeloid vs. lymphoid) and stage of differentiation in more than 95% of cases. In the remainder, either no lineage-specific antigens are expressed (acute undifferentiated leukemia) or antigens of more than one lineage are present (mixed-phenotype acute leukemia). In the latter scenario, antigens of several lineages can be found on one (bi-phenotypic) or separate populations of blasts (bilineal). Karyotyping and gene mutation analysis may add diagnostic information in morphologically ambiguous situations but is otherwise of more interest in determining prognosis. Additional information (exposure to previous chemotherapy and/or radiation therapy, history of an antecedent hematologic disorder, dysplasia) forms the basis for the 2016 revision of the WHO classification of AML. *WHO*, World Health Organization. *(Adapted from Dohner H, et al. Diagnosis and management of AML in adults: 2017 ELN recommendations from an international expert panel. Blood. 2017;129(4):424–447.)*

fine chromatin, and two to four distinct nucleoli; type 2: basophilic cytoplasm with 20 or fewer azurophilic granules and similar nuclear features as type 1 blasts; type 3: basophilic cytoplasm with more than 20 azurophilic granules), although the morphologic variety of blasts exceeds the defined categories (Fig. 60.2). Auer rods are linear aggregates of primary granules composed predominantly of myeloperoxidase (MPO) that are found in 30% to 50% of newly diagnosed patients with AML and, if present, are one of the hallmark morphologic features to establish a diagnosis of AML (see Fig. 60.2C). Malignant promyelocytes have moderately basophilic cytoplasm with numerous azurophilic granules, frequent Auer rods including cells with multiple Auer rods ("faggot cells"), and bilobed or sliding-plate nuclei. Monoblasts and promonocytes usually exhibit folded or convoluted nuclei and may contain prominent vacuoles. Promyelocytes, promonocytes, and atypical pronormoblasts are all considered blast equivalents. Micromegakaryocytes and pronormoblasts are not considered blasts (see Fig. 60.2K and L).

AML marrows are typically hypercellular with decreased or absent megakaryocytes. Exceptions are marrows of older patients or those with t-AML, which may be hypocellular with dysplastic changes of one or more hematopoietic lineages. Prominent dysplasia may suggest a previous diagnosis of MDS but can also be found in patients with de novo AML, where the prognostic significance of dysplastic changes is less clear. For example, multilineage dysplasia in natural killer (NK) AML with *NPM1* or biallelic *CEBPA* mutations does not appear to affect the otherwise more favorable outcome of AML patients with these mutations. Cases with extensive fibrosis may be due to a preceding myeloproliferative neoplasm or acute megakaryocytic leukemia.

Several cytochemical reactions further highlight morphologic characteristics (MPO, periodic acid–Schiff, Sudan black B, naphthol AS-D chloroacetate esterase [specific esterase], α-naphthyl acetate/butyrate esterase [nonspecific esterase], acid phosphatase; Fig. 60.3). MPO is the most specific granulocytic marker, and MPO positivity in at least 3% of

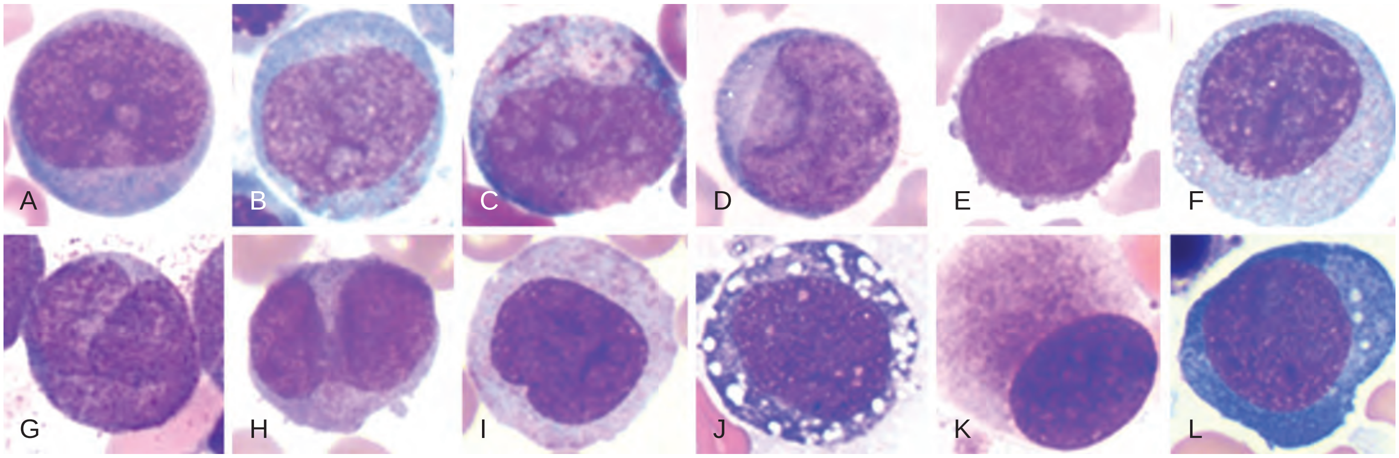


Figure 60.2 SPECTRUM OF BLASTS, BLAST EQUIVALENTS, AND OTHER CELLS. Blast cells in acute myeloid leukemia (AML) exhibit a wide spectrum of morphologic features. The French–American–British classification described three types of blasts depending on the granule content (A–C). However, blasts with nuclear invagination (frequently associated with *NPM1* and/or *FLT3* mutations) (D); blasts with pseudopods (frequently shown to be megakaryoblasts) (E); and monoblasts (F) are also quite distinctive. Blast equivalents include granular or hypogranular promyelocytes (G and H) for acute promyelocytic leukemia, promonocytes (I) for AML with a monocytic component, and atypical pronormoblasts (frequently with cytoplasmic vacuoles) (J) for acute erythroleukemia of the pure erythroid type. Micromegakaryocytes (K) and pronormoblasts (L) are not considered blasts.

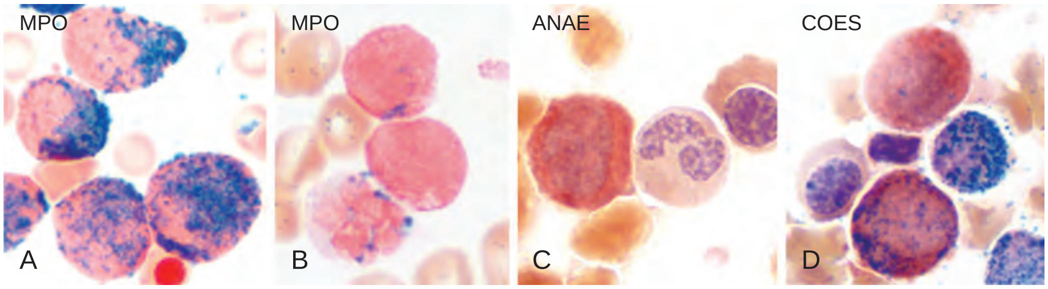

Figure 60.3 CYTOCHEMISTRY: MYELOPEROXIDASE, α-NAPHTHYL ACETATE ESTERASE, AND COMBINED ESTERASE REACTIONS. The MPO reaction is easily performed, can be done in less than a few minutes, and provides important initial information about the lineage of the blasts, particularly in cases in which morphologic assessment is difficult. In many laboratories it is routinely performed for all new acute leukemias. The MPO reaction should be interpreted in the blast population and expressed as a percentage of blasts that are positive. (A) The positive MPO reaction is strong. (B) The reaction is weak and seen in only some blasts. A counterstain would have obscured the weak reaction product. A weak MPO reaction is not uncommon in cases of acute myeloid leukemia (AML) associated with myelodysplasia (as in [B]). The neutrophils in such cases are also only weakly positive (*bottom cell* [B]). The ANAE reaction is a nonspecific esterase reaction positive in most monocytic cells ([C] *orange-brown* cell on *left* compared to negative neutrophil, and erythroid cell, *middle* and *right*). The ANAE reaction is interpreted as positive in cells as a percentage of nonerythroid elements. A significant monocytic component is usually defined as 20% or greater of the nonerythroid elements and is usually required for making a diagnosis of acute myelomonocytic leukemia. It is notable that in some cases of AML with inv(16) (i.e., AML with abnormal eosinophils), the monocytes are ANAE negative. A COES reaction uses another nonspecific esterase reaction for monocytes, α-naphthyl butyrate esterase, together with the specific esterase, chloroacetate esterase, for granulocytes. The combination allows simultaneous evaluation of granulocytes (*blue* reaction product) and monocytes (*orange-brown* reaction product). (D) Acute myelomonocytic leukemia. A monocyte *(top)*, a granulocyte *(right)*, and a myelomonocytic hybrid cell that exhibits both the orange-brown and blue reaction products *(bottom)*. *ANAE*, α-Naphthyl acetate esterase; *COES*, combined esterase; *MPO*, myeloperoxidase.

the blasts is consistent with a diagnosis of AML. On the other hand, lack of MPO staining does not rule out AML because it is often not present in AML with minimal differentiation, acute monoblastic leukemia, and acute megakaryocytic leukemia. Monoblastic leukemias are stained by nonspecific esterase. The diagnostic utility of cytochemical reactions is limited by the more rapid availability of immunophenotypic data by flow cytometry. Nonetheless, cytochemical stains of a touch imprint of the core biopsy can be very useful in the event of a "dry tap." Likewise, immunohistochemical staining for CD34 and CD117 can be used to estimate the blast percentage in a bone marrow core biopsy.

The first systematic attempt to classify AML was made by the French–American–British (FAB) Cooperative Group in 1976 and updated in 1985, and was based solely on morphology (blast percentage, degree of differentiation, lineage involvement). Because of its limited scope, the FAB system is now considered inadequate. Rapidly growing insights from genetic mutation analyses, their association with prognosis, and, in some cases, prediction of response to therapy triggered a revision of the old system and led to the changes in the 2008 edition of the World Health Organization (WHO) classification of AML and updated in 2016. The focus has shifted to identification of recurrent cytogenetic and molecular abnormalities, information regarding exposure to prior leukemogenic therapy, and morphologic features related to dysplasia-related changes as well as morphologic remnants of the FAB system (Table 60.1). Several categories have been defined:

1. AML with recurrent genetic abnormalities. This includes AML with relatively common cytogenetic changes: AML with t(8;21)(q22;q22), *RUNX1-RUNX1T1* (Fig. 60.4); AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22), *CBFB-MYH11* (Fig. 60.5); AML with t(15;17)(q22;q12); *PML-RARA* (Fig. 60.6); and AML with t(9;11)(p22;q23), *MLLT3-KMT2A* (Fig. 60.7). Less common subtypes are AML with t(6;9)(p23;q34), *DEK-NUP214*; AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2), *GATA1*, *MECOM*; and AML with t(1;22) (p13;q13), *RBM15-MKL1* (Fig. 60.8). Normal karyotype AML with nucleophosmin 1 mutation (*NPM1*; see Fig. 60.8G and H), and biallelic *CEBPA* mutations (and in the absence of additional mutations) were initially considered as provisional, but are now incorporated in this subtype, with other molecular subsets expected to be added in subsequent editions.
2. AML with myelodysplasia-related changes (AML-MRC) is defined in one of three ways: (a) AML in patients with a preceding diagnosis of MDS or MDS/MPN; (b) AML with multilineage dysplasia recognized morphologically by the presence of dysplastic features in 50% or more of cells in two separate lineages (Fig. 60.9); and (c) AML associated with a myelodysplasia-related cytogenetic abnormality. Patients with AML-MRC appear to have a worse outcome compared with AML-not otherwise specified (AML-NOS). However, the OS of patients treated with intensive chemotherapy for AML-MRC as defined solely by multilineage dysplasia is similar to that of patients with AML-NOS.
3. The category of t-AML was retained from the 2001 WHO classification, although the distinctions between AML associated with alkylating agents or radiation and those with topoisomerase II inhibitors were abandoned. Many patients receive complex therapeutic regimens, making this distinction difficult and impractical. Nonetheless, AML following exposure to topoisomerase II inhibitors typically have a shorter latency (less than 2 years) and frequently have monoblastic morphology with fusions of the *KMT2A* (previously *MLL*) gene. CBF AML and APL have also been associated with topoisomerase II inhibitors exposure. AML following alkylating agents typically have a longer latency, are preceded by MDS, and have complex cytogenetic changes including monosomy and deletions of chromosomes 5 and/or 7 as well as *TP53* mutations (Chapter 59). Immunosuppressive therapies are now considered potentially leukemogenic.
4. NOS subtypes are AML cases that do not fit the categories already described and for the most part are classified using the FAB scheme (AML with minimal differentiation, AML without maturation, AML with maturation, acute myelomonocytic leukemia, acute monocytic or monoblastic leukemia, acute erythroleukemia,

TABLE 60.1 WHO 2016 Classification of Acute Myeloid Leukemia (AML) and Related Neoplasms

Myeloid Neoplasms With Germline Predisposition
AML and Related Neoplasms
AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22.1); *RUNX1-RUNX1T1*

From Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391-2405.

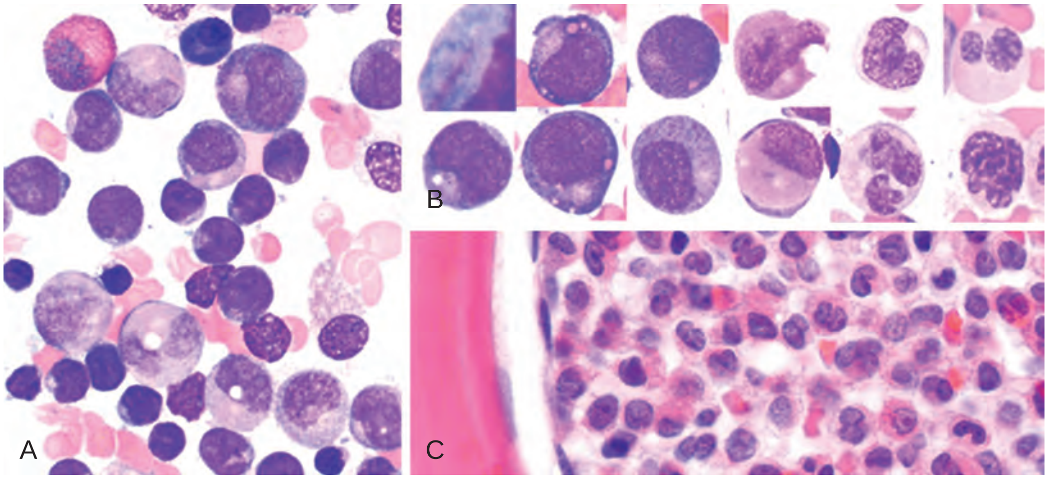

Figure 60.4 ACUTE MYELOID LEUKEMIA WITH T(8;21)(Q22;Q22), (*RUNX1-RUNX1T1*). (A) Low-power, Wright-stained bone marrow aspirate smear showing increased blasts associated with differentiating myeloid cells. (B) Details illustrating some of the features associated with this leukemia. They include blasts with long thin Auer rods *(top left)*, immature cells with abnormal eosinophilic globules *(top and bottom, second from left)*, abnormal salmon-colored granulation in the maturing cells, sometimes associated with a basophilic periphery *(top and bottom, fourth from left)*, and slightly abnormal features in the mature neutrophils *(far right)*. Pseudo–Chediak-Higashi granules were not seen in this case. (C) Biopsy specimen illustrates the significant degree of maturation that can sometimes be seen. In fact, in some cases the blast count can be less than 20%, but the diagnosis of acute myeloid leukemia is still made with the cytogenetic finding of t(8;21).

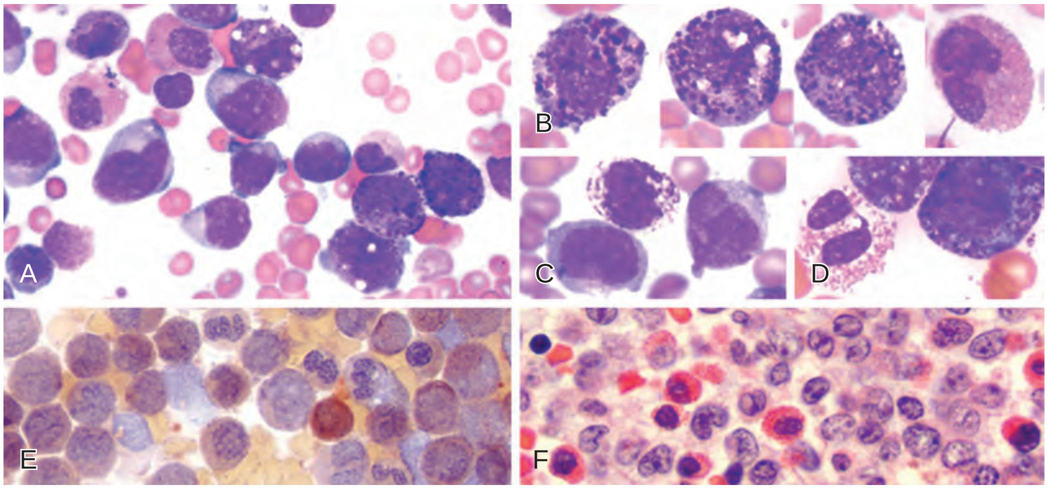

Figure 60.5 ACUTE MYELOID LEUKEMIA WITH ABNORMAL BONE MARROW EOSINOPHILS AND INV(16)(P13.1;Q22) OR T(16;16)(P13.1;Q22), (*CBFB-MYH11*). (A) Low-power, Wright-stained bone marrow aspirate showing blasts, monocytic cells, granulocytic cells, and abnormal eosinophils. (B) Features of the abnormal eosinophils in three abnormal eosinophils *(left three cells)*. Note the abnormal basophilic granules in the eosinophilic myelocytes. These granules are large, tend to cluster or coalesce, and are interspersed among the large eosinophilic granules, which are more difficult to see. As the eosinophils mature, the abnormal basophilic granules are less prominent and sometimes disappear *(far right)*. A common misconception is that the basophilic granules are the granules of basophils and that the abnormal eosinophils are "hybrid cells." (C) A basophil in the same case *(top cell)* for comparison. (D) Cells from a case of reactive eosinophilia, also for comparison. Immature eosinophils *(cell to the right)* do have primary blue granules. However, they are usually less prominent and less atypical than the basophilic granules of the abnormal eosinophils. It is notable that the monocytes in cases of AML with inv(16) or t(16;16) are sometimes α-naphthyl acetate esterase (ANAE) reaction negative. (E) Negative ANAE reaction. (F) Abnormal eosinophils cannot be recognized in hematoxylin and eosin-stained sections of the biopsy.

acute megakaryoblastic leukemia, acute basophilic leukemia). The AML-like disease of acute panmyelosis with myelofibrosis is included here (Fig. 60.10).

5. Lastly, the classification now includes myeloid sarcoma (Fig. 60.11), myeloid proliferations associated with Down syndrome, and the rather rare entity of blastic plasmacytoid dendritic cell neoplasm (BPDCN) (Fig. 60.12) (Chapter 64).

PROGNOSIS

Prognosis in AML is dependent on patient characteristics and disease-related factors. The former determines the likelihood of surviving initial induction chemotherapy as well as eligibility for potentially curative post-remission therapy. Age and performance status are key determinants of early mortality as well as long-term outcome (Chapter 157). Comorbidity scores such as the Charlson comorbidity index and the hematopoietic cell transplantation comorbidity index have been incorporated into predictive models of early mortality with intensive therapy (Chapter 157). Comorbidity indices (ideally as part of a more global geriatric assessment strategy) are particularly useful in older patients where the question of intensive chemotherapy versus lower-intensity interventions assumes more significance. AML prognostic models often include both factors that determine early treatment-related mortality as well as OS, since the impact of these features on early death and long-term outcome are difficult to separate. More recently, the approval of drugs for

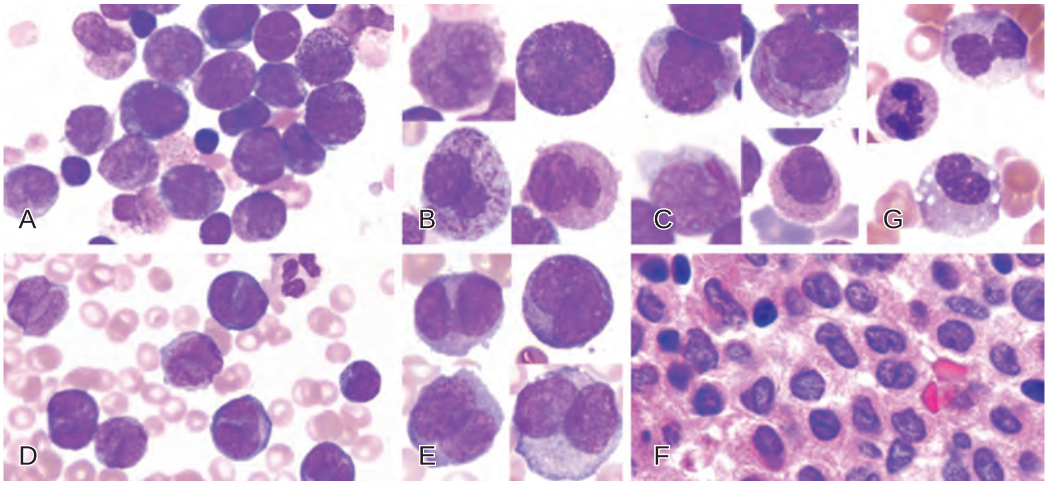

Figure 60.6 ACUTE PROMYELOCYTIC LEUKEMIA, ACUTE MYELOID LEUKEMIA WITH T(15;17)(Q22;Q12), (*PML-RARA*). (A–C) Acute promyelocytic leukemia (APL). (D and E) Hypogranular or microgranular subtype. (F) Bone marrow biopsy. (G) APL cells maturing after all-trans retinoic acid (ATRA) therapy. In the typical granular type of APL (A), the abnormal promyelocytes can exhibit variable morphologic features. Even within the same case, the granules can range from coarse, dark, and dense to fine and dust-like (B). The nuclei in the abnormal promyelocytes frequently exhibit a bilobed, dumbbell, or reniform shape. This is a diagnostically important feature, which can sometimes be difficult to recognize beneath the granules (B). Auer rods can be single, multiple, coalesced into Auer bodies, and even present in maturing cells (C). The microgranular type usually presents with an elevated white blood cell count (D). Although granules cannot be readily appreciated at the light microscope (E), granules can be demonstrated by electron microscopy. The abnormal nuclear shapes (bilobed, dumbbell, and reniform) can be easily appreciated (E). Bone core biopsy sample typically shows sheets of cells with abundant granular cytoplasm (F). After ATRA therapy the abnormal promyelocytes mature to abnormal neutrophils ([G] *top and bottom right*, compared with normal neutrophil, *left*). These can be seen for weeks after therapy and do not signify a failed response to the differentiating agent.

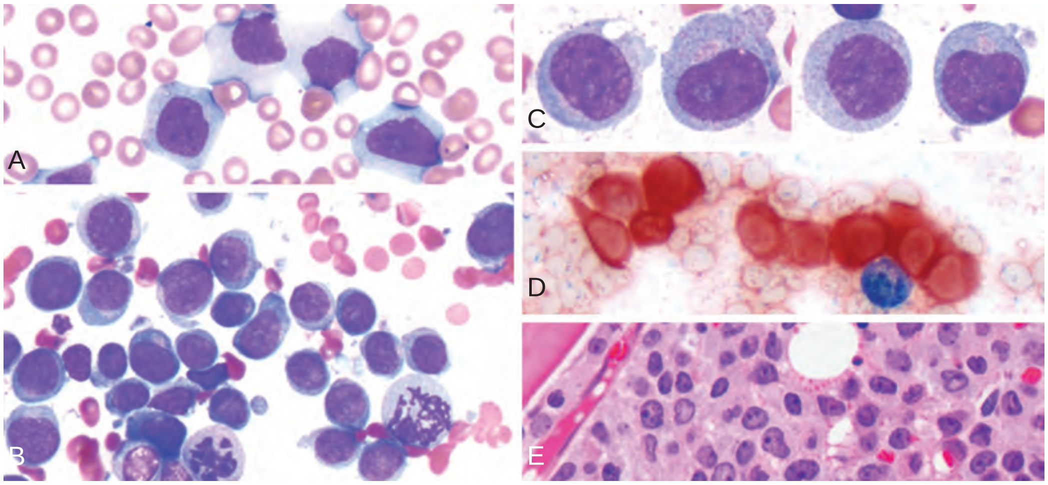

Figure 60.7 ACUTE MONOBLASTIC LEUKEMIA WITH T(9;11)(P22;Q23), (*KMT2A-MLLT3*). Acute monoblastic leukemia with t(9;11). (A) Such cases typically present with high counts because of circulating monoblasts. (B and C) Bone marrow aspirate is packed with monoblasts and shows few granulocytic elements. (D) Absence of a granulocytic component can be illustrated with the combined esterase reaction, in which most of the cells show the α-naphthyl butyrate reaction product *(orange-brown)*, with only rare granulocytes with the blue reaction product from the chloroacetate esterase reaction. (E) The biopsy sample is usually packed with sheets of monoblasts with fine nuclear chromatin and abundant pink cytoplasm.

AML patients unfit for intensive chemotherapy have used some of the criteria identified by Ferrara and colleagues to define this population, including age 75 years or older, performance status greater than 2, left ventricular ejection fraction ≤50%, congestive heart failure, pulmonary DLCO or FEV1 less than 65% predicted, and hepatic disease.

Disease-related factors determine resistance to therapy. Secondary AML, herein defined as AML following an antecedent hematologic neoplasm (MDS, MPN, MDS/MPN) or prior exposure to leukemogenic chemotherapy or ionizing radiation, has been associated with a worse prognosis. The response rates following intensive therapy are lower in patients with an antecedent hematologic neoplasm. Patients with therapy-related AML (t-AML) are typically older and have reduced survival due to other cancers or comorbid illnesses. The cumulative toxicity of prior therapy likely contributes to the higher rate of treatment-related mortality in t-AML patients. Regardless of age, patients with t-AML have lower remission rates, higher relapse rates, and increased early therapy-related mortality compared with de novo AML patients. The multi-drug resistance (MDR) phenotype due to expression of transmembrane drug efflux proteins negatively impacts outcomes of AML patients. Anthracyclines, etoposide, and calicheamicin (a component of Gemtuzumab Ozogamicin [GO]) are substrates for these drug efflux proteins. The MDR phenotype is commonly observed in secondary AML.

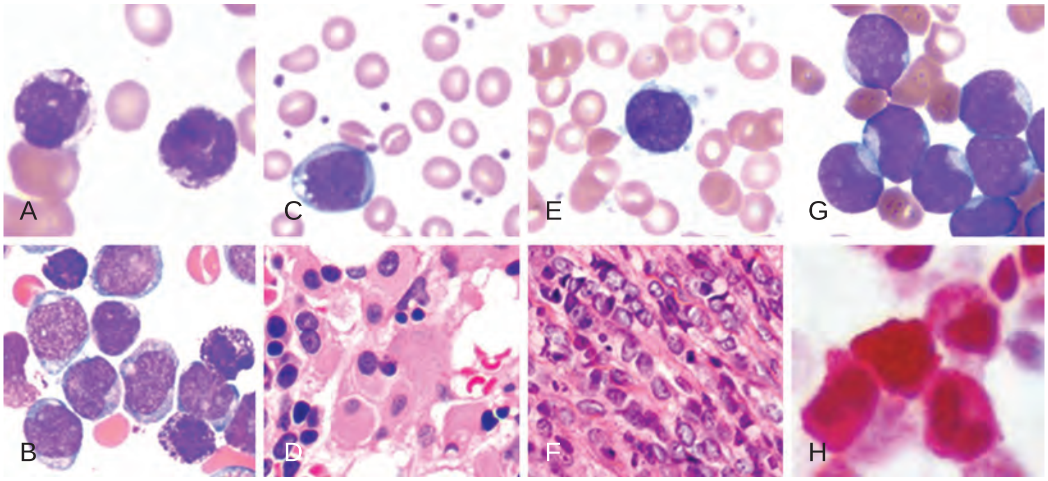

Figure 60.8 ACUTE MYELOID LEUKEMIA WITH LESS COMMON CYTOGENETIC AND GENETIC CHANGES. (A and B) Acute myeloid leukemia (AML) with t(6;9)(p23;q34). These cases are characterized by marrow dysplasia and basophilia. However, the morphologic characteristics can be quite varied among cases. AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2) is characterized by normal or high platelet counts (C), and by a bone marrow with numerous micromegakaryocytes (D). AML with t(1;22)(p13;q13) is uncommon and occurs in infants. The blasts are megakaryoblasts (E) but in the bone marrow can have a sarcomatous appearance (F). AML with *NPM1* or *NPM1* and *FLT3* mutations frequently presents with high peripheral blast counts, and the blasts sometimes have nuclear invaginations (G). *NPM1* mutation is associated with the abnormal cytoplasmic localization of *NPM1* rather than the normal nuclear staining (H).

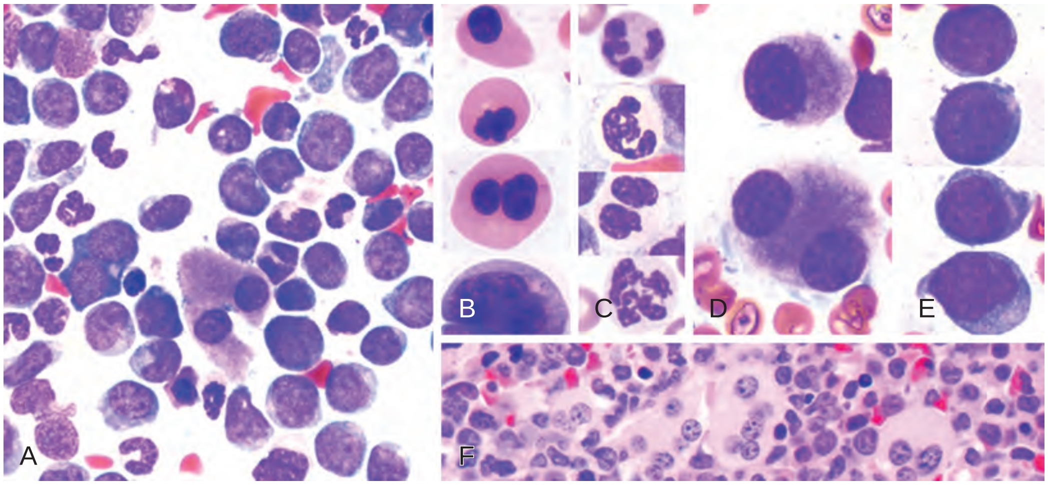

Figure 60.9 ACUTE MYELOID LEUKEMIA WITH MULTILINEAGE DYSPLASIA. (A) Bone marrow aspirate shows increased blasts and maturing cells with dysplastic features. (B–D) Details of the dysplasia. (B) Maturing erythroid elements exhibit megaloblastoid change and bizarre nuclear abnormalities. (C) Dysplastic granulocytes *(bottom three)* are compared with a rare normal granulocyte *(top)*. The dysplastic forms have pale cytoplasm and abnormal nuclear shapes with hypolobation, hypersegmentation, and prominent nuclear excrescences. (D) Dysplastic micromegakaryocytes have single or double small nuclei but mature cytoplasm with platelet material within. (E) Increased blasts. (F) Dysplasia is difficult to appreciate on a biopsied section. This is true except for the megakaryocytes. Dysplastic megakaryocytes can be recognized on the biopsy specimen by their abnormally small nuclei, which are sometimes multiple and widely spaced.

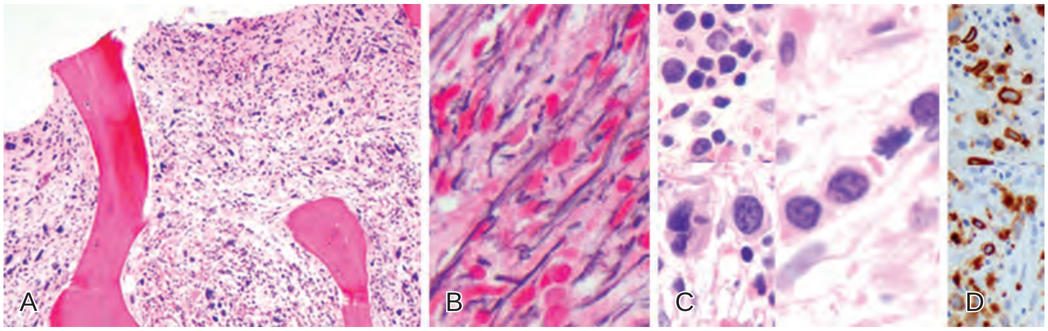

Figure 60.10 ACUTE PANMYELOSIS WITH MYELOFIBROSIS. (A) Bone marrow biopsy specimen shows a loosely packed marrow with a swirling appearance to the cellular elements due to underlying fibrosis. (B) The latter is illustrated on the reticulin stain. (C) Proliferations of erythroid cells *(top left)*, megakaryocytes *(bottom left)*, and immature cells within the fibrotic areas *(right)*. (D) Immunohistochemical staining shows increased megakaryocytes (*top*, CD61) and increased blasts (*bottom*, CD34).

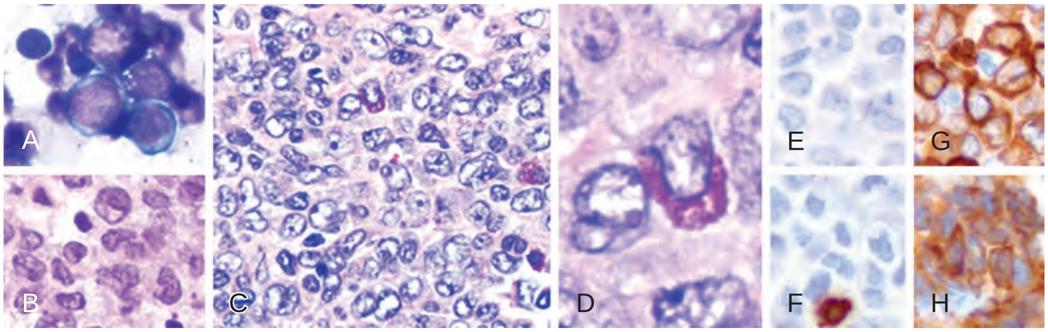

Figure 60.11 MYELOID SARCOMA. Myeloid sarcomas can sometimes present a diagnostic challenge. In this case the touch imprints (A) and frozen section preparation (B) from a mass lesion in the cecal area from a 44-year-old patient were thought to represent a high-grade lymphoma. However, initial immunohistochemical stains did not support the diagnosis, and on closer inspection of the tumor and with subsequent immunomarkers, a diagnosis could be reached. The tumor (C) is composed of sheets of non-cohesive cells. A diagnostic clue to the origin was the presence of eosinophilic myelocytes (D), which indicate that some tumor cells have the capacity to differentiate into eosinophils. The granules of neutrophilic myelocytes cannot be recognized on tissue section. The immunohistochemical stains showed the cell to be CD45$^+$ (not shown), (B) and T marker negative (E and F), but myeloid marker (myeloperoxidase and CD33) positive (G and H). Cytogenetic analysis showed the case was inv(16)(p13.1;q22).

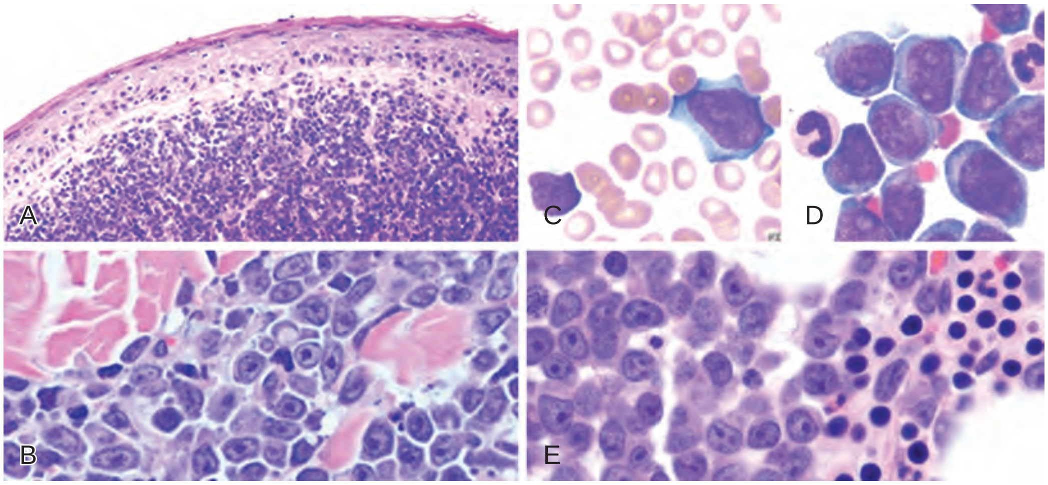

Figure 60.12 BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM. The blastic plasmacytoid dendritic cell tumor is an unusually aggressive malignancy that was previously called *hematodermic* malignancy. It is now classified in the acute myeloid leukemia category of myeloid neoplasms. It frequently presents in the skin with a blastic proliferation of cells in the dermis (A and B), which inevitably spreads to the blood (C) and bone marrow (D and E).

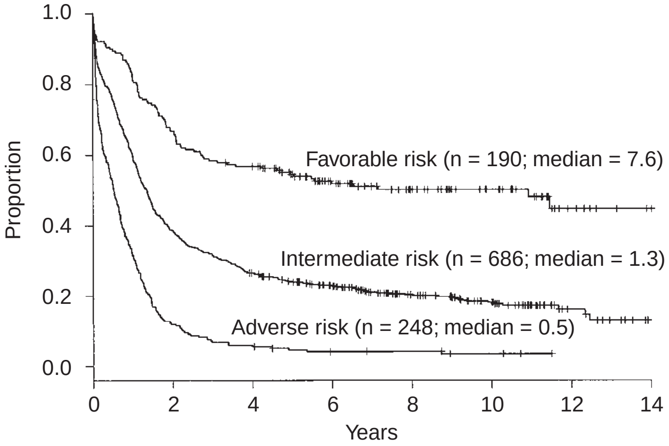

Figure 60.13 DISEASE-FREE SURVIVAL BY CYTOGENETIC RISK GROUP. *(Data from Byrd JC, et al. Pretreatment cytogenetic abnormalities are predictive of induction success, cumulative incidence of relapse, and overall survival in adult patients with de novo acute myeloid leukemia: Results from Cancer and Leukemia Group B [CALGB 8461],* Blood *100:4325, 2002.)*

Among the disease-related factors, karyotype (Chapter 57) has historically been considered as the most important prognostic factor dividing patients into those with favorable (CBF leukemias associated with t[8;21] and inv[16] or t[16;16]; APL with t[15;17]), unfavorable (complex abnormalities and monosomies, among others), and intermediate prognosis (mainly diploid; Fig. 60.13). Fluorescence in situ hybridization (FISH) can identify some of the more common AML gene deletions (deletions of chromosomes 5 and/or 7) and AML gene rearrangements in AML, including *RUNX1/RUNX1T1*, *CBFB/MYH11*, *PML/RARA*, and *KMT2A* fusions. FISH analysis can provide more rapid identification of these common changes and can help guide initial therapeutic choices. DNA based assays may replace classical cytogenetic and FISH analyses in the future.

Karyotype is supplemented by analyses of commonly mutated genes (Chapter 59). Whereas prognosis is hardly or not at all augmented by gene mutation testing in cytogenetically unfavorable groups, the situation is different in the intermediate cytogenetic risk group. Identification of *NPM1* mutation or biallelic *CEBPA* mutations in the absence of a *FLT3* ITD mutation has been associated with a more favorable outcome than other patients with intermediate risk karyotype. Normal diploid karyotype, associated with intermediate risk, is the largest subset of both younger and older AML patients.

Even in older, normal karyotype AML patients treated with intensive therapy, the presence of *NPM1* or *CEBPA* mutations, and absence of the *FLT3* ITD mutation, along with age, performance status, and WBC count, determine prognosis. On the other hand, even in the absence of an adverse risk karyotype, identification of the *FLT3* ITD (especially high allelic burden), *ASXL1, RUNX1,* and *TP53* variants are considered poor risk.

Core binding factor (CBF) leukemias are characterized by translocation t(8;21) and inv(16)/t(16;16) and, at the molecular level, by a disruption of the genes for the CBFα and CBFβ subunits, respectively. The CBF transcription factor plays a crucial role in hematopoietic differentiation. CBF AML comprises about 15% to 20% of patients with AML, but only 5% in AML patients over age 60 to 65 years. Although generally considered favorable risk, the prognosis of AML patients with CBF translocations is adversely affected by other clinical, cytogenetic, and mutational features. Poor prognostic factors in t(8;21) AML include high WBC count at diagnosis, presentation with granulocytic sarcoma, and expression of CD56. In general, cytogenetic abnormalities in addition to CBF translocations do not appear to influence outcome; these more complex karyotypes with CBF translocations are still considered favorable risk by ELN 2017 and NCCN risk stratification. However, del(9q) and loss of Y chromosome in t(8;21) AML have been associated with an inferior OS. The presence of a *KIT* tyrosine kinase activating mutation has been considered to have a negative impact on OS in CBF AML due to a higher rate of relapse. More recently, the prognostic impact of *KIT* has been shown to vary according to the variant allelic frequency as well as the concomitant mutations in t(8;21). Mutations in genes for chromatin modifying enzymes and cohesin complex proteins increase the risk of relapse in patients with t(8;21) and *KIT* mutations. The impact of *KIT* mutation is much less clear in inv(16) compared with t(8;21).

The first cancer genome to be completely sequenced was a cytogenetically normal AML. Whole-genome sequencing identifies a finite number of genes that are recurrently mutated in AML samples (Chapter 3,59). These repetitively mutated genes encode proteins/enzymes that generally fall into just a few classes including DNA methylation, epigenetic/chromatin modifiers, transcription factors, RNA splicing, activating signals, and the cohesin complex. These mutations are considered in risk assessment, but often with incongruous results (e.g., *NPM1*, *FLT3*, *CEBPA*, *ASXL1*, *RUNX1*, *TP53*, *KIT*, *IDH1*, *IDH2*, *TET2*, *DNMT3A*). Nonetheless, a comprehensive cytogenetic and mutational analysis of samples from 1540 AML patients treated with intensive chemotherapy identified 5234 driver mutations across 76 genes. At least one pathogenic mutation was found in 96% of the samples. Eleven prognostic groups were identified, allowing classification of 80% of patients into mutually exclusive prognostic subsets (Fig. 60.14). The ELN currently recommends testing for mutations of *NPM1*, *CEBPA*, *FLT3*, *RUNX1*, *ASXL1*, *TP53* in all patients with a new presentation of AML. Evaluation for specific germline mutations associated with familial AML (e.g., *RUNX1*, *CEBPA*, *TP53*, *BRCA1/2*, *GATA2*, *DDX41*, *DKC*, *TERC*, *TERT*) should be performed in those with a family history of AML or patients with physical stigmata of congenital marrow failure syndromes; this information may guide genetic counseling and donor selection for allo HSCT (Chapter 30). The ELN has published a revised risk model based on integration of cytogenetic and gene mutation information (Table 60.2). Mutations of the chromatin modifying proteins (*ASXL1*, *EZH2*, *BCOR*), spliceosome enzymes (*SRSF2*, *U2AF1*, *SF3B1*, *ZRSR2*), and the cohesin complex protein *STAG2* are more commonly identified in AML evolving from MDS compared with de novo AML. In fact, patients with apparently de novo AML with one of these mutations have inferior response to and survival following intensive therapy compared with those who do not have this genotype.

Assessment of post-therapy response provides additional valuable information. Achievement of morphologic complete remission (CR) after one or two courses of induction therapy is associated with improvement in survival. The most powerful post-treatment prognostic factor is the degree of minimal (or measurable) residual disease (MRD). The deeper the response, the better the long-term outcome. MRD is defined as disease that is detected below the arbitrary definition of persistent AML, 5% blasts by morphology and/or immunohistochemical assays. It is estimated that patients in morphologic CR still harbor up to 10^9 leukemic cells, which constitute an important reservoir for later recurrences. Assessing MRD has several advantages: (1) better determination of the quality of response, (2) more timely diagnosis of an impending relapse and possibly improvement of outcome by early intervention, and (3) potential indication to intensify post-remission therapy (allo HSCT) or not.

Persistence of karyotypic abnormalities by cytogenetic analysis at the time of morphologic CR is associated with increased relapse risk and inferior OS. However, the cytogenetic analysis only evaluates 20 metaphases. FISH analysis can detect lower levels of persistent karyotypic abnormalities. MRD, as detected by reverse-transcriptase quantitative polymerase chain reaction (RT-qPCR) or multiparameter flow cytometry (MFC), is even more sensitive. RT-PCR requires a suitable molecular target such as fusion transcripts (e.g., *PML-RARA*, *RUNX1-RUNX1T1*, *CBFB-MYH11*, *DEK-CAN*, *BCR-ABL*), *NPM1* insertion mutations, or overexpressed genes (e.g., *WT1*). Persistence of these transcripts following intensive chemotherapy has been associated with higher risk of relapse and inferior survival. For example, detection of the clone-specific NPM1 mutant transcript in the peripheral blood by RT-PCR following 2 cycles of intensive chemotherapy was associated with increased risk of relapse at 3 years (82% if MRD positive vs. 30% if MRD negative) and inferior survival at 3 years (24% if MRD positive vs. 75% if MRD negative). An expert

	Mutated *RUNX1*
	Mutated *ASXL1*
	Mutated *TP53*

From Dohner H, et al. Diagnosis and management of AML in adults: 2017 ELN recommendations from an international expert panel *Blood.* 2017;129(4):424–447.

panel has recommended the use of RT-PCR for MRD assessment at informative clinical timepoints only in AML patients with *PML-RARA*, *RUNX1-RUNX1T1*, *CBFB-MYH11*, and *NPM1* insertion mutations.

Since only the minority of AML patients harbor a leukemia-specific marker that can be identified by RT-PCR, MFC is more widely applicable to the assessment of MRD in AML patients. MRD is based on the identification of a leukemia-associated immunophenotype, which can be detected in the majority of patients with AML in various ways: (a) "different-from normal" antigen expression in leukemic blasts; (b) detection of lineage-foreign markers; (c) asynchronous expression of markers; (d) altered density of surface antigens. Commonly, a level of 0.1% has been determined to distinguish patients with MRD from those without. MRD levels following induction or early in consolidation have been associated with relapse and survival in all age groups regardless of cytogenetic and mutational status. Even though MRD levels tend to be higher in patients with unfavorable pretreatment characteristics, the prognostic impact of MRD extends to all risk groups and has shown to improve standard risk classification independently of cytogenetic–molecular markers.

Despite the clear prognostic significance of persistent MRD even in the setting of CR, there are many barriers to fully adopting MRD assessments into the routine care of AML patients. The list of these obstacles includes lack of assay standardization, absence of a universal definition of most appropriate cut-point for reporting positive MRD, choice of peripheral blood versus bone marrow for MRD analysis, quality of the bone marrow aspirate sample, timing of the assay following therapy, and variation in the kinetics of MRD clearance. The persistence of specific mutations by NGS may not actually affect prognosis. For example, persistence of mutations in *DNMT3A*, *TET2*, and *ASXL1* following intensive chemotherapy has not been shown to affect prognosis. Intensification of therapy by means of allo HSCT is associated with the lowest risk of relapse in AML patients with MRD persistence after initial therapy. However, even with a myeloablative preparative regimen, risk of relapse and OS are negatively impacted by persistence of disease by MFC at the time of the allo. Reduced intensity preparative regimens seem to provide little protection from relapse in patients with genomic evidence of persistent AML using highly sensitive duplex DNA sequencing. Effective strategies to eradicate MRD following intensive chemotherapy are not currently available, but novel agents are being assessed for this purpose (e.g., antibody-drug conjugates, Bispecific T-cell engagers [BiTE], targeted therapies, and cellular therapy).

THERAPEUTIC CONSIDERATIONS AT INITIAL PRESENTATION

Leukocytosis with 100,000 WBC/μL or higher is considered an emergency and requires immediate efforts to reduce the disease burden. Hyperleukocytosis may result in leukostasis. The clinical features of leukostasis are due to the rheologic effects of the large blasts in the microvasculature as well as the presence of endothelial adhesion molecules on the leukemic blasts. Leukostasis is a multisystem syndrome due to compromise of blood flow in the lungs (dyspnea, hypoxemia, diffuse alveolar hemorrhage), CNS (encephalopathy, coma, tinnitus, dizziness, visual disturbance, retinal hemorrhages), and heart (myocardial ischemia). Patients with leukostasis require urgent cytoreduction with chemotherapy (immediate start of intensive induction therapy, high-dose hydroxyurea, single dose of cytarabine) and/or leukapheresis. Retrospective studies have not confirmed any survival benefit with leukapheresis compared with chemotherapy alone. Furthermore, leukapheresis is contraindicated in the setting of significant DIC and hypotension; extracorporeal leukapheresis can be associated with respiratory failure due to cytokine release and exacerbation of pulmonary capillary leak. Leukapheresis also requires placement of large-bore central venous catheters which may result in traumatic hemorrhage.

Other complications of AML requiring urgent intervention are TLS and DIC. Either may be present at the time of diagnosis, and both may worsen as therapy is started. Therefore, frequent laboratory assessments (2 to 4 times daily) may be needed, especially as therapy is initiated in patients with high tumor burden, e.g., hyperleukocytosis. DIC is managed with aggressive transfusion of cryoprecipitate, plasma, and platelet transfusion based on close monitoring of the fibrinogen, PT/PTT, and platelet count, respectively (Chapter 137). The use of heparin and/or anti-fibrinolytic agents have not been shown to decrease the risk of serious hemorrhagic complications associated with DIC. However, prospective evaluation of these interventions versus transfusion support alone is not available. TLS should be anticipated, and prophylactic therapy with xanthine oxidase inhibitors (allopurinol, febuxostat) and intravenous hydration are recommended with initial therapy. Urine alkalinization to increase urinary excretion of uric acid is not recommended, since alkalinization may exacerbate metastatic calcinosis due to hyperphosphatemia. Instead, hyperuricemia, especially if accompanied by poor renal function, can be corrected rapidly with intravenous rasburicase. Rasburicase metabolized uric acid to the more soluble allantoin. However, patients with G6PD deficiency are at risk of fulminant oxidative hemolysis with rasburicase due to the concomitant production of hydrogen peroxide. Phosphate binders are given for the hyperphosphatemia. Insulin with glucose, sodium bicarbonate, and sodium polystyrene sulfonate in sorbitol (a potassium exchange resin) are used to control life-threatening hyperkalemia. Patiromer may also be used but has not been evaluated for hyperkalemia associated with TLS. Finally, urgent renal replacement therapy (dialysis) should be considered for management of acute renal failure due to TLS that is not adequately controlled by the management outlined above.

Initial Therapy: Intensive Versus Less Intensive Treatment Algorithm

Until 2017, the general therapeutic algorithm following the diagnosis of AML had not changed substantially in the preceding four decades. The physician first assessed the patient's ability to tolerate intensive chemotherapy approaches, which may ultimately include allo HSCT. Therapeutic options for "unfit" AML patients were quite limited and included DNA methyltransferase inhibitors (also known as DNA hypomethylating agents [HMA]) such as azacitidine and decitabine, Low-Dose Cytarabine (LoDAC), and Best Supportive Care (BSC) alone. Cytarabine 20 mg by subcutaneous injection twice daily for 10 days every 4 weeks (LoDAC) was compared with hydroxyurea and BSC (with or without all trans-retinoic acid) in older, unfit AML patients. Both the median survival and CR rate (18% vs. 1%; $P < .001$) were superior with LoDAC, except for those patients with adverse cytogenetics, who did poorly on either treatment arm. The survival benefit was only observed in those achieving remission.

Azacitidine 75 mg/m^2/day for 7 days improved the survival of AML patients with 20% to 30% marrow blasts compared with conventional care regimens (BSC, LoDAC, and intensive chemotherapy) in a phase III study enrolling high-risk, high-grade MDS patients (median OS 24.5 vs. 16 months, $P = .005$). Subsequently, azacitidine was compared with conventional care regimens (predominantly, LoDAC) in AML patients ages 60 years and older. There was a trend for improvement in the median survival with azacitidine (10.4 vs. 6.5 months, $P = .1009$); however, subsequent therapies confounded the assessment of any survival benefit. The rate of CR was similar with both azacitidine and LoDAC (19.5% vs. 21.9%). Decitabine 20 mg/m^2 IV daily for 5 days every 4 weeks was evaluated in a phase II study of treatment-naïve older AML patients and subsequently compared to either LoDAC (in most subjects) or BSC alone in a large randomized multicenter study. The decitabine arm achieved a higher CR rate (17.8% vs. 7.8%; $P = .001$). In a post hoc sensitivity analysis of the mature data a survival advantage was observed with decitabine at fixed time points over 2 years, and median survival improved from 5.0 to 7.7 months. A phase II study suggested that an extended schedule of decitabine 20 mg/m^2/day for 10 days may result in better response (CR 47%) and survival (median OS 55 weeks). However, a randomized phase II study of 5 versus 10 days did not detect any benefit in terms of CR/CRi rate (43% vs. 40%), median relapse-free survival (RFS) (5.7 vs. 4.6 months), median OS (5.5 vs. 6.0 months), or 1-year survival (25% both arms). With both azacitidine and decitabine, several monthly cycles may be required to achieve the response. Although some analyses suggested a higher response rate in MDS patients with *TET2* mutations, there are no clear predictors of response to HMA therapy in AML patients.

In AML patients over the age of 65 years, there has even been conflicting data regarding the benefit of intensive versus less intensive chemotherapy from randomized trials conducted in the 1980s. A randomized trial conducted by the European Organization for Research and Treatment of Cancer (EORTC) compared immediate induction therapy with daunorubicin, cytarabine, and vincristine with supportive care until disease progression (leukocytosis, thrombocytopenia, pain) and then therapy with hydroxyurea 3 g on days 1 and 4 with cytarabine 100 mg/m^2 twice daily on day 2 to 3 and 5 to 6. The remission rate was higher (58% vs. 0%), median survival longer (21 vs. 1 weeks), and survival at 2.5 years higher (17% vs. 0%) with the immediate induction therapy; early mortality was higher with the more palliative approach. On the other hand, another randomized trial comparing an anthracycline and cytarabine induction therapy with LoDAC demonstrated higher CR rate with intensive therapy, but lower early mortality with LoDAC, resulting in no significant difference in the OS. In a retrospective analysis of AML patients older than 65 years treated at the M.D. Anderson Cancer Center from 2000 to 2010, OS was similar regardless of initial therapy, either intensive chemotherapy or epigenetic-directed therapy. Given the low response rate with less intensive therapy, greater toxicity with intensive therapy, and minimal (if any) survival benefit, it is not surprising that the majority of AML patients age ≥65 years chose not to receive any form of chemotherapy for AML. In an analysis of SEER and Medicare data between 2000 and 2007, only 38.6% of U.S. Medicare recipients with AML received any form of chemotherapy. Increasing age, higher Charlson Comorbidity Index, and prior MDS diagnosis were associated with a lower rate of treatment. However, those who were selected for therapy had a longer median survival than those who were not (6 vs. 2 months).

With the recent availability of more effective, less intensive treatment regimens (see section Less Intensive Therapy), more older AML patients are now eligible for therapy. On the other hand, younger, fit AML patients may potentially benefit from less intensive therapies that have demonstrated efficacy in AML subtypes typically associated with chemotherapy resistance. Conversely, AML patients may become candidates for allo HSCT in first remission even if initially treated with less intensive therapy. The current AML treatment algorithm is summarized in Fig. 60.15.

When selecting initial therapy now, the clinician needs to consider a more global assessment of fitness (performance status, comorbidities, geriatric assessment scores), disease biology, as well as the goal of therapy (see box on Selection of Initial Therapy for the Patient With Acute Myeloid Leukemia). Age alone is considered

Figure 60.15 GENERAL APPROACH TO ACUTE MYELOID LEUKEMIA THERAPY.

inadequate for determination of initial and subsequent therapy. On the other hand, comorbidities are frequent in older patients, who are more likely to have a poor performance status. Hence, tolerance to the myelosuppressive and immunosuppressive consequences of intensive chemotherapy is diminished and there is greater risk of early therapy-related mortality. There are also differences intrinsic to the blast biology between older and younger patients. Patients over 60 years of age are more likely to have secondary AML, demonstrate unfavorable cytogenetics, and more often express multidrug-resistant phenotypes. Nevertheless, a select group of patients may still benefit from more intensive interventions. Older patients are not a homogeneous group and several models have been devised to identify variables that predict which patients may do well with intensive therapy versus those who will not. These models are comprised of patient characteristics, easily accessible clinical variables, and tumor characteristics. Efforts are therefore underway to capture multiple patient characteristics (physical and cognitive function, nutritional status, comorbidity, psychological state, and social support) as part of a comprehensive geriatric assessment and to better distinguish patients into fit, vulnerable, and frail (indicating a significantly increased risk of treatment complications). Despite thorough discussions with their oncologist regarding the goals of therapy, patients often misunderstand terms, e.g., equating remission with cure; patients may overestimate the benefit of therapy in terms of long-term survival and cure.

The initial goal of either intensive or less intensive therapy is the prolongation of survival through the achievement of a CR. Following CR, further post-remission therapy is required to maintain remission by eliminating or reducing residual disease. CR is defined as achievement of less than 5% marrow blasts (even if these are known to be leukemic blasts by immunophenotypic, cytogenetic, or mutational analyses), absence of Auer rods, and clearance of the peripheral blood and all extramedullary deposits of leukemic blasts. CR also requires restitution of relatively normal marrow function, indicated by an absolute neutrophil count (ANC) greater than 1000/µL, a platelet count greater than 100,000/µL, and independence of transfusion support. CR defines a landmark point in time because patients who achieve CR after beginning therapy have longer survival than patients who are resistant to therapy. Lesser response criteria (CR with incomplete platelet recovery [CRp], CR with incomplete recovery of neutrophils or platelets [CRi], CR with partial hematologic recovery [CRh], partial remission [PR], and morphologic leukemia-free state [MLFS]) may serve as useful end points in the context of early phase clinical trials, but they do not necessarily carry the same significance for survival as does CR. Each of these (except CRh) are defined by International Working Group and ELN criteria. The definition of CRh is identical to that of CR, except that the ANC must only be greater than 500/µL and the platelet count only greater than 50,000/µL.

After achievement of an initial response, the continued therapeutic path is different for patients treated with intensive versus less intensive therapy. Early clinical trials demonstrated the need to provide some post-remission therapy following achievement of CR with intensive chemotherapy. For example, in an ECOG trial AML patients $\leq$ age 65 years in first CR were assigned to allo HSCT (if family member donor available and age $\leq$40 years), or randomly assigned to observation, 2 years of oral mercaptopurine (MP) maintenance, or 1 cycle of high-dose cytarabine. The observation arm was closed early after 28 subjects assigned to this arm were noted to have inferior remission duration compared with continuing maintenance therapy. Post-remission therapy following intensive remission induction therapy consists of chemotherapy (typically 1 to 4 cycles), and/or HSCT, and/or maintenance therapy. Patients may receive one of these post-remission treatments or all of them, depending on initial risk stratification, eligibility for allo HSCT over time, as well as MRD assessments. For patients receiving less intensive regimens, the same therapy is continued in the absence of disease progression, disease relapse, or unacceptable toxicity (discussed later). However, even patients achieving CR after less intensive therapy may become candidates for potentially curative allo HSCT.

SELECTION OF INITIAL THERAPY FOR THE PATIENT WITH ACUTE MYELOID LEUKEMIA

The selection of either an intensive or less intensive chemotherapeutic regimen for AML patients remains a matter of significant debate and part of the art of medicine. The choice has been made more difficult by the recent approval of less intensive regimens with high initial response rates, even in patients with adverse AML biology. Fitness for intensive chemotherapy has never been adequately defined. I weigh multiple factors that will determine tolerance to chemotherapy including age, functional or performance status, comorbid illnesses, organ dysfunction, tobacco use, and nutritional status. However, I no longer consider only fitness; I also consider whether intensive chemotherapy is appropriate. The disease biology is critical to decision making. AML with adverse features based on cytogenetic and mutational analysis has a low response rate with intensive chemotherapy, and the only potentially curative option will ultimately be allogeneic hematopoietic stem cell transplantation once a remission is achieved.

For patients appropriate for intensive therapy, I base my choice of initial therapy on the following features: documented history of antecedent myeloid neoplasm, prior leukemogenic therapy for another disease, presence of a *FLT3* ITD or TKD mutation, presence of *RUNX1/RUNX1T1* or *CBFB/MYH11* fusion, and presence of the *PML/RARA* fusion. I have partnered with our pathology colleagues to expedite PCR for the *FLT3* ITD and TKD mutations and FISH analysis for *PML/RARA*, *RUNX1/RUNX1T1*, *CBFB/MYH11*, as well as deletions of chromosomes 5q, 7q, and 17p. These results are available within 72 hours. If there are 20% circulating myeloblasts, the diagnosis of AML is confirmed, and these assays can be done on a peripheral blood sample without waiting for a bone marrow biopsy to be performed.

If there is any suggestion of APL at initial presentation, I start ATRA immediately, before the diagnosis is confirmed. A myeloid immunophenotype lacking the stem cell markers CD34 and HLA-DR, blasts with bilobed nuclei without cytoplasmic granules, or even leukopenia with DIC, may suggest the diagnosis of APL. The ATRA can be discontinued, after the diagnosis is excluded. If APL is confirmed, I treat with ATRA and ATO. I add GO 9 mg/m^2, if the WBC count is over 10,000/µL. If the patient has CBF AML, I treat with cytarabine and daunorubicin (7+3) with GO 3 mg/m^2. If the *FLT3* ITD or TKD is present, I treat with daunorubicin 60 mg/m^2/day for 3 days and cytarabine 200 mg/m^2/day for 7 days with midostaurin 50 mg twice daily on days 8–21. Finally, if the patient has t-AML or AML following MDS or MDS/MPN, I treat with liposomal daunorubicin/cytarabine (CPX-351). If the patient apparently has a de novo AML but with multiple abnormalities on the FISH panel including del(5q) and del(7q), I will also treat with CPX-351. However, I will also consider a HMA and venetoclax (VEN) for these patients, especially if there is del(17p), and the patient had not been previously treated with an HMA. If none of these markers are present, I often select 7+3 with idarubicin 12 mg/m^2/day for 3 days, to avoid the controversy surrounding the optimal dose of daunorubicin (90 vs. 60 mg/m^2).

For patients who are truly unfit for intensive chemotherapy, or decline intensive chemotherapy, I treat with azacitidine 75 mg/m^2/day for 7 days plus VEN once daily for up to 28 days. I do not wait for any cytogenetic or mutational data since this information would not change the decision to use AZA/VEN in this approved population. Although certain subsets of patients did not have a survival benefit with AZA/VEN compared with AZA/placebo (e.g., *FLT3* ITD- or *TP53*-mutated), the initial response rate is over 50%. The one possible exception are those patients with *IDH1*- or *IDH2*-mutated AML. If these patients had previously received an HMA for MDS, or if they decline any form of parenteral therapy, ivosidenib and enasidenib would be acceptable alternatives for *IDH1*- and *IDH2*-mutated AML, respectively. Therefore, our pathologists also provide the *IDH* mutation status within 72 hours as well.

I will treat patients with HMA/VEN as an outpatient if they live close to our center, have a caregiver at home, have normal renal function, do not have leukocytosis, and do not already have complications from active AML such as infection. Otherwise, I will admit patients for the first week of therapy. I generally give posaconazole to all patients during initial induction due to the high rates of invasive fungal infection seen in our population. I give venetoclax 100 mg once daily in combination with posaconazole. If there is clearance of the peripheral blood blasts by day 21, I repeat a bone marrow biopsy at that time. If morphologic leukemia-free state (MLFS) or marrow aplasia has been achieved, I hold venetoclax at that time and allow for neutrophil recovery. In that case, I only prescribe 21 days of venetoclax during cycle #2. If the patient has not achieved MLFS, I proceed with cycle #2 as planned at day 29. Generally, remission is achieved with the first 2 cycles, but I will continue AZA/VEN if there appears to be clinical benefit even if CR or CRi has not been achieved.

Of course, I consider every patient for a clinical trial if available and appropriate.

Intensive Therapy: Induction

Since first published by Yates and colleagues in 1973, intensive AML therapy is still built on the same two drugs as 50 years ago: cytarabine (also known as cytosine arabinoside or Ara-C) and an anthracycline. Cytarabine, an analogue of a physiologic pyrimidine nucleoside, is a cell cycle-specific antimetabolite that requires intracellular conversion to its triphosphate compound, ara-CTP, and incorporation into DNA to become active (Chapter 58). When given by itself at standard doses of 100 to 200 mg/m^2 intravenously (IV) daily for 5 to 7 days, it produces CR rates of around 40%. The anthracyclines, daunorubicin and idarubicin, and the anthraquinone, mitoxantrone, have been the most extensively evaluated agents in combination with cytarabine. The anthracycline doxorubicin was associated with more mucositis and gastrointestinal toxicity compared with daunorubicin and is not used in AML therapy. These agents intercalate into DNA and stabilize the complex between DNA and the enzyme topoisomerase II, thereby leading to apoptotic cell death (Chapter 58). Daunorubicin achieves similar CR rates as does cytarabine alone. The combination of cytarabine 100 to 200 mg/m^2 as a continuous IV infusion (its serum half-life is only 15 minutes) daily on days 1 to 7 and daunorubicin 45 to 90 mg/m^2 IV daily on days 1 to 3 has become known as the "7+3" regimen and, for more than 40 years, has been the standard induction combination for AML patients selected for intensive therapy. Remission rates range from 50% to 80% (depending on patient age and cytogenetic risk), and long-term disease-free survival (DFS) is 35% to 40%.

Early clearance of the peripheral blood blasts (e.g., less than 3 days by flow cytometry) is associated with superior long-term survival. In clinical practice, patients undergo a repeat bone marrow examination between 14 and 21 days from the start of treatment (Fig. 60.16). If the marrow continues to show blasts and is cellular, a reinduction is usually given. However, there is little consensus on what degree of persistent disease at day 14 to 21 can be tolerated. It is not uncommon for a patient to be too ill 2 weeks after intensive therapy to receive re-induction therapy for persistent disease, and yet ultimately achieve remission without further therapy. Clinical trials often recommend re-induction, if there are more than 10% blasts, and the marrow cellularity is ≥15%. The reinduction may be an attenuated repetition of the induction ("5+2") or an intensification with intermediate-dose cytarabine (IDAC) or high-dose cytarabine (HiDAC) or fludarabine, HiDAC and granulocyte colony stimulating factor (G-CSF) (FLAG). There has been debate regarding the prognostic significance of requiring 2 versus 1 cycle of induction therapy to achieve first CR. Earlier studies reported a negative impact on RFS whereas others showed no impact on outcome. However, younger AML patients treated on SWOG S0106 and S1203 studies with 7+3 containing daunorubicin 60 and 90 mg/m^2, respectively, the requirement of 2 induction cycles to achieve remission had a significant negative impact on RFS and OS.

On the other hand, if the day 14 or 21 marrow is hypoplastic and appropriately ablated, supportive care continues until bone marrow recovery. If blood counts are not recovering, the bone marrow studies are repeated every 2 weeks to determine if there is recurrent AML causing the pancytopenia or delayed marrow recovery. If in CR, post-remission therapy starts shortly thereafter, once the patient has recovered from the toxicities of induction therapy. The degree of neutrophil and platelet recovery at the time of remission has prognostic significance. Higher neutrophil and platelet count at the time of remission are predictive of better RFS. In some cases, a regenerating marrow may have an increased number of blasts, which may look like persistent leukemia. Immunophenotyping by flow cytometry often helps to make that distinction. If due to regeneration, then follow-up marrow studies will show reduction in blasts concomitant with

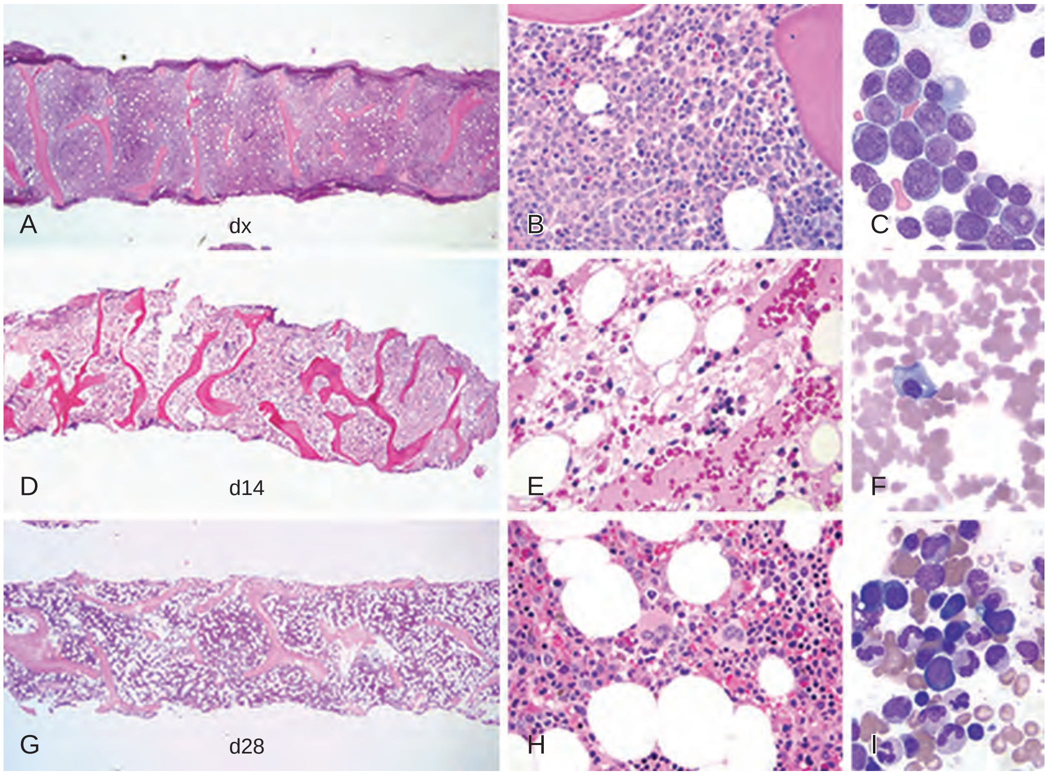

Figure 60.16 ACUTE MYELOID LEUKEMIA AT DIAGNOSIS AND AT DAY 14 AND DAY 28 FOLLOWING THE START OF STANDARD INDUCTION CHEMOTHERAPY. A 43-year-old man presented with fatigue and was found to have a white blood cell count of 70,300/µL composed of mostly blasts. A bone marrow study (A–C) showed a 90% cellular marrow packed with blasts (80%). The blasts were myeloperoxidase positive and had the following phenotype: CD34$^+$, HLA-DR$^+$, CD117$^+$, CD13$^+$, CD33$^+$ with partial CD15 and CD11b. Cytogenetic analysis demonstrated a normal male karyotype, and molecular studies showed wild-type *FLT3* and *NPM1*. The patient was treated with standard induction chemotherapy, and a day-14 bone marrow study (D–F) showed chemoablation effects with an empty marrow, stromal injury, dilated sinuses, and only scattered stromal cells and plasma cells with no obvious blasts. A bone marrow study performed at day 28 (G–I) showed regenerative changes of trilineage hematopoiesis.

a rise of neutrophils and platelets. In case of no response to one or two courses of induction therapy ("primary refractory"), treatment is often changed.

Many modifications to the 7+3 regimen have been evaluated over the years. Until recently, modifications of 7+3 have not improved outcomes for AML patients (see below). Two different standard cytarabine dose regimens were compared: 100 versus 200 mg/m^2 continuous IV infusion once daily days 1 to 7 with daunorubicin. The rates of remission, median DFS, median OS, and 5-year survival were not statistically different. However, there was a higher mortality rate related to chemotherapy with 200 mg/m^2 (21% vs. 13%, $P = .05$). Likewise, 10 days instead of 7 days of cytarabine (10+3) did not improve outcomes. Other cytotoxic agents (e.g., vincristine, etoposide, thioguanine, topotecan, fludarabine) have been added to 7+3 without proven benefit, but often with increased toxicity. Inhibitors of multi-drug efflux protein MDR1 (also known as P-glycoprotein or P-gp) could potentiate the cytotoxicity of P-gp substrates, such as the anthracyclines and etoposide, by allowing intracellular accumulation of these drugs. However, P-gp inhibitors also affect clearance of these drugs. Therefore, the doses of anthracyclines and etoposide needed to be reduced due to increased toxicity in the presence of the P-gp inhibitor. Neither the response rates nor OS of AML patients was improved by the addition of the P-gp inhibitors, valspodar or zosuquidar, to induction chemotherapy in phase III randomized trials. The B-cell lymphoma/leukemia-2 (BCL2) anti-sense oligonucleotide, oblimersen, did not improve OS when administered with 7+3 induction therapy. Since cytarabine is a cell-cycle specific cytotoxic agent, priming with hematopoietic growth factors (G-CSF and granulocyte-macrophage colony stimulating factor [GM-CSF]) has been performed during the week of chemotherapy to force leukemic blasts into S phase. However, priming has not been shown to improve OS. The greatest risk of intensive chemotherapy is morbidity and mortality due to neutropenic infection. The addition of either G-CSF or GM-CSF following chemotherapy shortens the duration of absolute neutropenia by a few days, but did not improve CR rate, early mortality, or OS.

The intracellular concentration of ara-CTP is increased by culturing leukemic cell lines in the presence of both a purine analog and cytarabine, due to increased expression of cytidine kinase. Based on this pharmacokinetic interaction and other effects of the purine analogs, many studies have evaluated the addition of purine analogs to cytarabine-based chemotherapy. The Polish Adult Leukemia Group published the outcome of an open-label, randomized study where addition of cladribine 5 mg/m^2 once daily days 1 to 5, but not fludarabine, to a daunorubicin 60 mg/m^2 for three days and cytarabine 200 mg/m^2 for 7 days resulted in significantly increased rates for remission (68% vs. 56%; P=.01) and 3-year OS (OS; 45% vs. 33%; P=.02). Interestingly, leukemia-free survival was not improved by the addition of cladribine. The survival benefit was less significant when subjects were censored at the time of allo HSCT. The addition of the second-generation purine analog, clofarabine at 20 mg/m^2/day for five days, to idarubicin 10 mg/m^2/day on days 1 to 3 and cytarabine 1 g/m^2/day on days 1 to 5 (IA) led to significantly better event-free survival (EFS) and OS in the three-drug combination when compared with a historical IA-treated group, especially in patients younger than 40 years of age. The effect of ludarabinee on cytarabine accumulation in leukemic blasts was also demonstrated in patients with relapsed/refractory AML receiving high-dose cytarabine salvage therapy with or without fludarabine; however, there was no apparent clinical benefit in this phase III study. The use of fludarabine with idarubicin and high-dose cytarabine in the United Kingdom Medical Research Council (UK MRC) trials is discussed later.

The dose of daunorubicin has been the subject of debate. A study by the Eastern Cooperative Oncology Group (ECOG 1900) randomized patients between the ages of 17 and 60 years with untreated AML to a 7+3 combination with either standard-dose daunorubicin (45 mg/m^2 daily for 3 days) or high-dose daunorubicin (90 mg/m^2 daily for 3 days). The higher dose of daunorubicin achieved higher CR rates (70.6% vs. 57.3%, $P < .001$) and improved the median OS (23.7 vs. 15.7 months, $P = .003$). This improvement was limited to patients younger than 50 years and with intermediate-risk cytogenetics. The daunorubicin dose of 90 mg/m^2/day did not lead to a higher incidence of adverse events (particularly cardiomyopathy and infectious complications). For patients with *FLT3* ITD mutations, CR rates (70% vs. 48%), median survival (15.2 vs. 10.1 months), and 4-year survival estimates (28% vs. 17%) were also superior with 90 versus 45 mg/m^2. The study can be criticized on the basis that the dose of the comparator arm, daunorubicin 45 mg/m^2/dose, is no longer considered the standard of care for younger AML patients, and instead 60 mg/m^2/dose should be considered standard. In older AML patients ages 60 to 83 years (median 67 years), daunorubicin 90 mg/m^2/day for 3 days was compared with the standard dose for this population, 45 mg/m^2/day for 3 days both in combination with cytarabine 200 mg/m^2/day for 7 days. The CR rate was greater with the high-dose daunorubicin (64% vs. 54%, $P = .002$) without an increase in induction mortality. There was no difference in EFS or OS for the entire population. In the patients ages 60 to 65 years, 2-year survival was superior with high-dose daunorubicin (38% vs. 23%). The UK MRC AML 17 trial compared daunorubicin 60 versus 90 mg/m^2 during induction and showed equivalent CR and relapse rates as well as survival. However, in the patients with *FLT3* ITD mutation, the 90 mg/m^2 daunorubicin resulted in higher RFS and OS. The UK MRC AML 17 trial did not settle the debate, because patients received a second cycle of daunorubicin-containing chemotherapy. The cumulative dose of daunorubicin was higher in both arms of the UK MRC AML17 trial compared with the two arms of the ECOG 1900 study.

Idarubicin is a 4-demethoxy anthracycline analogue of daunorubicin, which results in increased lipophilicity and better cellular uptake compared with daunorubicin. Idarubicin, and its metabolite idarubicinol, are not substrates for the multidrug resistance efflux pump. Idarubicin 12 to 13 mg/m^2 for 3 days appeared to be superior to daunorubicin 45 to 50 mg/m^2 for 3 days in several phase III studies. However, the doses did not appear to be biologically equivalent, since idarubicin was associated with greater myelosuppression in those studies continuing the comparison into the post-remission setting. In younger adults with treatment naïve AML receiving cytarabine 200 mg/m^2 for 7 days with either daunorubicin 90 mg/m^2/day (AD) for 3 days or idarubicin 12 mg/m^2/day for 3 days (AI), there was no difference in CR rates (AD 74.5% vs. AI 80.5%), cumulative incidence of relapse (AD 25.1% vs. AI 35.2%), and 4-year survival (AD 54.7% vs. AI 51.1%). However, EFS and OS were significantly better with IA in patients with *FLT3* ITD positive AML.

A meta-analysis of 29 randomized controlled trials compared the efficacy of different anthracyclines and dosing schedules during induction therapy for AML patients less than age 60 years. Idarubicin compared with daunorubicin improved remission rates, although this effect was limited to studies with a daunorubicin/idarubicin ratio of less than 5. Likewise, higher-dose compared with lower-dose daunorubicin improved remission rates. Survival estimates suggest that both high-dose daunorubicin (90 mg/m^2/dose × 3 days or 50 mg/m^2/dose × 5 days) and idarubicin (12 mg/m^2/dose × 3) can achieve 5-year survival rates of between 40% and 50%. On the other hand, there was no difference in CR rates or OS in AML patients older than age 55 years treated with cytarabine 100 mg/m^2/day for 7 days with either idarubicin 12 mg/m^2/day, daunorubicin 45 mg/m^2/day, or mitoxantrone 12 mg/m^2/day for 3 days. However, the induction mortality was greater in the idarubicin treatment arm.

A meta-analysis of 3 randomized clinical trials using HiDAC during induction encompassed 1691 patients and arrived at the following conclusions: there were no differences between HiDAC and standard-dose cytarabine (SDAC) with respect to percent CR and rates of persisting leukemia and early death. On the other hand, 4-year OS and RFS were significantly better with HiDAC but at the cost of more toxicities (infections, nausea/vomiting, CNS). HiDAC benefited mostly patients who already were more likely to achieve CR (i.e., patients with intermediate and favorable karyotype). The major drawback of HiDAC during induction is that it may make further consolidation therapy difficult. It is also not clear if HiDAC should be used during initial induction or is best used as a post-remission therapy after marrow function has been restored. The UK MRC AML 15 trial randomized 1268 treatment-naïve younger AML patients to receive fludarabine, HiDAC, G-CSF, and idarubicin (FLAG-Ida; fludarabine 30 mg/m^2 IV on days 2 to 6, cytarabine 2 g/m^2 IV on days 2 to 6, idarubicin 10 mg/m^2 IV on days 4 to 6, and G-CSF on days 1 to 7) and 1983 to receive cytarabine (ara-C), daunorubicin, and etoposide (ADE; daunorubicin 50 mg/m^2 IV on days 1, 3, 5; cytarabine 100 mg/m^2 IV on days 1 to 10; and etoposide 100 mg/m^2 IV on days 1 to 5), the latter representing the SDAC arm. FLAG-Ida resulted in higher response rates following the first induction and fewer patients on FLAG-Ida relapsed. However, more myelosuppression and deaths in CR offset the survival benefit except in the FLAG-Ida treated patients who were able to receive four courses (FLAG-Ida × 2, HiDAC × 2) where 8-year survival was 63% versus 47% with ADE with intermediate-risk patients and 95% for those with favorable risk.

The EORTC and the Italian Cooperative Group for Hematologic Diseases in Adults (GIMEMA) AML-12 trial randomized 1942 newly diagnosed AML patients between ages 15 and 60 years to an induction with SDAC or high-dose cytarabine (3 g/m^2 every 12 hours on days 1, 3, 5, and 7). The study demonstrated significantly higher CR rates in all patients and significantly improved EFS (43.6% vs. 35.1%; *P* =.003) and OS (51.9% vs. 43.3%; *P* =.009) for patients between 15 and 45 years of age. The impact on survival was particularly evident in younger patients with secondary AML, high-risk cytogenetics, and *FLT3* mutations, emphasizing that HiDAC may overcome poor-risk features during induction that SDAC cannot.

Increasing the efficacy of induction therapy has been attempted with the use of additional cytotoxic chemotherapy shortly after completion of the first course and prior to recovery of normal marrow function. This approach is known as timed-sequential chemotherapy and is based on the observation that leukemic blasts will enter cell cycle shortly after completion of chemotherapy, theoretically increasing the sensitivity to cytarabine-based chemotherapy. OS was improved in pediatric patients treated with multi-agent chemotherapy (dexamethasone, cytarabine, thioguanine, etoposide, daunorubicin, and intrathecal cytarabine) followed by the same regimen at day 10 to 14 regardless of initial response compared to standard sequencing of these two courses based on initial response. On the other hand, the German AML Cooperative Group did not detect any difference in CR rate or OS with a dose dense regimen of high-dose cytarabine and mitoxantrone on days 1 to 4 and 8 to 11 compared with their standard double induction regimen with thioguanine, cytarabine, and daunorubicin (TAD) followed by high dose cytarabine and mitoxantrone (HAM) 21 days later. The duration of neutropenia was shorter with the dose dense sequential HiDAC and mitoxantrone.

Intensive Therapy: Post-Remission

In CR, as many as 10^9 leukemia cells survive below the threshold of detection by morphologic assessment. Further therapy is therefore necessary to reduce this number and minimize the chances of relapse. In a series of clinical studies in which patients did not receive post-remission therapy, relapse was universal, and the median remission duration was about 4 months. Post-remission therapy is mainly predicated by pretreatment prognostic factors and can take the form of continued chemotherapy (termed consolidation) and/or high-dose chemotherapy followed by HSCT (see box on Post-Remission Therapy: Allogeneic Hematopoietic Stem Cell Transplantation Versus Consolidation Alone in First Remission). As for the former, debate continues regarding the optimal cytarabine dose, incorporation of anthracyclines, and number of cycles. Three doses of the anti-CD33 antibody-drug conjugate, GO (see below), was compared with no further therapy for older AML patients in first remission following 2 induction cycles; there was no clinical benefit of post-remission GO (5-year DFS 17% vs. 16%). DFS of younger AML patients in first CR was also not improved with three doses of GO following induction and consolidation chemotherapy (SWOG 0106).

POST-REMISSION THERAPY: ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION VERSUS CONSOLIDATION ALONE IN FIRST REMISSION

Allo HSCT is associated with the lowest risk of relapse of any post-remission intervention. Unfortunately, allo HSCT is also associated with the greatest risk of treatment-related morbidity and mortality. Therefore, I attempt to determine which patients are more likely to be cured with chemotherapy alone, and I will recommend allo HSCT for all others. Regardless of my opinion, I generally refer all my patients to a SCT specialist for consultation regarding risks and benefits of allo HSCT in CR1. Almost all patients will now have an acceptable donor given the expansion of the alternative donor pool (haploidentical donors and umbilical cord blood). Nonetheless, there are significant obstacles to allo HSCT even if the patient would be best served by this post-remission intervention. Some of the barriers to allo HSCT in CR1 include poor performance status, serious infection, or organ dysfunction after initial AML therapy, early relapse, and lack of caregiver. I will consider allo HSCT for AML patients in CR1 regardless of the initial induction therapy: intensive versus less intensive regimens.

I consider three factors in my recommendation for allo HSCT in CR1: initial risk stratification, MRD status following initial therapy, and ability to achieve a second CR if the patient does not undergo allo HSCT in CR1. For patients with adverse risk karyotype, I strongly recommend allo HSCT in CR1. If these patients do not undergo allo HSCT in CR1, I am not convinced that high-dose cytarabine would be beneficial. Instead, I would recommend oral azacitidine maintenance therapy to delay relapse. If the patient has CBF AML regardless of other mutations or biallelic *CEBPA* mutations, I recommend high-dose cytarabine alone (with GO for CBF AML). The situation is more complicated for those with *NPM1* mutation and depends on the presence of other mutations as well as the mutational burden. It is in this population that the *NPM1* mutant transcript level by peripheral blood RT-qPCR after 2 cycles of chemotherapy may be most helpful. If still positive, I recommend allo HSCT. I also generally recommend allo HSCT for those patients without favorable risk features (intermediate risk). If the intermediate-risk AML patient does not proceed with allo HSCT in CR1, I generally prescribe up to 3 cycles of high-dose cytarabine consolidation followed by oral azacitidine maintenance therapy to delay relapse. I make it clear to patients that oral azacitidine is not an equally effective alternative to allo HSCT.

I generally prescribe cytarabine 1.5 g/m^2 for six doses as consolidation therapy: 3 cycles for younger patients and two for older. However, for younger patients with CBF AML in CR1 I still prescribe cytarabine 3 g/m^2 during consolidation. If the patient received CPX-351 during induction, I proceed with 1 or 2 cycles of CPX-351 consolidation prior to allo HSCT. I do not use high dose cytarabine consolidation if the first remission was achieved with CPX-351.

Relapse is also common for AML patients with MRD following allo HSCT. However, if such patient has already received induction and consolidation therapy, I strongly recommend allo HSCT despite the presence of MRD, since further attempts to achieve an MRD-negative remission are likely to be unsuccessful and/or lead to toxicities that will preclude allo HSCT in first remission.

In a landmark study by the Cancer and Leukemia Group B (CALGB), patients with newly diagnosed AML in CR following a 7+3 induction were randomized to SDAC (100 mg/m^2 continuous IV infusion daily × 7), IDAC (400 mg/m^2 continuous IV infusion daily × 5), or HiDAC (3 g/m^2 IV over 3 hours every 12 hours on days 1, 3, and 5) for a total of 4 cycles. This was followed by an additional 4 cycles of 5+2, a consolidation-maintenance omitted from all subsequent CALGB studies. The probability of remaining in continuous CR after 4 years was 24% for SDAC, 29% for IDAC, and 44% for HiDAC (*P* =.002). It is important to recognize an important safety signal identified in this study. In the 31 subjects ages 60 years and older who received HiDAC, 32% developed severe neurologic toxicity (seizures, cerebellar dysfunction), which was permanent in 40% of those affected. In fact, age greater than 40 years, creatinine greater than 1.2 mg/dL, and threefold elevation of alkaline phosphatase were all associated with a higher risk of neurologic toxicity. The study was amended to exclude further enrollment of AML patients over age

60 years based on this observation. Patients with CBF translocations and normal diploid karyotypes benefited from HiDAC consolidation. The survival of patients with any other karyotype with SDAC, IDAC, and HiDAC consolidation were similar and very poor. Over the ensuing years, studies have shown that there is no benefit by extending consolidation therapy by a fifth cycle and that even 3 cycles may be equivalent.

CBF AML is very sensitive to cytarabine-based therapy, which is reflected in high remission rates (80% to 90%) and more patients achieving long-term OS (about 60% at 5 years). Post-remission therapy with HiDAC (e.g., 3 g/m^2 IV every 12 hours on days 1, 3, and 5) for 3 to 4 cycles is commonly used. Questions remain regarding the optimal number of cycles, intensification, and addition of further drugs. One cycle (with a cumulative dose of up to 18 g/m^2 of cytarabine) is worse than 3 or 4 cycles (cumulative dose 54 to 72 g/m^2) for patients with t(8;21) translocation. Repetitive cycles of HiDAC consolidation also benefit patients with inv(16) and t(16;16). DFS and OS were similar for younger AML patients in first CR with either 4 cycles of multiagent chemotherapy with SDAC or 3 cycles of HiDAC consolidation. However, in the subset of patients with CBF AML DFS was significantly better with HiDAC, and there was a trend for improvement in OS as well. Given the excellent long-term outcome with HiDAC consolidation, and the higher risk for treatment-related mortality and morbidity with allo HSCT, allo HSCT is generally not recommended for CBF AML patients in first remission. However, allo HSCT may be considered by some for CBF AML patients with *KIT* mutation in first remission. Less frequently in the United States compared with other regions, autologous HSCT is sometimes performed following 1 or 2 cycles of cytarabine-based consolidation, albeit with comparable results to chemotherapy-only regimens.

Patients in the intermediate-risk group comprise the largest and most heterogeneous AML population (about 60% of AML). The majority demonstrate a diploid karyotype. It is in this group of patients where there is an ongoing debate about the role of consolidation chemotherapy versus allo HSCT for post-remission therapy. It is also in this group where the prognostic impact of gene mutation analysis is most helpful to facilitate this decision. Nevertheless, the reported data can be conflicting. For example, the German AML Cooperative Study Group did not observe any benefit of allo HSCT in terms of RFS for younger AML patients with *NPM1* mutation and normal karyotype based on a donor versus no-donor analysis. On the other hand, the Study Alliance Leukemia (SAL) cooperative group demonstrated superior 3-year RFS of younger AML patients with normal karyotype and *NPM1* mutation (without *FLT3* ITD) in those with a sibling stem cell donor compared with those without (83% vs. 53%, $P = .004$). However, there was no difference in OS (81% vs. 75%, $P = .300$), likely related to the ability to achieve a second remission followed by an alternative donor allo HSCT. The outcome of patients in first CR or second CR at the time of allo HSCT is similar, but second CR must be achieved prior to allo HSCT. Some patients will choose to reserve allo HSCT in the event of relapse. Patients need to be informed that remission rates are typically lower in relapsed AML than in previously untreated AML patients (see Relapsed AML). Monitoring for MRD following intensive therapy may help to identify those patients with *NPM1* mutated AML most likely to benefit from allo HSCT in first CR.

Outcome following standard chemotherapy remains poor for patients with adverse-risk cytogenetics and unfavorable gene mutations. In general, allo HSCT is strongly recommended for this group of patients in first remission. There is an ongoing discussion about the significance of allele burden with respect to *FLT3* ITD mutations. In a German AML Study Group report, the CR rate and OS were adversely affected by increasing burden of *FLT3* ITD mutated AML, as measured by the allelic ratio (AR, defined as ratio of mutated-to-wild type *FLT3* by PCR assay). In fact, in this retrospective analysis, there was no apparent benefit of allo HSCT compared with chemotherapy/auto HSCT for AML patients with *FLT3* ITD AR ≤ 0.5 in first CR. However, there are technical barriers to adopting use of allelic ratio by PCR, and NGS can underestimate the allelic frequency, especially with longer insertions. In the United States, allo HSCT is generally recommended for eligible patients in first CR with unfavorable risk AML including *FLT3* ITD mutated (regardless of allelic ratio); however, risk of relapse following allo HSCT remains high.

The value of intensive consolidation therapy is a matter of debate for older patients with AML. Older patients appear to tolerate intermediate doses of cytarabine, e.g., 6 to 12 doses of 1.5 g/m^2. There is little consensus on the number of post-remission cycles and the required intensity of post-remission therapy. Older AML patients in first CR had similar relapse rate (77% vs. 82%), DFS (11 vs. 10 months), and OS with 4 cycles of cytarabine 100 mg/m^2/day for 5 days versus 2 cycles of cytarabine 0.5 g/m^2 with mitoxantrone 5 mg/m^2 every 12 hours for 3 days. There was a trend for improved DFS and OS for AML patients age 65 years and older in first CR treated with 6 cycles of cytarabine 60 mg/m^2 subcutaneous injection every 12 hours for 5 days and a single dose of idarubicin or daunorubicin administered in the ambulatory setting compared with 1 cycle of intensive chemotherapy similar to induction (idarubicin 9 mg/m^2/day or daunorubicin 45 mg/m^2/day for 4 days with cytarabine 200 mg/m^2 for 7 days) as an inpatient. The patients receiving the ambulatory post-remission therapy spent fewer days in the hospital and required fewer red blood cell and platelet transfusions. It is generally accepted that intensive post-remission consolidation therapy is most likely to benefit older patients with favorable risk AML (CBF AML, *NPM1* mutation without *FLT3*-ITD mutation, and biallelic *CEBPA* mutation). The benefit of intensive consolidation chemotherapy for unfavorable risk AML is doubtful.

Allo HSCT is typically preferred over the use of autologous HSCT (Chapters 105, 106, 107). The benefit of allo HSCT is derived at least in part from the graft-versus-leukemia effect of the donor immune system. Allo HSCT also avoids the potential re-infusion of leukemic cells if autologous stem cells are used as a hematopoietic rescue after high-dose chemotherapy. The allogeneic donor may be HLA-identical, partially HLA-mismatched, or haploidentical. The source of allogeneic stem cells may be a family member (typically first-degree relative), unrelated donor from a registry, or umbilical cord blood. The preparative regimen prior to infusion of the allogeneic stem cells is both immunosuppressive and myelosuppressive. The intensity of the myelosuppressive regimen varies. The choice of a myeloablative versus reduced intensity preparative regimen depends on a number of factors, including patient age, organ function, and disease status (e.g., presence of MRD). Patients with CBF AML do not appear to benefit from allo HSCT in first CR. On the other hand, patients with poor risk cytogenetic or mutational features have better outcomes with allo HSCT in first remission. The debate as to which patients should receive chemotherapy consolidation alone versus allo HSCT is most divisive for patients with intermediate-risk disease. In this population, characterization of the genotype as well as MRD status are helpful in guiding that decision.

Maintenance Therapy

Maintenance therapy (i.e., additional therapy following consolidation) aims to improve the quality of remission, eliminate residual disease, delay relapse, and ideally extend survival. Initial studies focused on stimulation by IL-2 of immune effector cells such as tumor-specific cytotoxic lymphocytes and NK cells. Although IL-2 has demonstrated antileukemic activity in preclinical models, not one study applying low-dose IL-2 (high doses of IL-2 were not feasible because of drug-related toxicities) showed any improvement of DFS or OS. However, the combination of IL-2 plus histamine dihydrochloride did improve leukemia-free survival at 3 years when compared with a randomized observation cohort (40% vs. 26%; $P = .01$). The benefit was restricted to patients in first CR; OS was not extended.

HMA have been studied as maintenance therapy following remission induction, following consolidation therapy, and following allo HSCT. Azacitidine 50 mg/m^2/day for 5 days for up to 12 cycles improved the DFS of older AML patients following 2 cycles of induction therapy compared with observation (12-month DFS

64% vs. 42%); however, there was no improvement in OS with or without censoring at the time of subsequent allo HSCT. The ECOG 2906 study demonstrated improved OS ($P = .06$) with up to 1 year of decitabine maintenance therapy for older patients in first CR. However, the study was terminated before the accrual to the maintenance randomization could be completed. The HMA have also been evaluated as maintenance therapy following allo HSCT; however, the benefit has not yet been established.

CC-486 is an oral formulation of azacitidine with a distinct pharmacokinetic profile from parenteral azacitidine. The QUAZAR AML-001 study was an international, randomized trial of oral azacitidine for 14 consecutive days every 28 days versus placebo as maintenance therapy. Maintenance therapy was continued until relapse or unacceptable toxicity. Eligible patients were age 55 years or older and had achieved first CR with cytarabine- and anthracycline-based induction therapy. Eighty percent of patients had received between 1 and 3 cycles of consolidation. Subjects could not be candidates for allo HSCT in first remission. The median OS was increased from 14.8 months with placebo to 24.7 months with oral azacitidine. The benefit was due to a delay in relapse; the survival at 5 years was similar in the two treatment arms. The survival benefit was observed regardless of MRD status at study registration and number of consolidation cycles. The major toxicities of oral azacitidine included gastrointestinal adverse events (nausea, emesis, and/or diarrhea in 50% or more of subjects, improving over time) and myelosuppression (49% grade 3/4 neutropenia and 23% grade 3/4 thrombocytopenia). CC-486 is being evaluated as a maintenance therapy following allo HSCT.

Recent Advances in Intensive Therapy

Subsets of AML patients have been shown to benefit from specific modifications of intensive therapy. Currently, these subsets and modifications are defined by mutations (midostaurin for *FLT3* ITD or TKD mutations), clinical features (CPX-351 for AML-MRC and t-AML), and cytogenetic features (GO for CBF translocations). Clinical trials are evaluating the addition of investigational agents to intensive therapy in other subgroups, e.g., Menin inhibitors in *KMT2A* rearranged and *NPM1* mutated AML, and KIT inhibitors in CBF AML. Enasidenib and ivosidenib have been approved for the treatment of *IDH*-mutated AML. Identification of these patients requires knowledge of cytogenetic and molecular features at the time of AML diagnosis. However, cytogenetic and mutational assays currently require more time to complete than the assays for confirming the AML diagnosis (morphology and flow cytometry). There has been concern that this could result in a delay from diagnosis to therapy that may adversely affect survival. Two retrospective analyses have not shown any effect of the time from diagnosis to treatment on early mortality, remission rate, or OS. It is expected that advances in whole genome sequencing assays will shorten the turnaround time even further; the cost of NGS assays will likely continue to decrease over time as well.

Midostaurin for *FLT3*-mutated AML

Midostaurin (previously known as PKC412) is an inhibitor with a broad spectrum of activity against many protein kinases. Midostaurin is a type I inhibitor of FLT3 with activity against both ITD and TKD mutations as well as unmutated FLT3. As a single agent, midostaurin has minimal clinical activity in *FLT3*-mutated AML. Pre-clinical studies suggested synergistic activity of midostaurin in combination with chemotherapy. A phase IB study defined the optimal dosing schedule of midostaurin with 7+3, demonstrated an acceptable safety profile of the combination, and showed encouraging activity of midostaurin added to 7+3 in patients with *FLT3*-mutated AML.

The RATIFY trial, an international, double-blind, placebo-controlled, randomized phase III trial, established the benefit of adding midostaurin to induction and consolidation chemotherapy for *FLT3*-mutated AML patients ages 18 to 59 years. At preregistration, 3277 potential subjects were screened for *FLT3* ITD and tyrosine kinase domain (TKD) mutations by a PCR-based assay, and 717 *FLT3*-mutated AML patients (allelic ratio ≥0.05) were randomly assigned 1:1 to 7+3 induction and up to 4 cycles of HiDAC consolidation with either midostaurin or placebo. Midostaurin 50 mg was administered orally every 12 hours on days 8 to 21 of each cycle of induction and consolidation; placebo was given in the same dosing schedule as midostaurin. If in remission, patients received maintenance therapy with daily midostaurin or placebo for 1 year according to their initial treatment assignment. The primary endpoint of the study was reached. OS was significantly longer with the addition of midostaurin; the hazard ratio for death was 0.78, indicating a 22% reduction in the risk of death ($P = .009$). EFS was also significantly longer despite no apparent difference in the CR/Cri rate. At 4 years, 51% of patients were still alive in the midostaurin group compared with 44% with placebo. The survival benefit was observed in *FLT3* ITD high allelic ratio, low allelic ratio, and *FLT3* TKD subsets. The toxicities were similar except for higher rate of anemia and rash with midostaurin. Allo HSCT was performed in first remission in one quarter of study patients (similar number in both arms). The median OS had not been reached in either group, but there was a trend for improved survival with allo HSCT in the midostaurin compared with placebo group.

On April 28, 2017, the US FDA approved midostaurin in combination with daunorubicin and cytarabine induction and cytarabine consolidation therapy for newly diagnosed adult AML patients with *FLT3* ITD or TKD mutations. Based on the trial design, the independent benefit of midostaurin maintenance could not be established. Midostaurin became the first of nine drugs to be approved by the U.S. FDA between 2017 and 2021 for AML patients. Currently, more selective, second-generation FLT3 inhibitors (quizartinib, gilteritinib, and crenolanib) are being evaluated in phase III studies in combination with initial induction and consolidation therapy.

CPX-351 for t-AML and AML-MRC

CPX-351 is a liposomal formulation of cytarabine and daunorubicin at a fixed 5:1 molar ratio within 100-nm bilamellar liposomes. This formulation allows preferential delivery to the bone marrow and leukemic blasts of a maximally synergistic drug ratio that may enhance treatment efficacy. In a phase II randomized study of CPX-351 versus 7+3 in older patients with untreated AML, CPX-351 achieved significantly higher remission rates than standard 7+3; however, the EFS and OS were not better. However, in the subgroup with secondary AML, both EFS and OS were superior with CPX-351. This observation led to a pivotal, prospective, randomized phase III study of induction and consolidation with CPX-351 versus 7+3 followed by 5+2 in treatment-naïve AML patients ages 60 to 75 years and fit for intensive chemotherapy. The patients had either an antecedent MDS or CMML, prior leukemogenic therapy, or de novo AML with poor risk karyotype. The CR+Cri rate was higher with CPX-351 (47.4% vs. 33.3%, $P = .016$) without an increase in induction mortality. The median OS improved from 5.95 years with 7+3 to 9.56 years with CPX-351 (hazard ratio 0.69, $P = .003$). The survival benefit was observed even in patients ages 70 to 75 years. More subjects were able to proceed with allo HSCT following initial therapy with CPX-351 compared with 7+3. A survival analysis from the time allo HSCT favored CPX-351. CPX-351 was associated with delay in both neutrophil and platelet recovery in remission patients compared with those treated with 7+3. The 5-year survival rate was superior for patients treated with CPX-351 versus 7+3 (18% vs. 8%) as well as those patients undergoing allo HSCT (52% vs. 23%). Remarkably, the clinical benefit of CPX-351 over 7+3 chemotherapy was observed even though the total cumulative doses of both daunorubicin and cytarabine were lower with CPX-351, supporting the hypothesis that the fixed molar ratio as well as liposomal formulation targeting the marrow may be critical features.

On August 3, 2017, the US FDA approved liposomal daunorubicin/cytarabine for adults with newly diagnosed t-AML or AML-MRC. On March 30, 2021, the FDA expanded the approved population to patients with t-AML and AML-MRC ages 1 year and older based on safety data gathered from two studies including pediatric patients.

Addition of Gemtuzumab Ozogamicin to Intensive Therapy

CD33 is a cell surface antigen that is present in more than 80% of patients with AML but is absent from pluripotent hematopoietic stem cells. GO is a humanized anti-CD33 monoclonal antibody covalently linked to the DNA-binding cytotoxin, calicheamicin. As a single agent in relapsed/refractory AML patients, nearly 30% achieved either CR or CRp, resulting in accelerated approval by the U.S. Food and Drug Administration (FDA) in 2000. The major toxicities of GO are infusion reactions, myelosuppression, and hepatic toxicity, especially hepatic veno-occlusive disease / sinusoidal obstructive syndrome (VOD/SOS). The risk of VOD/SOS was shown to be related to dose (initially approved at 9 mg/m^2), schedule, and temporal proximity to allo HSCT especially with a myeloablative preparative regimen. In the randomized trial SWOG S0106, the addition of GO 6 mg/m^2 to 7+3 induction therapy failed to improve the survival of previously untreated younger AML patients. Induction mortality was also higher in the GO treatment arm. The results of the SWOG S0106 study led the FDA to revoke the approval in 2010, and GO was voluntarily withdrawn from the US market.

The ALFA 0701 study randomly assigned AML patients ages 50 to 70 years to receive or not a fractionated schedule of GO (3 mg/m^2 on days 1, 4, and 7) with 7+3 induction. The GO dose was capped at 5 mg (a single vial, which is now felt to deliver only 4.5 mg). Patients in remission received 2 cycles of consolidation with daunorubicin and cytarabine 1000 mg/m^2 every 12 hours on days 1 to 4. If randomly assigned to the GO arm, the patient also received a single dose of GO 3 mg/m^2 with each cycle. Hematologic toxicity (especially thrombocytopenia) was increased with GO but without increase in early mortality. There were three cases of hepatic VOD/SOS among the 139 patients in the GO arm. There was no difference in CR rate. The 2-year RFS was superior with the addition of GO to intensive induction and consolidation therapy (50.3% vs. 22.7%, $P = .0003$). At 5 years, there remained a significant improvement in EFS with GO; there was a trend for improved OS with GO.

A meta-analysis of 3325 patients treated in five randomized trials evaluating GO in combination with intensive chemotherapy (including SWOG S0106 and ALFA 0701) confirmed the potential benefit of GO in AML therapy. GO did not increase the remission rate. The 5-year OS is significantly improved by GO (34.6% vs. 30.7%, $P = .01$) due to reduction in the relapse rate. The survival benefit is most obvious in patients with favorable-risk CBF karyotypes (76.3% vs. 55.2%, $P = .0005$). There was also a benefit in the intermediate cytogenetic risk group (39.4% vs. 34.1%, $P = .007$). There was no benefit in the adverse cytogenetic risk group. Doses of 3 mg/m^2 are as effective as higher doses and were associated with fewer early deaths.

A single dose of GO 3 mg/m^2 was added to 1 cycle of induction and 1 cycle of intensification (consolidation) therapy for children, adolescents, and young adults with AML in the Children's Oncology Group AAML0531 study. GO improved the EFS and DFS due to a reduction in the risk of relapse; OS was not improved. A controversial correlate of this study was the demonstration that a CD33 gene splice site polymorphism, resulting in loss of the epitope for GO binding, negated the benefit of GO, even if the polymorphism was heterozygous.

Since CBF AML patients do not typically undergo allo HSCT in first CR, the risk of hepatic VOD/SOS is of lesser concern. The situation is more controversial in *NPM1* mutated patients. In the prospective, randomized AMLSG 09-09 trial, GO 3 mg/m^2 was added on day 1 of induction therapy with idarubicin, cytarabine, etoposide, and ATRA and day 1 of the first of 3 planned cycles of high-dose cytarabine and ATRA consolidation. Nearly 90% of the patients had de novo AML with normal karyotype; 75% were in the favorable ELN risk group. There was no benefit in the primary study endpoint, EFS. However, the cumulative incidence of relapse was significantly lower in the CR patients who had received GO. The benefit was offset by the higher early mortality (10.3% with GO vs. 5.7% without GO, $P = .05$), predominantly due to infection.

Based on the results of the meta-analysis as well as a trial of GO in older AML patients unfit for intensive chemotherapy (see Less Intensive Therapy), on September 1, 2017, the US FDA granted approval of GO in combination with daunorubicin and cytarabine for adults with newly diagnosed CD33 positive AML or for patients ages 2 years and older with relapsed/refractory AML. NCCN guidelines recommend the addition of GO to chemotherapy for CBF AML. Although the dose of GO with cytotoxic chemotherapy is capped at 3 mg/m^2 (4.5 mg maximum), the optimal GO schedule (one dose vs. three doses during induction therapy, number of doses over course of initial therapy) remains uncertain.

Less Intensive Therapy

The OS of AML patients is improved with therapy based on retrospective registry studies. LoDAC has improved the survival of older, unfit AML patients compared with BSC alone. The phase III EORTC-GIMEMA AML 19 trial demonstrated the survival benefit associated with single agent GO compared with BSC alone. Treatment-naïve AML patients ages 61 years and older were randomly assigned to receive GO 6 mg/m^2 on day 1 and 3 mg/m^2 on day 8 versus BSC alone. Patients achieving CR could receive up to 8 monthly doses of GO 2 mg/m^2. The median OS was significantly improved from 3.6 months with BSC to 4.9 months with GO. The benefit was restricted to patients without an unfavorable karyotype and those with higher CD33 expression. However, median survival remained very short (5 to 10 months) for older, unfit AML patients treated with LoDAC, GO, or HMA.

The cytotoxic agents, laromustine (an alkylating agent) and clofarabine, were evaluated in phase II studies of older AML patients felt to be unfit for intensive therapy. Clofarabine is a purine analog with activity in both AML and ALL patients; clofarabine is approved by the U.S. FDA for pediatric patients with relapsed/refractory ALL. The phase II study of clofarabine enrolled 112 treatment naïve AML patients age 60 and over with at least one of the following poor risk features: age ≥70 years, performance status 2, antecedent hematologic disorder, and intermediate or unfavorable risk. The 30-day mortality was 9.8%, overall response rate 46%, and median survival 41 weeks. The potential benefit of these two novel cytotoxic agents in these phase II studies was difficult to discern by comparison with historical controls; many of the subjects ultimately received intensive chemotherapy, further blurring the definition of the population. Clofarabine doubled the overall response rate compared with LoDAC (38% vs. 19%) in a randomized phase III study of 406 older AML (and high-risk MDS) patients unfit for intensive chemotherapy, but there was no improvement in OS. On the other hand, the survival of older patients, fit for intensive therapy, treated with clofarabine induction and consolidation was worse than those patients treated with 7+3 followed by HiDAC consolidation.

The outlook for older AML patients, unfit for intensive therapy, became brighter with the accelerated approval of the B-cell lymphoma-leukemia-2 (BCL2) inhibitor, venetoclax, in combination with azacitidine, decitabine, or LoDAC by the US FDA on November 21, 2018. BCL2 is an anti-apoptotic protein that is over-expressed in cells from patients with hematologic malignancies including AML. Earlier clinical trials investigating other BCL2 inhibitors failed to demonstrate any clinical benefit. Even venetoclax has limited single agent activity in AML patients. Thirty-two AML patients (30 relapsed/refractory, 2 treatment-naïve) were treated with venetoclax 800 mg orally once daily. The overall response rate was 19% (2 patients with CR, 4 with Cri). Among the 12 patients with *IDH1* or *IDH2* mutation, 4 (33%) achieved CR+Cri. The activity of venetoclax in *IDH*-mutated AML may be due to suppression of cytochrome c oxidase activity, which may lower the threshold for induction of apoptosis by BCL2 inhibition.

The concomitant inhibition of DNA methyltransferase and BCL2 synergistically induces apoptosis of AML cell lines. Based on this observation, as well as the need to improve outcomes for older AML patients being treated with HMA alone, a phase Ib study of either azacitidine or decitabine (physician choice) with venetoclax in 145 treatment-naïve, older, unfit AML patients was performed. The standard doses and schedules of azacitidine or decitabine were combined with venetoclax orally once daily on days 1 to 28 of a 28-day cycle. There was a short ramp-up of the venetoclax dose during cycle 1 to mitigate the risk of TLS. There was no laboratory or clinical evidence of TLS; however, patients were required to have a WBC count less than 25,000/μL (hydroxyurea could be used) at study entry and received TLS prophylaxis with allopurinol and IV fluids as an inpatient for the first cycle. The gastrointestinal toxicity was generally mild and did not result in discontinuation from study. The most common adverse events were cytopenias and infections, as expected in this population. The most common cause of dose interruption was neutropenia. The 30- and 60-day mortality were 5% and 11%, respectively. Based on hematologic and gastrointestinal toxicities with higher doses, the recommended venetoclax dose in combination with HMA was 400 mg once daily.

The overall response rate including CR, Cri, PR, and MLFS was 83%, and the median OS 17.5 months for the entire study population. The median time to first response was only 1.2 months. The CR+Cri rate was 73% in those patients treated at venetoclax 400 mg daily with HMA; response rates were similar with azacitidine and decitabine. The median OS for azacitidine with venetoclax 400 mg daily had not been reached; the median OS for decitabine with venetoclax 400 mg daily was 14.2 months. The CR+Cri rate was 67% in both the de novo and secondary AML subsets; however, it should be noted that patients with an antecedent myeloid neoplasm could not have received an HMA prior to study entry. Even in the *TP53*-mutated subset, the CR+Cri rate was 47%, although the median duration of response was only 5.6 months and median OS only 7.2 months. On the other hand, more than 72% of patients with *FLT3* mutation responded. The *NPM1* mutation predicted superior outcomes in multivariate analysis; the CR+Cri rate was 92% in *NPM1* mutated AML, and median OS had not been reached.

The results from this multicenter phase Ib study compared favorably with the prior reports of HMA alone in this population. An international, randomized, placebo-controlled, double-blind phase III study was launched comparing azacitidine 75 mg/m^2/day for 7 days with either venetoclax 400 mg orally once daily on days 1 to 28 with dose ramp-up during the first 3 days of cycle 1 of a 28-day cycle or placebo in the same schedule. Subjects were randomly assigned 2:1 to azacitidine/venetoclax (AZA/VEN, n = 286) or azacitidine/placebo (AZA/PLA, n = 145). The dose of venetoclax was increased from 100 mg on day 1, to 200 mg on day 2, to the final dose of 400 mg daily during cycle 1. Eligible patients had to be either 75 years of age or older or have a significant comorbidity precluding the use of intensive chemotherapy (congestive heart failure, left ventricular ejection fraction 50% or less, unstable angina, diffusing capacity of the lung for carbon monoxide 65% or less, forced expiratory volume in 1 second 65% or less, or ECOG performance status 2 or 3). The WBC count had to be less than 25,000/μL at study entry. Patients with a favorable risk karyotype, and those receiving prior HMA or other chemotherapy for MDS were excluded. The primary endpoint of the study was reached. The median OS was 14.7 months with AZA/VEN and 9.6 months with AZA/PLA; the hazard ratio for death was 0.66. Key secondary endpoints for AZA/VEN versus AZA/PLA were CR+Cri rate 66.4% versus 28.3%, median time to first response 1.3 versus 2.8 months, median duration of CR+CRi 17.5 versus 13.4 months, and CR+CRh 64.7% versus 22.8%, respectively. Remarkably, the rate of CR+Cri and the median OS in the control arm were very similar to these outcomes with azacitidine alone in the AML-001 study a decade. Thirty-day mortality was similar in the two groups (7% AZA/VEN vs. 6% AZA/PLA). Three patients (less than 1%) treated with AZA/VEN had laboratory evidence of TLS. There were no new safety signals with hematologic and mild gastrointestinal adverse events being the most common. Importantly, more patients required dose interruptions due to neutropenia in the AZA/VEN arm.

Venetoclax was also evaluated in combination with LoDAC in 82 treatment-naïve AML patients unfit for intensive therapy. In this phase I/II study, venetoclax 600 mg once daily on days 1 to 28 with dose ramp-up in the first 4 days was determined to be the optimal dose in combination with cytarabine 20 mg/m^2 by subcutaneous injection once daily on days 1 to 10 (LoDAC/VEN). Treatment was continued every 28 days until disease progression or unacceptable toxicity. TLS precautions were identical to those of the HMA/VEN study. Patients previously treated with HMA for MDS were eligible (29% had prior HMA); otherwise, the inclusion criteria were similar to those of the HMA/VEN phase I/II study. The median age was 74 years (range, 57 to 90 years old). The CR/CRi rate was 54% for the entire population, and 62% for those without prior HMA exposure. The median time to first CR or CRi was only 1.4 months. The median OS was 10.1 months. The toxicities were similar to those of the HMA/VEN combination.

Treatment-naïve AML adult patients unfit for intensive chemotherapy were treated with LoDAC with either venetoclax 600 mg or placebo once daily on day 1 to 28 in an international, randomized, double-blind, phase III study. There was a 25% reduction in the risk of death with LoDAC/VEN (P = .11). With further follow up, the improvement in survival became statistically significant (median OS, 8.4 vs. 4.1 months, P = .04). The response rate was higher with LoDAC/VEN (CR/Cri, 48% vs. 13%) in the entire population, as well as across cytogenetic and mutational subsets. Patients were more likely to become transfusion independent with LoDAC/VEN. The 30-day mortality was similar in both treatment arms (13% LoDAC/VEN, 16% LoDAC/PLA).

The combinations of azacitidine, decitabine, or LoDAC with venetoclax are the current standard of care for older AML patients unfit for intensive therapy. There are several important management issues to consider, including drug-drug interactions, TLS management, and management of the expected myelosuppression, that are beyond the scope of this chapter. Practical advice regarding management of AML patients receiving HMA or LoDAC with venetoclax has been published by investigators with extensive experience with these regimens. Some have argued that the HMA/VEN combination should become the new standard of care for all older adults with AML regardless of fitness. For example, the outcomes of patients treated with either decitabine (10 days during induction, 5 days with subsequent cycles) plus venetoclax (DEC/VEN) or intensive chemotherapy including cytarabine ≥1 g/m^2/dose (IC) were compared. The patients were matched by a treatment-related mortality score and other prognostic features. The median age was 72 years in the DEC/VEN cohort (range 69 to 78 years) and 73 years (67 to 76 years) in the IC group. The DEC/VEN combination was associated with higher rate of CR+CRi (81% vs. 52%), lower relapse rate (34% vs. 56%), lower 30-day mortality (1% vs. 24%), and longer median OS (12.4 vs. 4.5 months). The superior outcomes with DEC/VEN compared with IC were also seen in those patients with low treatment-related mortality scores. Nonetheless, there are older AML patients who may be cured of their disease with a time-limited IC approach.

The Hedgehog pathway is important in normal embryonic development. The Hedgehog pathway proteins have been shown to be overexpressed in AML, and activity of the Hedgehog pathway appears to enhance the survival of leukemic stem cells. Therefore, the Hedgehog pathway has been identified as a potential therapeutic target in AML. Glasdegib is an orally bioavailable antagonist of Smoothened, a cell surface protein in the Hedgehog pathway. Glasdegib demonstrated an acceptable safety profile and preliminary evidence of efficacy as a single agent or in combination with chemotherapy in patients with myeloid neoplasms.

The combination of LoDAC with glasdegib 100 mg orally once daily continuously was evaluated in patients with AML (and high-risk MDS) age 55 years and older, and not candidates for intensive therapy based on age 75 years or older or specified organ dysfunction. Subjects were randomly assigned 2:1 to the combination versus LoDAC alone. The assignment was not blinded, and there was no placebo. The median survival was improved from 4.9 months with LoDAC alone to 8.8 months with LoDAC/glasdegib. The survival benefit was only observed in those with intermediate risk karyotype, not adverse risk karyotype. The CR rate was 17.0% with LoDAC/glasdegib versus 2.3 % with LoDAC alone. Subjects receiving glasdegib were more likely to report alopecia, muscle cramps, dysgeusia, anorexia, nausea, emesis, and constipation; they were also more likely to report grade 3/4 fatigue.

Based on the results of this randomized phase II study, on November 21, 2018, the US FDA approved glasdegib in combination with low-dose cytarabine for treatment-naïve AML patients age 75 years or older or with comorbidities precluding use of intensive chemotherapy.

The IDH1 inhibitor ivosidenib and IDH2 inhibitor enasidenib have been approved for relapsed / refractory, *IDH*-mutated AML (see section of Salvage Therapy for Relapsed/Refractory AML). However, both were evaluated as initial therapy for patients unfit for intensive therapy in the phase I study that resulted in initial FDA approval. Thirty-four patients with *IDH1*-mutated AML were treated in a cohort of the phase I study at the maximally tolerated dose, 500 mg orally once daily. The median age of this patient cohort was 76.5 years, 76% had secondary AML, and 47% had received a prior HMA for an antecedent hematologic disorder. The CR+CRh rate was 42.4%, and median OS 12.6 months. Ivosidenib 500 mg daily continuously was evaluated in combination with azacitidine 75 mg/m^2/day for 7 days every 28 days in 23 adults with newly diagnosed, *IDH1* mutated AML ineligible for intensive therapy (median age 76, range 61 to 88 years). The overall response rate was 78.3%, and CR rate 60.9%. The 12-month survival was 82%.

Thirty-nine patients with *IDH2*-mutated AML were treated in a cohort of the phase I study at the maximally tolerated dose, 100 mg of enasidenib orally once daily. The median age was 77 years, and 59% had an antecedent hematologic disorder. The overall response rate was 30.8%, CR rate 18%, and median survival 11.3 months. Older, treatment naïve, *IDH2*-mutated AML patients ($n = 60$) were treated with single agent enasidenib in a sub-study of the BEAT AML program. The CR+Cri was 47% (37% CR), and median survival was 24.4 months. Azacitidine was added to the enasidenib in 17 patients with inadequate response following 5 cycles of enasidenib monotherapy; 41% achieved CR or Cri. The combination of azacitidine and enasidenib (AZA/ENA) was compared with azacitidine alone in a randomized, open label study of newly diagnosed *IDH2*-mutated AML patients ineligible for intensive chemotherapy (median age 75, range 57 to 85 years). The overall response rate (CR+Cri+PR+MLFS) was significantly higher with AZA/ENA compared with AZA alone (71% vs. 42%). The CR rate was also higher (53% vs. 12%), and the median duration of response was longer (24 vs. 12 months) with AZA/ENA versus AZA alone.

The toxicities of ivosidenib and enasidenib (including IDH Differentiation Syndrome [DS]) in newly diagnosed older AML patients were similar to those observed in relapsed/refractory AML. On May 2, 2019, the US FDA approved ivosidenib for newly diagnosed, *IDH1*-mutated AML patients age 75 years or older or those with comorbidities that preclude intensive chemotherapy. The NCCN AML Practice Guidelines list ivosidenib and enasidenib as therapeutic options for newly diagnosed, *IDH1*- and *IDH2*-mutated AML patients who are not candidates for intensive therapy.

Salvage Therapy for Relapsed/Refractory Acute Myeloid Leukemia

Most patients with AML relapse and do so within the first year following achievement of remission. In an analysis of 1069 consecutive AML patients in first CR who were treated and followed at the MD Anderson Cancer Center, the risk for treatment failure during the first year was 69%, 38% in the second year, 17% in the third year, and less than 10% in both the fourth and fifth years. The risk of AML relapse also declines over time following allo HSCT. In an analysis of 1265 patients with relapsed AML following allo HSCT, the median time to relapse was 6.1 months, and less than one per 100 patient-years relapsed after 3 years. The survival following AML relapse post allo HSCT was 19% at 2 years. It is reasonable to consider patients cured if in first CR for at least 3 years.

The prognosis for AML patients following relapse remains poor, but outcomes are variable. An important predictor for prognosis is the duration of first remission. In a study of 243 patients with AML in first relapse, the likelihood of CR was 60% if the duration of first remission exceeded 2 years and 19% if it was shorter than 1 year. In a multivariate analysis of 667 adult patients less than age 60 years in first relapse, a prognostic score was derived from four clinical parameters (duration of first remission, karyotype at diagnosis, age at relapse, and previous HSCT or not). The model identified three risk groups: (a) favorable group: CR 85% and 5-year OS 46%; (b) intermediate group: CR 60% and 5-year survival 34%; (c) poor risk group: CR 18% and 5-year survival 4%. The largest group of patients had poor risk disease (455 of the 667 patients). In another prognostic model for relapsed/refractory AML, first remission less than 12 months, *FLT3* ITD mutation, and high-risk cytogenetics were independent adverse prognostic factors for OS and EFS. Three subgroups with different outcomes at 2 years were identified: (a) favorable (no adverse features): OS 58%, EFS 45%; (b) intermediate (1 adverse factor): OS 37%, EFS 31%; (c) poor (≥2 adverse factors): OS 12%, EFS 12%. Prognosis is worse for patients after more than one salvage attempt; 1-year survival probabilities vary between 2% and 24%. Patients with primary refractory disease following at least 1 cycle of HiDAC-based induction therapy do equally poorly, with a subsequent CR rate of 22%, median CR duration of around 9 months, and survival of 3.8 months. The outcome of patients with relapse following HMA plus venetoclax is also very poor. The median survival of patients with either relapse following or refractory to first-line HMA plus venetoclax was only 2.4 months.

The only potentially curative therapeutic approach for patients with rel/ref AML is to recapture a remission with sufficient reduction of disease burden to then proceed with allo HSCT. For example, 66% of 1535 AML patients treated with intensive chemotherapy alone relapsed. A second CR could be achieved in half, and 3-year OS was 30%. Achievement of second CR, salvage allo HSCT, and first remission duration ≥1 year were independent prognostic factors. Allo HSCT in second CR was associated with superior 3-year survival compared with no HSCT (44% vs. 14%, $P = .001$). The Center for International Blood and Marrow Transplant Research (CIBMTR) evaluated the outcome of 1673 AML patients following allo HSCT for primary induction failure and first relapse. The 3-year OS was 19%. Five adverse risk factors were identified: first CR duration less than 6 months, peripheral blood blasts, donor other than HLA identical sibling, Karnofsky score less than 90%, and adverse risk karyotype. The 3-year OS was 42% if the score was 0, but only 6% for score ≥3. Those with primary refractory AML had a 3-year survival of 16%. Nonetheless, outcomes remain superior to non-transplant therapies across all scenarios.

AML refractory to initial intensive chemotherapy is not uncommon. In an analysis of 3324 adult AML patients treated with idarubicin, cytarabine, and etoposide induction therapy between 1993 and 2009, 31% had primary refractory disease; 845 had disease refractory to the first cycle, and another 180 relapsed after the second induction cycle. The CR/CRi rate was highest in those proceeding directly to allo HSCT compared with intensive chemotherapy. However, the 5-year survival was best for those undergoing allo HSCT in remission (48%) compared with those who proceeded to HSCT directly (36%) or with persistent AML after salvage chemotherapy (25%).

There is no one standard salvage chemotherapy regimen. An intensive chemotherapy regimen is most likely to benefit patients with favorable prognostic features at relapse. Commonly used intensive regimens include combinations of high-dose cytarabine, etoposide, idarubicin, and mitoxantrone. The response rates observed in the early reports of HiDAC-based salvage regimens such as mitoxantrone, etoposide, and cytarabine (MEC) were encouraging, but likely affected by the absence of high-dose cytarabine in the initial therapy of AML patients prior to 1990. The purine analogs (fludarabine and cladribine) administered prior to high-dose cytarabine will increase the intracellular accumulation of ara-CTP. This pharmacokinetic interaction has formed the basis of regimens such as cladribine, cytarabine, G-CSF, and mitoxantrone (CLAG-M) and fludarabine, cytarabine, G-CSF, and idarubicin (FLAG-Ida). Intensive regimens are associated with significant mucositis and treatment-related mortality. The goal of intensive chemotherapy must be carefully considered.

Although randomized clinical trials have been completed comparing different salvage chemotherapy regimens, none of these studies have resulted in the adoption of a clearly superior salvage regimen as standard of care. The outcomes reported in these clinical trials are more likely related to the patient characteristics (e.g., first CR duration, number of prior relapses, age, prior or subsequent allo HSCT, cytogenetics) than to any substantial differences in the biologic activity of the chemotherapy regimens. One international, multicenter trial randomized 326 patients ≥55 years of age with relapsed and refractory AML to cytarabine 1 g/m^2 daily for 5 days with or without clofarabine 40 mg/m^2/day for 5 days. CR rate and EFS were superior in the combination arm, but survival was not improved. In another multicenter study 711 adult patients with first relapse or refractory AML were randomly assigned to cytarabine 1 g/m^2 daily for 5 days with or without vosaroxin, a first-in-class anticancer quinolone derivative. There was no increase in early mortality, and the combination arm achieved significantly higher CR rates (30.1% vs. 16.3%, $P = .00001$). There was a trend for a survival benefit that appeared significant for those subjects age ≥ 60 years and those with early relapse. The apparent response benefit with the addition of either clofarabine or vosaroxin was questioned, since many leukemia experts felt the control arm was a suboptimal salvage regimen.

Although currently only approved for treatment-naïve AML patients unfit for intensive therapy, HMA with the BCL2 inhibitor venetoclax has been evaluated as a salvage regimen for patients with relapsed/refractory AML. Fifty-five patients with relapsed/refractory AML were treated with decitabine 20 mg/m^2 daily for 10 days (the duration was decreased to 5 days with subsequent cycles) with venetoclax 400 mg once daily for 28 days. The median age was 62 years, and 35% were age ≥70 years. The median number of prior therapies was 2 (range, 1 to 3). Seventy-six percent had received prior intensive chemotherapy, 22% had received both intensive chemotherapy and HMA, and 33% had prior allo HSCT. The rate of CR+CRi was 42%; another 18% achieved MLFS. Fourteen of 36 patients with adequate marrow samples were negative for MRD by flow cytometry. The median survival was 7.8 months.

CD33 is a cell surface antigen present on AML blasts in more than 80% of patients but is absent from pluripotent hematopoietic stem cells. GO is a humanized, murine anti-CD33 monoclonal antibody covalently linked to the DNA-binding cytotoxin, calicheamicin. The antibody-drug conjugate is internalized upon binding to CD33, transported to the lysosome, where the linker is hydrolyzed, releasing calicheamicin. Calicheamicin then binds to double-strand DNA, causing double-strand DNA breakage and apoptosis. Patients with AML in first relapse ($n = 277$) were treated with GO 9 mg/m^2 on three separate phase II studies. The rate of CR+CRp was 26%. Sixteen percent died within 30 days of GO. Infusion reactions, myelosuppression, and hepatic toxicity were among the most frequently observed toxicities. Hyperbilirubinemia was observed in 29%, and 5% of patients developed hepatic SOS. However, only 0.9% developed hepatic SOS, if they did not previously or subsequently undergo allo HSCT. Hepatic SOS developed in 8 of 46 patients who underwent allo HSCT in second CR after GO; 5 of 27 patients with relapsed AML following prior HSCT developed SOS with salvage GO. GO has been safely combined at lower doses (3 mg/m^2) with salvage chemotherapy. However, it is not clear how to best incorporate GO into the treatment of patients with relapsed/refractory AML.

The first-generation FLT3 inhibitors have minimal efficacy in *FLT3*-mutated AML as single agents. The first-generation, type I FLT3 inhibitor lestaurtinib was evaluated in combination with intensive salvage chemotherapy (MEC or HiDAC) in a randomized trial of patients with *FLT3*-mutated AML in first relapse. There was no benefit of lestaurtinib in terms of response or OS. However, it is instructive to note the low response rates in either arm (CR+CRp: 21% with chemo alone versus 26% with chemo plus lestaurtinib). Increased production of the FLT3 ligand as well as variability in the lestaurtinib plasma concentration (as measured by a pharmacodynamic plasma inhibitory assay) may account for the lack of observed benefit.

Higher single-agent activity (including objective remissions) has been observed with the more potent and selective second-generation FLT3 inhibitors, quizartinib, gilteritinib, and crenolanib. For example, 194 patients with relapsed/refractory *FLT3*-mutated AML received single agent gilteritinib on a phase I/II study. Gilteritinib demonstrated potent inhibition of the FLT3 tyrosine kinase at doses ≥80 mg once daily. The rate of CR+Cri+CRp in patients receiving greater than 80 mg daily was 41%. Gilteritinib was well tolerated; the adverse event profile was as expected in patients with active AML. Four percent developed QTc prolongation greater than 500 ms. There have been reports of DS with gilteritinib. Based on the efficacy, toxicity, and pharmacodynamic data, the recommended phase II dose was 120 mg once daily.

Patients with first relapse or primary refractory *FLT3*-mutated AML were randomly assigned to single agent gilteritinib 120 mg orally once daily ($n = 247$) versus salvage chemotherapy ($n = 124$). The investigator could treat the patient with intensive chemotherapy (FLAG-IDA, MEC) or less intensive therapy (azacitidine or LoDAC). The primary endpoint of the study was achieved; the median survival was longer with gilteritinib (9.3 vs. 5.6 months, hazard ratio for death = 0.64, $P = .001$). More patients achieved a remission with gilteritinib: CR 21.1% versus 10.5%; CR+CRh 34.0% versus 15.3%; CR+CRi+CRp 54.3% versus 24.8. More patients were able to undergo allo HSCT following gilteritinib (25.5% vs. 15.3%). Those patients who restarted gilteritinib following allo HSCT had a better survival than those who did not. Based on the results of the ADMIRAL trial, on November 28, 2018 the U.S. FDA approved gilteritinib for patients with relapsed or refractory *FLT3*-mutated AML.

Quizartinib is a second-generation, type II FLT3 inhibitor. Quizartinib only inhibits FLT3 with an ITD mutation, not TKD-mutated *FLT3*. A series of phase I and II studies established an effective and safe dose of quizartinib. Quizartinib was compared with salvage chemotherapy for patients with first relapse or primary refractory *FLT3* ITD mutated AML. The median OS was longer with quizartinib: 6.2 versus 4.7 months ($P = .02$). Although not approved in the United States, quizartinib has been approved in Japan. Crenolanib, a second-generation, type I FLT3 inhibitor, is clinically effective for *FLT3* ITD- and D835-mutated and is being evaluated in both treatment-naïve and relapsed/refractory *FLT3*-mutated AML.

FLT3 mutations may be acquired at the time of disease relapse. Presentation with leukocytosis at the time of relapse, especially if not present at initial diagnosis or previous relapse, may indicate the acquisition of a *FLT3* mutation by the leukemic progenitor cells. Therefore, it is strongly recommended to evaluate for *FLT3* mutation at the time of AML relapse or for chemotherapy-refractory AML. Resistance to FLT3 inhibitors is not uncommon. *FLT3* ITD-mutated AML patients treated with a type II FLT3 inhibitor frequently have *FLT3* TKD mutations at the time of resistance. On the other hand, mutations in the *RAS/MAPK* pathway are associated with resistance to the type I FLT3 inhibitors.

Somatic mutations in the genes for isocitrate dehydrogenase isoforms 1 and 2 (IDH1 and IDH2) are gain of function mutations that result in accumulation of the oncometabolite R-2-hydroxyglutarate. The mutations are identified in 20% of AML patients and are typically mutually exclusive; *IDH2* mutations are more common. R-2-hydroxyglutarate (2-HG) is a competitive inhibitor of several histone and DNA demethylating enzymes. High levels of 2-HG lead to epigenetic changes and impaired cellular differentiation. Ivosidenib is a selective, potent, and orally bioavailable inhibitor of IDH1 with an R132 missense mutation. Enasidenib is a selective, potent, and orally bioavailable inhibitor of mutant IDH2 with either R140 or R172 missense mutation. Ivosidenib and enasidenib have minimal activity against the unmutated IDH1 and IDH2, respectively.

Enasidenib was evaluated in a phase I/II study of 176 relapsed/refractory, *IDH2*-mutated AML. The overall response rate (CR + Cri + PR = MLFS) was 40.3%, and the CR rate was 19.3%. The median time to first response was 1.9 months; 87% achieved the first response by cycle 5. The median response duration was 5.8 months, median OS was 9.3 months, and the 12-month OS was 39%. The most notable toxicities were DS (10%), leukocytosis, and indirect hyperbilirubinemia. The approved enasidenib dose is 100 mg orally once daily. Ivosidenib was evaluated in a separate phase I/II study of 179 relapsed/refractory, *IDH1*-mutated AML. Among the 125 patients receiving the recommended phase II dose (500 mg orally once daily), CR or CRh was achieved in 30.4% with CR in 21.6%. Clearance of the *IDH1* R132 variant by PCR analysis was achieved in 7 of the 34 CR/CRh patients. The median duration of CR or CRh was 8.2 months. The most notable toxicities were DS, leukocytosis, and QT prolongation.

The symptoms and signs of IDH-differentiation syndrome (IDH-DS) include dyspnea, hypoxia, fever, weight gain, edema, unexplained hypotension, bone pain, and acute renal failure. Chest radiographic imaging often demonstrates pulmonary infiltrates, pleural effusions, and/or pericardial effusion. IDH-DS is frequently associated with leukocytosis. The incidence of IDH-DS in patients with relapsed/refractory AML treated with ivosidenib and enasidenib ranges from 11% to 14% of patients. When suspected, IDH-DS is treated with dexamethasone 10 mg IV twice daily and patients are observed closely until resolution of the symptoms and signs. Approximately half of patients with IDH-DS received corticosteroid therapy and continue therapy without interruption. If associated with severe pulmonary symptoms and/or renal dysfunction lasting more than 48 hours after corticosteroid treatment is initiated, the IDH inhibitor is withheld until symptoms improve. Symptoms may not resolve immediately. Due to the prolonged half-life of enasidenib and ivosidenib, drug treatment interruption is not an alternative to dexamethasone therapy.

IDH-DS remains a clinical diagnosis; there is no laboratory test that will confirm the diagnosis. However, the signs and symptoms can overlap significantly with those of disease progression, leukostasis, and pulmonary infection. Since CR is only achieved in the minority of *IDH*-mutated AML patients treated with IDH inhibitors, and since IDH-DS does not necessarily predict for subsequent achievement of CR, the distinction between IDH-DS and disease progression with leukostasis, pulmonary infiltration, or pneumonia can be challenging. In practice, when IDH-DS is suspected, the patient will be treated with dexamethasone, antibiotics, and hydroxyurea for leukocytosis. Rapid clinical improvement with steroids and/or the presence of granulocytic precursors in the peripheral blood are consistent with the IDH-DS and are helpful clues when present.

Serial bone marrow samples indicate that the responses are achieved by differentiation; marrow aplasia is not observed. The 2-HG levels decline with therapy but do not predict response. The *IDH1* or *IDH2* variant allelic frequency does not predict response. However, the presence of a greater mutational burden is associated with lower response rates, as is the presence of *FLT3* mutations, *RAS* mutations, and other *MAPK* pathway mutations.

Enasidenib was approved for *IDH2*-mutated, relapsed/refractory AML by the U.S. FDA on August 1, 2017. Ivosidenib was approved for *IDH1*-mutated, relapsed/refractory AML by the US FDA on July 20, 2018. Since these inhibitors were approved based on the results of single arm, open label clinical trials, it remains uncertain which relapsed/refractory, *IDH*-mutated AML patients should be treated with an IDH inhibitor, and which should receive salvage chemotherapy. As indicated, responses with enasidenib and ivosidenib often do not occur quickly, and response rates are low in the presence of *RAS*/*MAPK* pathway and *FLT3* mutations. Enasidenib was compared to salvage chemotherapy (LoDAC, azacitidine, intermediate dose cytarabine) for *IDH2* mutated AML following two or three prior lines of therapy. The response rates were higher with enasidenib (CR + Cri, 29.7% vs. 6.2%), but EFS and OS were similar. Nonetheless, the IDH inhibitors provide an effective oral therapeutic option, especially for those who are not necessarily candidates for curative therapy (i.e., allo HSCT). Both ivosidenib and enasidenib may result in transfusion independence, even in patients who did not experience a morphologic leukemia free state.

ACUTE PROMYELOCYTIC LEUKEMIA

APL is a rare subtype (approximately 10% of all AML diagnoses) with unique pathophysiologic, clinical, and therapeutic features. The median age at diagnosis (40 years) is younger than for other types of AML; APL occurs more frequently in Hispanics and the obese. APL was first recognized as a separate clinical subtype of AML based on the promyelocytic morphology and the rapidly fatal course due to hemorrhage associated with fibrinolysis. Now, if diagnosed promptly and managed appropriately, APL has the most favorable prognosis of all types of AML. Nevertheless, catastrophic bleeding events, due to coagulopathy and thrombocytopenia, may still result in high early mortality (in some reports 20% to 30%, typically in those with leukocytosis at presentation). In 80% of the cases, APL cells are hypergranular with Auer rods (see Fig. 60.6 D and E). Blasts with multiple Auer rods, also known as faggot cells, are commonly observed in this subtype. A microgranular variant (M3v) is often associated with leukocytosis (see Fig. 60.6E). The nuclei of APL blasts have characteristic features including two lobes separated by an isthmus, two overlapping nuclei (sliding plates), or butterfly shape. The APL cells are strongly positive for MPO and CD33, and lack expression of the stem cell markers, CD34 and HLA-DR. The *FLT3* ITD mutation is present in 25% of APL patients and is often associated with leukocytosis at presentation and M3v morphology. However, unlike other AML subtypes, the presence of the *FLT3* ITD is not an independent predictor of increased risk of relapse in APL with current therapy. However, the induction mortality may be higher in this subset given the association of *FLT3* mutation with leukocytosis and risk of hemorrhagic death. FLT3 inhibitors are not included in APL treatment.

APL is almost always the result of the translocation t(15;17)(q24.1;21.1) (Chapter 57), which fuses the retinoic acid receptor alpha (*RARA*) gene on the long arm of chromosome 17 with the promyelocytic leukemia (*PML*) gene on the long arm of chromosome 15. In rare cases (<5%) translocation partners other than *PML* result in alternative fusion genes (e.g., *PLZF-RARA*, *NPM1-RARA*, *NuMA-RARA*, *STAT5b-RARA*, *BCOR-RARA*), which often convey resistance to all trans-retinoic acid (ATRA). The *PLZF-RARA* fusion is clearly resistant to ATRA therapy; the others are very uncommon. PML-RARA is an abnormal retinoic acid (RA) receptor that represses transcription of RA-activated target genes by recruiting large protein complexes through the coiled-coil domain of PML, which in turn act as potent transcriptional corepressors. Pharmacologic doses of RA release the corepressors and allow recruitment of coactivators, resulting in the transcription of previously silenced genes. This leads to a sudden arrest in proliferation and a differentiation response that can be seen in vitro and in vivo within a few days following administration of ATRA (Fig. 60.17). APL is the most dramatic example of the success of differentiating therapy.

Prior to the use of ATRA, the anthracyclines were seen as the most active agents in APL and were used as single agents or in combination with cytarabine. The treatment of APL began to diverge from that of other AML subtypes following the initial report of the clinical activity of ATRA in a study from China. Twenty-three of 24 APL patients, eight of whom had disease resistant to prior chemotherapy, achieved either PR or CR with oral ATRA alone given over 30 to 90 days. The single agent efficacy of ATRA was confirmed by groups in North America and Europe. ATRA has a dramatic effect on the coagulopathy, substantially reducing the risk of serious bleeding events, and should be instituted immediately upon suspicion of a diagnosis of APL, even before confirmatory assay results are available. However, continuation of single agent ATRA does not result in long-term DFS due to inevitable relapse. ATRA resistance may be due to increased metabolism of the drug over time, mutations in the *PML-RARA* ligand-binding domain, acquisition of *FLT3* ITD, and/or additional chromosomal abnormalities.

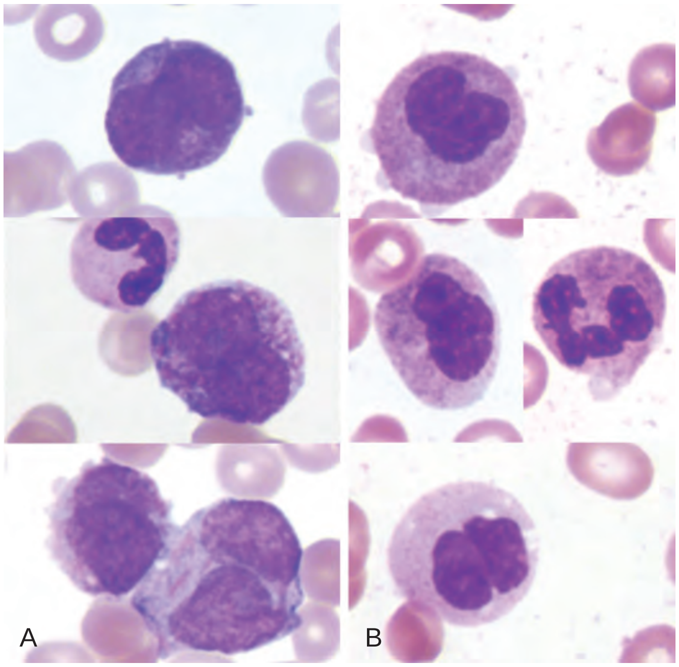

Figure 60.17 EFFECT OF ALL-TRANS RETINOIC ACID THERAPY ON ACUTE PROMYELOCYTIC LEUKEMIA CELLS. All-trans retinoic acid (ATRA) therapy in acute promyelocytic leukemia (APL) causes the malignant promyelocytes (A) to differentiate, and the effects of differentiation can be seen within days of treatment (B). The differentiated APL cells are still somewhat atypical, frequently with bilobed nuclei (compare with normal neutrophil [B, *inset center right*]).

ATRA induces differentiation of APL blasts in patients. ATRA therapy has been associated with the APL DS. APL DS was initially called "retinoic acid syndrome" until it was realized that the syndrome also occurs with the use of arsenic trioxide (ATO) (see below). DS was described in 10% to 25% of patients treated with single agent ATRA. DS can occur within a few days of the start of therapy and has features of a capillary leak syndrome. DS is a clinical diagnosis based on the occurrence of fever, dyspnea, hypoxemia, pulmonary infiltrates, pleural / pericardial effusions, weight gain, peripheral edema, hypotension, and renal and/or hepatic dysfunction. DS carries a high mortality unless recognized and managed promptly. Therapy consists of immediate administration of steroids (dexamethasone 10 mg intravenously twice daily until resolution of signs and symptoms). This intervention will rapidly reverse the manifestations of DS and has substantially reduced mortality to below 5%. If there is no response, or in the case of life-threatening complications, APL treatment should be interrupted. The potential benefit of prophylactic steroids with any APL differentiating therapy is unclear, and the use of prophylactic prednisone, methylprednisolone, or dexamethasone remains controversial. APL DS will not occur during post-remission therapy.

Women of childbearing potential must be warned of the teratogenic effects of ATRA. Other toxicities associated with ATRA include headache, xerosis, mucosal dryness, rash, hypertriglyceridemia (and risk of acute pancreatitis), and hepatic toxicity. Pseudotumor cerebri may occur. Persistent, severe headache with signs of increased intracranial pressure, such as nausea and emesis, should prompt a dilated fundoscopic examination for papilledema. Lumbar puncture can be diagnostic and therapeutic. Acetazolamide is typically prescribed for pseudotumor cerebri, while ATRA is held.

Subsequent clinical studies confirmed significantly better DFS with the combination of ATRA plus chemotherapy. The North American Intergroup study demonstrated superior DFS with ATRA induction, daunorubicin/cytarabine consolidation, followed by ATRA maintenance compared with standard AML induction and consolidation chemotherapy alone (5-year DFS 74% vs. 16%). In the French APL 93 trial, concurrent administration of ATRA with chemotherapy in APL patients with WBC count less than 5000/μL and age ≤ 65 years achieved CR rates of 94%. The relapse rate at 2 years was lower with concurrent (6%) compared with sequential administration (16%, $P = .04$). As standard induction therapy for patients with APL evolved, the combination of ATRA with an anthracycline (daunorubicin or idarubicin) became the standard of care. The role of non-anthracycline agents in ATRA-based therapy was called into question by a comparison of two large trials from Italy (GIMEMA) and Spain (PETHEMA). Both study groups used the same induction [ATRA and idarubicin (AIDA)] and maintenance regimens. However, the GIMEMA consolidations included cytarabine, etoposide, and thioguanine with an anthracycline, whereas the PETHEMA trial only used idarubicin and mitoxantrone during consolidation. The 3-year RFS was not significantly different (90% vs. 86%). A risk-stratification model was proposed based on WBC and platelet count. High risk was defined as a WBC greater than 10,000/μL at diagnosis with significant differences in RFS between patients with high- and those with intermediate- or low-risk disease.

Nonetheless, the role of cytarabine in APL therapy remained controversial. The European APL Group evaluated ATRA/daunorubicin +/−cytarabine during induction followed by daunorubicin +/−cytarabine consolidation (ATRA was omitted from consolidatio n in both arms) in younger, low-/intermediate-risk APL. The CR rates were comparable, but the risk for relapse was increased when cytarabine was omitted from both induction and consolidation (2-year risk of relapse 4.7% vs. 15.9%). On the other hand, in the MRC15 trial daunorubicin, cytarabine, etoposide, and ATRA was compared with the AIDA induction regimen. There was no difference in the risk of relapse or 5-year OS (84% vs. 83%); however, the cytarabine-treated patients experienced greater degree of myelosuppression and higher use of medical resources. In a joint analysis of the European results with those of the PETHEMA group, the benefit of cytarabine was restricted to patients with higher-risk disease.

The APL treatment algorithm continued to evolve with the recognition of arsenic trioxide (ATO as the single most active agent in APL. The precise mechanism of action is not well defined. ATO appears to induce apoptosis of APL cells at higher concentrations and differentiation at lower concentrations. ATO targets the PML/RARA fusion protein for proteasomal degradation. Single-agent ATO was evaluated in patients with relapsed/refractory APL based on the initial reports of activity, again from China. Following a small, single institution pilot study, a larger phase II study of ATO 0.15 mg/kg IV daily until CR was performed in 40 patients with relapsed/refractory APL. Patients received induction followed by 1 cycle of consolidation. Maintenance ATO was administered on a separate clinical trial; 11 patients underwent subsequent allo or auto HSCT. The CR rate was 85%; the rate of complete molecular remission by RT-qPCR at the end of 1 cycle of consolidation was 86%. The 18-month RFS and OS were 56% and 66%, respectively. The most notable toxicities were QT prolongation and risk of torsade de pointes, differentiation syndrome, and leukocytosis. ATO can also cause vasomotor reactions (flushing, hypotension, headache), peripheral neuropathy, and hepatic toxicity. The vasomotor reactions can be ameliorated by slowing the infusion rate.

In two studies, single-agent ATO achieved 85% CR rates in previously untreated APL patients. The estimated 3-year DFS and OS rates were 87% and 86%, respectively, in the report by Mathews. The use of single agent may be particularly attractive where medical resources are scarce and access to cheaper therapies is an economic necessity. In the United States, there is no patient assistance programs for ATRA; some patients face unacceptably high out-of-pocket expenses for ATRA forcing the use of single agent ATO.

The North American Intergroup trial examined the addition of 2 cycles of ATO consolidation to daunorubicin, cytarabine and ATRA induction therapy, daunorubicin plus ATRA consolidation, and ATRA, MP, and methotrexate (MTX) maintenance therapy. The addition of ATO to this backbone resulted in superior 3-year EFS (80% vs. 63%, $P < .0001$), DFS (90% vs. 70%), and OS (86% vs. 81%, $P = .059$). However, the concurrent use of both ATRA and

ATO appeared to result in deeper remissions by RT-qPCR compared with either agent alone. The MD Anderson Cancer Center evaluated the efficacy and safety of ATRA plus ATO for previously untreated APL patients. A single dose of GO 9 mg/m^2 on day 1 was added to therapy for patients with high-risk disease; otherwise, all patients received ATRA 45 mg/m^2 in two divided doses daily with ATO 0.15 mg/kg IV daily. The CR+CRp rate was 92% with an estimated 3-year OS of 85% for the entire study population. The 3-year OS for lower-risk APL patients was 90%. Importantly, therapy with ATRA and ATO was only continued for 28 weeks after achievement of CR; maintenance therapy was not given.

The MD Anderson experience led to the phase III, Italian/German, multicenter APL0406 trial comparing ATRA plus ATO with ATRA plus chemotherapy in low- and intermediate-risk APL patients. ATRA 45 mg/m^2 in two divided doses and ATO 0.15 mg/kg/day were administered concurrently until CR. Patients in CR received 4 cycles of ATO 0.15 mg/kg/day for 5 days/week (20 doses) for 4 consecutive weeks every 8 weeks and 7 cycles of ATRA for 14 days every 4 weeks. CR rates in the ATRA/ATO and the ATRA/chemotherapy group were similar (100% vs. 95%, $P = .12$). Although designed as a noninferiority trial, EFS and OS at 2 years were superior in the ATRA/ATO-treated patients. The ATRA/ATO arm was also associated with less hematologic toxicity and fewer infections. In fact, significant myelosuppression is extremely unlikely during ATRA/ATO consolidation. ATRA/ATO was associated with higher rates of hepatic toxicity and peripheral neuropathy. Moderate to severe DS occurred in 17% of ATRA/ATO-treated patients despite the use of prednisone 0.5 mg/kg/day during induction for DS prophylaxis. The results of the APL0406 trial have been updated. The 50-month OS was 99.2% with ATRA/ATO and 92.6% with ATRA/chemo ($P = .0073$). Two of 132 patients developed therapy-related myeloid neoplasms following ATRA/chemo. There were 2 relapses and one death in CR among the 127 patients treated with ATRA/ATO compared with 15 relapses and 5 deaths in CR among the 132 ATRA/chemo patients. The combination of ATRA and ATO has emerged as the new standard of care for low- and intermediate-risk APL patients. ATO was initially approved in 2000 by the US FDA for relapsed/refractory APL. On January 16, 2018, the FDA expanded the approval of ATO in combination with ATRA for newly diagnosed patients with low-risk APL.

The optimal therapy for high-risk APL is not as clearly defined. Cytoreduction at the beginning of ATRA/ATO induction has been accomplished with either GO or idarubicin. In the MD Anderson study, 26 high-risk patients received ATRA/ATO until CR with a single dose of GO 9 mg/m^2 on day 1. Five patients died during induction; all others achieved remission (81% CR). Patients in CR then received four 8-week cycles of ATO (20 doses per cycle) and seven 14-day cycles of ATRA completed in 28 weeks; maintenance was not prescribed. Three of the 21 high-risk patients in first CR relapsed. In the United Kingdom AML17 trial, 28 of 30 high-risk APL patients received ATRA/ATO induction and consolidation with a single dose of GO 6 mg/m^2 during the first 4 days of induction. The 4-year OS of these 28 high-risk patients was 89%. Maintenance therapy was not administered in the AML17 trial. SWOG S0535 evaluated 70 high-risk APL patients. The treatment algorithm included ATRA/ATO with GO 9 mg/m^2 on day 1 during induction, 2 cycles of ATO consolidation, 2 cycles of ATRA/daunorubicin consolidation, two doses of GO 9 mg/m^2, and 1 year of ATRA/MP/MTX maintenance. The CR rate was 86% and 6-week mortality 11%. The 3-year EFS and OS were 78% and 86%, respectively. In the Australasian APML4 trial, 124 APL patients received induction therapy with ATRA, ATO, and four doses of idarubicin (age-adjusted dose), 2 cycles of ATRA/ATO consolidation, and 2 years of ATRA/MP/MTX maintenance therapy. The 2-year OS of the entire population was 93%. Twenty of the 24 high-risk patients achieved CR; only one of these 20 patients relapsed.

Primary resistance to first-line ATRA/ATO therapy has not been observed, with 100% rate of complete hematologic remission in patients who survive the initial induction therapy. However, at the end of induction and by the time a morphologic remission is achieved, *PML-RARA* transcript is frequently still detectable by RT-qPCR and should not be interpreted as a sign of treatment resistance. RT-qPCR testing is essential in the follow-up of patients with APL. In no other leukemia, apart from chronic myeloid leukemia, does molecular testing influence clinical decision-making processes. Patients who do not achieve a molecular response by the end of the consolidation have a worse prognosis with a higher likelihood of relapse. Positive PCR test results should be confirmed by a second PCR test within 1 to 4 weeks. Single agent GO resulted in a complete molecular remission in 14 of 16 patients with molecular relapse of APL. RT-qPCR monitoring should take place every 3 months for 2 years, especially for those patients with high-risk disease, those older than 60 years, and patients for whom treatment delays occurred during consolidation.

Prior to the addition of ATO to ATRA/chemotherapy-based therapy, maintenance therapy was incorporated into every regimen. For patients who were treated with an ATRA/chemotherapy combination, common practice was to give another two or three anthracycline-based cycles of consolidation. Following consolidation, maintenance therapy for 1 to 2 years with ATRA ± MP/MTX was recommended. The benefit of maintenance appeared to be greatest in those with high-risk disease. However, the addition of ATO consolidation to an ATRA plus chemotherapy regimen eliminated the need for any maintenance therapy in low-/intermediate-risk APL patients. Maintenance was not used in non-high-risk APL patients receiving ATRA/ATO induction and consolidation with excellent long-term outcomes. There remains uncertainty and debate as to the benefit of maintenance in high-risk APL with ATRA/ATO-based therapy, but many leukemia experts do not include maintenance therapy even for these patients.

The choice of therapy for relapsed APL will be determined by the therapeutic agents used for initial therapy, duration of first response, and presence or absence of CNS disease at relapse. The incidence of CNS involvement at first relapse 5 years after initial ATRA and anthracycline therapy without CNS prophylaxis was 1.7%. Two independent risk factors for CNS disease at first relapse in this study were WBC greater than 10,000/μL at diagnosis and occurrence of CNS hemorrhage during induction; the 5-year cumulative incidence of CNS relapse was 5.5% (8/149) and 18.8% (3/18) in patients with these risk factors, respectively. Some experts recommend intrathecal CNS prophylaxis in APL patients with these high-risk features at initial diagnosis and also at relapse. ATO, ATRA, anthracyclines, high-dose cytarabine, and GO (alone or in various combinations) can be considered for relapsed APL patients. HSCT should follow achievement of a second remission. Auto HSCT is recommended for relapsed APL patients who have again achieved a complete molecular remission. For those whose PCR results remain positive, allo HSCT is favored.

The outcome of APL patients has dramatically improved from the initial description by Hillestad in 1957. Primary resistance to ATRA/ATO therapy is virtually unheard of, and relapse is uncommon. HSCT is not considered for patients achieving first CR with negative RT-qPCR for *PML/RARA* fusion transcripts (i.e., complete molecular remission). Current clinical studies focus on improving the quality of life of APL patients undergoing therapy, by replacing intravenous ATO with oral arsenic formulations. However, early mortality due to hemorrhage remains the greatest risk facing patients with APL worldwide. International efforts aim to expedite administration of ATRA to newly diagnosed APL patients.

BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM (CHAPTER 64)

BPDCN is a rare hematopoietic neoplasm involving bone marrow, skin, and lymph nodes (Chapter 64). CNS disease may occur with disease progression, especially in patients not receiving CNS-directed therapy. The disease was previously known as agranular CD4+ NK cell leukemia, blastic NK-cell lymphoma, and CD4+, CD56+ hematodermic neoplasm. BPDCN is now classified by the WHO as a myeloid neoplasm, being derived from type II (plasmacytoid) dendritic cells. BPDCN cells express CD4, CD56, and CD123 (the alpha chain of the low-affinity interleukin-3 receptor). The median age at diagnosis is 65 to 70 years but can occur at any age, affecting all races and geographies. Patients may present with a single cutaneous nodule, multiple nodules, hyperpigmented red-brown macules, and/or purpuric macules.

Until recently, there was no standard of care for patients with BPDCN. Although localized radiation therapy is effective for local control, relapse rapidly follows, and systemic therapy is preferred from the time of initial diagnosis. Intensive chemotherapy regimens used for acute lymphoblastic leukemia or AML may lead to remissions with typically short duration. CNS prophylaxis appears to improve outcomes. For eligible patients, allo HSCT is recommended. For patients ineligible for intensive therapy, several regimens have been reported such as bendamustine, asparaginase with MTX, gemcitabine, and HMA with venetoclax.

More recently, CD123 directed therapy has shown promise. Tagraxofusp is a cytotoxic agent composed of interleukin-3 (IL-3) fused to a truncated diphtheria toxin, a protein synthesis inhibitor. IL-3 binds to CD123, leading to internalization of the conjugate and cellular apoptosis. A phase I/II study in newly diagnosed and relapsed/refractory BPDCN patients established the maximally tolerated dose of tagraxofusp. In an expansion of this study, 29 newly diagnosed BPDCN patients were treated with tagraxofusp 12 mcg/kg IV once daily on days 1 to 5 of a 21-day cycle. Treatment is continued until progression or unacceptable toxicity. The CR and clinical CR rate was 72% and 2-year survival 52%. The response rate was 65% in a cohort of 15 relapsed/refractory BPDCN patients. The most serious adverse event is capillary leak syndrome; hepatic transaminase elevations and hypoalbuminemia were also observed. On December 21, 2018, the US FDA approved tagraxofusp for newly diagnosed and relapsed/refractory BPDCN patients ages 2 and older. Other CD123-directed therapies (antibody-drug conjugates, BiTE, and chimeric antigen receptor T cells [CAR-T]) are in development.

EXTRAMEDULLARY ACUTE MYELOID LEUKEMIA

AML blasts may infiltrate any tissue. A tumor composed of myeloid blasts is known as a myeloid sarcoma (or granulocytic sarcoma or chloroma). The term chloroma derives from the green hue of the tumor due to the presence of copper in MPO. Myeloid sarcomas can occur in any tissue but most commonly present in the skin (leukemia cutis), lymph nodes, gastrointestinal tract, testes, ovaries, CNS, soft tissue, and bones. They can easily be confused with lymphomas and soft-tissue sarcomas; immunohistochemical stains are often required to establish the correct diagnosis. Myeloid sarcomas can be isolated or multiple. Myeloid sarcomas may occur at the same time as blood and marrow involvement, may precede the diagnosis of AML in the marrow (primary extramedullary AML), or may occur at the time of relapse without marrow involvement. Isolated extramedullary relapse is particularly common following allo HSCT. Immune checkpoint inhibitors, such as the CTLA-4 inhibitor ipilimumab, appear to be particularly active in extramedullary relapse following allo HSCT. In the context of chronic myeloid malignancies (e.g., MDS, myeloproliferative neoplasms, chronic myeloid leukemia, chronic myelomonocytic leukemia), their appearance represents progression to a blast phase.

Myeloid sarcoma, even if primary extramedullary myeloid sarcoma, should be treated with systemic chemotherapy. In the absence of systemic therapy, subsequent progression to systemic AML is very likely in patients with primary extramedullary AML. Radiation therapy may be of help to optimize local control (especially if residual disease present after systemic therapy) and provide palliation. There is controversy over whether patients with myeloid sarcoma do better or worse than those with AML. It is likely that the prognosis depends more on the biologic features of the disease (e.g., presence of a CBF gene translocation) than on the extramedullary presentation.

CENTRAL NERVOUS SYSTEM DISEASE

CNS involvement occurs in less than 5% of patients with AML. The risk for CNS involvement is higher in AML with monoblastic differentiation and those cases with a high WBC (>100,000/μL) at presentation, and perhaps in FLT3-mutated AML. HiDAC penetrates the blood–brain barrier and appears to have contributed to a lower rate of CNS involvement over the years. For example, prior to the use of HiDAC, inv(16) AML was associated with a 30% incidence of CNS leukemia, particularly intracerebral masses. This problem has been virtually eliminated with the use of HiDAC. Nonetheless, once a patient has achieved a CR, some experts recommend intrathecal therapy for prophylaxis. This is a more common practice after allo HSCT in patients with monoblastic AML or those with CNS disease at presentation.

In the presence of symptoms suggestive of CNS disease (headache, persistent nausea/emesis, cranial nerve dysfunction), further evaluation should be pursued. Symptoms are due to raised intracranial pressure, mass effect, or infiltration of cranial nerves. Although CT scan is adequate to evaluate for large masses and intracerebral hemorrhage, a magnetic resonance image with contrast of the brain and/or spinal cord should be obtained for suspected leukemic meningitis. Lumbar puncture is a crucial component of the evaluation but may need to be repeated several times to establish the diagnosis. Flow cytometry of the CSF sample can help to establish the diagnosis. However, the results of the CSF flow cytometry must be evaluated cautiously and only with knowledge of the CSF cell counts, since a positive result may be due to peripheral blood contamination of the CSF specimen. Treatment consists of intrathecal therapy with cytarabine and/or MTX via lumbar route or an intraventricular catheter (Ommaya reservoir). A typical schedule includes twice-weekly treatments until the cerebrospinal fluid is free of leukemic blasts. The frequency is then changed to weekly for 2 months, then every other week for 2 months, followed by monthly injections for up to 1 year. However, various schedules are used in practice. Radiation therapy can be a useful alternative, especially in the case of localized lesions such as isolated cranial nerve findings as well as for palliation.

PREGNANCY

AML is rarely diagnosed during pregnancy. The response to treatment is not affected by pregnancy. AML therapy during the first trimester is problematic due to the toxic and teratogenic effects of chemotherapy on the fetus; termination of pregnancy before institution of induction therapy should be strongly considered in the first trimester. Pregnancy outcome during the second and third trimester is more favorable, and successful treatment of the AML and delivery of normal infants have been reported. Daunorubicin is preferable over idarubicin because the latter is more lipophilic and has higher DNA affinity, raising the possibility of higher maternal–fetal transfer and toxicity to the fetus. In general, it is not advisable to delay therapy once the diagnosis of AML is made given the high risk for maternal death. However, in situations where the leukemia behaves indolently and women are close to delivery, a conservative approach can be chosen with supportive care and induction of labor as soon as possible. These decisions are based on clinical judgment and discussion with the patient.

FUTURE DIRECTIONS

The survival of younger AML patients has improved over the last 40 years. The use of intensive post-remission therapy (HiDAC) and allo HSCT has contributed to this improvement. Patients are more likely to have stem cell donors for allo HSCT, since the unrelated donor international registries have increased in size, and alternative donors such as haploidentical donors and cord blood are now routinely used. There have been improvements in supportive care. The use of broad-spectrum triazole antibiotics has decreased the incidence and mortality associated with invasive fungal infections following AML induction therapy. The prevention of fungal and viral (CMV) infections, as well as advances in the prevention and treatment of graft-versus-host disease, following allo HSCT have decreased the transplant-related mortality. On the other hand, the survival of older AML patients has not improved. However, with the availability of effective, better tolerated regimens, especially HMA/venetoclax, we expect that the survival of older AML patients will also improve.

Nonetheless, the risk of relapse remains high with currently available therapies, and OS remains poor. With few exceptions, attempts to improve outcomes with intensive chemotherapy have been largely disappointing. Nevertheless, it remains possible that the efficacy of intensive chemotherapy may be improved with the addition of novel agents. For example, the BCL2 inhibitor venetoclax is being evaluated with 7+3, HiDAC, FLAG-Ida, and liposomal daunorubicin/cytarabine. E-selectin inhibitors are hypothesized to increase chemotherapy sensitivity of leukemic stem cells by displacing these cells from a protective niche in the bone marrow; these agents are being evaluated in combination with intensive chemotherapy regimens. Agents that target specific mutations such as *FLT3*, *IDH1*, and *IDH2* are commercially available. However, these targeted inhibitors result in remissions for a minority of patients with these mutations, and the responses are not durable. This should not be surprising, since the pathogenesis of AML (with the possible except of APL) is due to multiple genetic events. Nonetheless, inhibitors of other potential targets are being evaluated such as Menin, which is central to AML pathogenesis due to *KMT2A* rearrangements and *NPM1* mutation. KIT inhibitors are being evaluated in AML with CBF fusions.

Given the genetic heterogeneity of AML, it should not be surprising that targeted therapies do not result in high response rates or long DFS. The lowest risk of relapse occurs following allo HSCT, at least partially due to a graft-versus-leukemia effect. This observation suggests that manipulation of the immune system may improve the outcome of AML patients. Checkpoint inhibitors against PD1 and PD-L1 have been evaluated in AML, but the results of these studies have been disappointing to date. However, it remains possible that we just have not been able to identify a specific immune signature that will predict for response. Other components of the immune regulation are being targeted in clinical trials. CD47, integrin-associated protein, is present on the cell surface of nearly all cells. CD47 binds to SIRP alpha on macrophage, providing a "don't eat me" signal and preventing phagocytosis. Anti-CD47 monoclonal antibodies are in clinical development. Magrolimab, a first generation anti-CD47 monoclonal antibody, has demonstrated very encouraging efficacy in combination with azacitidine for patients with MDS and AML. Durable CRs, including MRD negative responses, have been seen even in *TP53*-mutated MDS and AML. TIM3 is present on leukemic stem cells but is also a T-cell immune checkpoint. Anti-TIM3 monoclonal antibodies are in clinical development. BiTE and CART targeting cell surface antigens present on AML blasts are in development as well. These approaches are complicated by the presence of the target on normal myeloid cells, which may contribute to significant myelosuppression. The cytokine release syndrome and encephalopathy observed with currently available BiTE and CAR-T therapies have also complicated the clinical development of these agents in AML patients.

We need to develop a better understanding of the cellular perturbations that lead to uncontrolled proliferation, block of normal differentiation, and avoidance of apoptosis by neoplastic hematopoietic stem cells. We also need to have a deeper knowledge of the immune dysregulation associated with active disease. Advances in DNA sequencing technology and proteomics will help us identify targets in the individual AML patient more rapidly. We will also develop these technologies to evaluate not just the prognostic significance of measurable residual disease, but hopefully identify targets for earlier intervention to prevent relapse. This knowledge will continue to drive clinical research and highlights the importance of clinical trial participation as an integral component of AML therapy.

MYELODYSPLASTIC SYNDROMES

Christopher J. Gibson and David P. Steensma

The myelodysplastic syndromes (MDS) include a group of clonal hematopoietic disorders characterized by ineffective hematopoiesis and blood cytopenias, abnormal blood and bone marrow cell morphology (Fig. 61.1), and a risk of clonal evolution including progression to acute myeloid leukemia (AML).[1] The syndromes have a highly variable clinical course, manifesting in some patients as indolent asymptomatic cytopenias or only necessitating occasional transfusions over a course of many years, and in others as aggressive diseases that rapidly evolve into treatment-refractory acute leukemias and cause death from infection or other complications within a few months.[2]

Despite this phenotypic variability, individual cases of MDS share many pathophysiologic mechanisms at the molecular and cellular levels, and our collective understanding of these mechanisms has evolved substantially in the last decade. At the same time, although MDS also shares features with AML and other myeloid malignancies, mounting evidence shows that it is appropriately conceived as a distinct class of diseases, and that the older conceptualization of MDS as "pre-leukemia" is overly simplistic.

While our collective understanding of MDS pathophysiology is improving, the condition remains difficult to treat, and outcomes for many patients with MDS are poor. This chapter describes our current understanding of the classification, pathobiology, clinical features, and treatment approaches for this heterogeneous group of disorders.

Central to an understanding of how MDS is diagnosed and classified is the concept of morphologic dysplasia. Although specific criteria for diagnosis of MDS as a distinct clinical syndrome exist and are discussed below, the term "myelodysplasia" refers more generally to an abnormal appearance of hematopoietic precursors during pathologic examination of bone marrow, which may result from many different causes (e.g., drug toxicity, nutritional deficiency (see chapter on nutritional deficiencies), viral infection).[3] The process by which our understanding of MDS has evolved from that of a morphologic oddity associated with cytopenias to that of a distinct clonal disease process has been a century in the making, propelled forward at several points by paradigm shifts in pathologic and molecular characterization of hematologic diseases.[4]

HISTORY

In describing the history of MDS as a distinctly categorized disease entity, it is perhaps most useful to separately describe the history of its three major conceptual components.[4] The earliest recognized of these, not surprisingly, was that of cellular dysplasia in association with cytopenias. Although studies of blood morphology in anemic patients were reported in the 19th century not long after the quantitative hemocytometer debuted,[5] the first detailed characterization of dysplasia was probably made by Giovanni di Guglielmo in Pavia in 1923, when he described abnormal erythroid forms in the marrows of patients with various types of cytopenias.[6]

A second major concept, that of ineffective hematopoiesis, developed in the 1930s with the description of "refractory anemia" in patients unresponsive to iron pills or liver extract (the precursor to B_{12} supplementation), and later to folic acid supplementation.[7] In the 1950s, others expanded this to include similarly treatment-refractory leukopenia and thrombocytopenia.[8] Importantly, however, ineffective hematopoiesis and marrow dysplasia were initially incompletely linked, and the ineffective hematopoiesis of many early "refractory anemia" patients was probably rooted in other disorders, such as anemia of inflammation due to advanced rheumatologic disease or non-myeloid neoplasia.

The third major component of MDS, and possibly the most prominent, is its conceptualization as a pre-leukemic state. In 1942, a group from France led by Paul Chevallier described a case of anemia evolving into leukemia as "odo-leukemia" ("odo" from the Greek for edge or threshold), which they attributed to benzene exposure.[9] A similar disorder was termed "preleukaemic anemia" by a British hematologist, J.L. Hamilton-Paterson, in 1949.[10] This term was then adopted and expanded by an American group at the University of Chicago including Leon Jacobson in the early 1950s,[11] providing one of the clearest descriptions of a disorder clinically defined by both cytopenias and a risk of leukemia. Other groups published similar descriptions in the 1950s and 1960s under different terminologies.[12]

In 1970, Bernard Dreyfus in Paris and colleagues coined the term refractory anemia with excess blasts (RAEB, described in French as "les anémies réfractaire avec excès de myeloblasts")[13] and later attempted to further characterize components of RAEB based on morphology and clinical characteristics.[14] The term "hematopoietic dysplasia" was used in the early 1970s to describe a heterogeneous group of disorders distinct from AML, and the term was later simplified to "myelodysplasia."

One of the key events in the history of myeloid disease classification was the formation of the French-American-British (FAB) Cooperative Group in 1976, which in that year issued a comprehensive and influential categorization of AML[15] based on the 1975 classification of David Galton and John Dacie in London.[16] The FAB classification persisted as the dominant descriptive system for AML until the early 2000s. The original FAB AML formulation from 1976 included two types of "dysmyelopoietic syndromes" that the group warned should not be confused with AML: RAEB and chronic myelomonocytic leukemia (CMML), which had first been described in the late 1960s.[17] However, in 1982 the FAB recognized MDS as a separate group of diseases and accorded a distinct classification system, described in more detail below.[18]

CLASSIFICATION

The currently accepted classification scheme for MDS was initially published by the World Health Organization (WHO) in 2001, revised in 2008,[19] and revised again in 2016 (Table 61.1).[20] Like the classifications of the FAB group, the WHO classification is principally a morphology-based hematopathology system with limited inclusion of cytogenetic and molecular markers, and classifies disease chiefly based on the number of dysplastic lineages and the percentage of marrow blasts.

The WHO classification was intended to replace the FAB classification system, which included 5 subtypes of MDS. Those 5 FAB subtypes were refractory anemia (RA, <5% blasts and any cytopenia pattern); refractory anemia with ring sideroblasts (RARS, defined by <5% myeloblasts and ring sideroblasts—formerly called "ringed"—representing $\geq$15% of erythroid precursors); RAEB (5% to 19% blasts in the marrow); RAEB in transformation to AML (RAEB-t, defined as 20% to 29% blasts in the marrow); and CMML (defined by $>1 \times 10^9$ peripheral monocytes).[18]

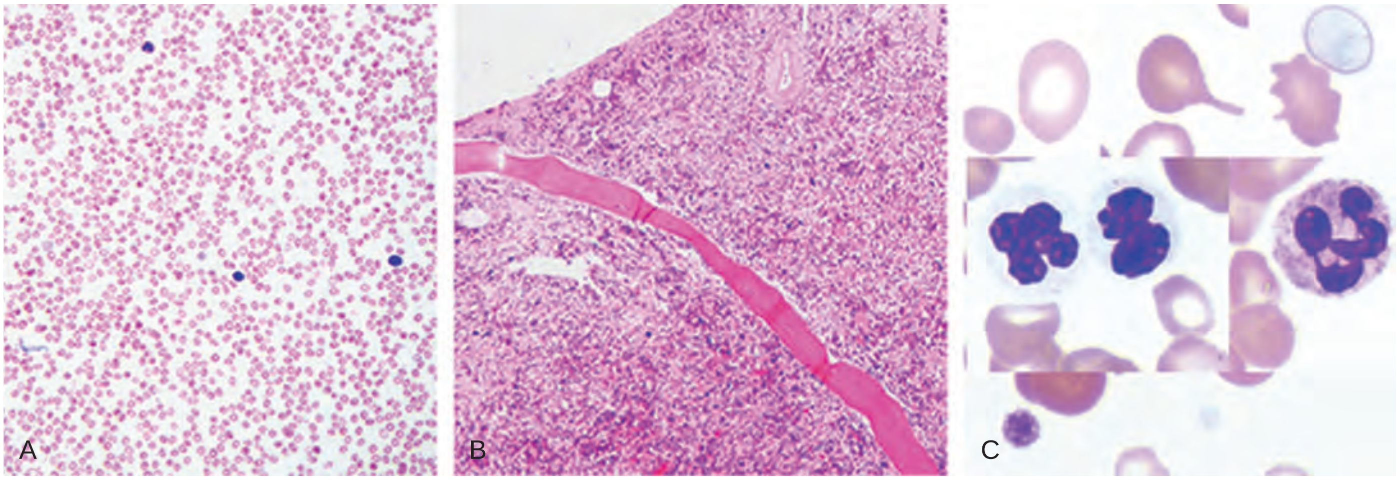

Figure 61.1 ELEMENTS OF MYELODYSPLASTIC SYNDROME. Myelodysplastic syndromes are generally characterized by cytopenias (A) caused by ineffective hematopoiesis (B), which is related to multilineage dysplasia (C). (A) This patient presented with a white blood cell count of 1500/μL, hemoglobin 8.9 g/dL, and platelet count 47,000/μL. (B) The bone marrow was hypercellular, indicating ineffective hematopoiesis. (C) Evidence of trilineage dysplasia was apparent on the peripheral smear. Anisocytosis with macroovalocytes and poikilocytosis is seen in the red blood cells (C, *top*). The latter included the somewhat uncommon finding of Cabot ring forms *(right)*. A large proportion of the granulocytes were severely hypogranular (C, *middle left*) compared to some normal forms still in the circulation *(right)*. Platelets (C, *bottom*) were decreased in number, and many were severely hypogranular (*middle*, barely visible) compared with residual normal platelets *(left)*.

The WHO systems bear some similarities to the FAB scheme, but there are several notable changes. First, the WHO system recognizes that MDS may present with isolated leukopenia or thrombocytopenia, albeit uncommonly, hence the change from RA to "MDS with single lineage dysplasia" (MDS-SLD), and the addition of a second distinct class for patients with more than one affected cell line/ multilineage dysplasia (MDS-MLD). Second, a mounting body of evidence suggested that MDS with concomitant myeloproliferative features such as CMML is clinically and biologically distinct from MDS without such features, especially when the white count is elevated, and thus warranted separate designation.[21] Third, the unique clinical syndrome associated with low-risk MDS with isolated deletion of chromosome 5q, in combination with its particular responsiveness to treatment with lenalidomide, warranted its designation as a specific clinicopathologic entity.[22] Fourth, in the 2016 edition, the WHO removed the obsolete "refractory anemia" terminology from the 1930s.[23] Finally, the blast threshold for diagnosis of AML instead of MDS was changed with the 2001 classification from 30% to 20%, rendering the FAB designation of RAEB-t obsolete, and RAEB was divided into two categories reflecting different prognoses for patients with 5% to 9% versus 10% to 19% blasts.[24]

The WHO revision improved on certain aspects of the FAB system, including refining prognostic categories.[25] However, artificial boundaries such as the 10% cell threshold in a lineage to define dysplasia, 15% ring sideroblasts to define MDS-RS (unless *SF3B1* mutation is present, in which case the threshold is lowered to 5% ring sideroblasts), and 5%/10%/20% blast cutoffs often prove themselves to be of variable relevance, both biologically and clinically. These thresholds fail to capture a number of variables important in MDS, including patient age and comorbidities, kinetics of disease, and cytogenetic and molecular genetic data. Newer classifications are likely to evolve as molecular characterization of MDS improves; for instance, in 2020, an International Working Group (IWG) proposed definition of *SF3B1* mutant MDS as a distinct entity.[26]

While the FAB and WHO subgroups carry some prognostic information (for instance, patients with FAB RAEB or WHO RAEB-2 are at higher risk of progression to AML than subgroups without excess blasts[27]), other systems specifically dedicated to estimating disease risk, such as the International Prognostic Scoring System and its Revised version (IPSS and IPSS-R; see below), are better suited to the task of risk stratification. Future iterations of classification systems will incorporate elements of genetic or clinical data that better group MDS patients based on disease biology, prognosis and natural history, or anticipated responsiveness to treatment modalities.[28] For now, however, the WHO classification remains a key component of several descriptive tools applied to patients with MDS.

EPIDEMIOLOGY

Most available data suggest that MDS is one of the most common hematologic malignancies, although this claim has been difficult to validate until recently due to confusing terminology and incomplete reporting of cases to registries.[29,30] Cases of MDS were not reported to the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) until 2001, and reporting was inconsistent for several years thereafter. Initial reports to the registry suggested an incidence of only about 10,000 new cases per year.[31] Subsequent comparison of these data with Medicare and insurance claims for MDS suggested that a substantial proportion of MDS cases went unreported to SEER, with an estimated age-adjusted incidence of >5.3 per 100,000, compared to the SEER estimate of 3.3.[32]

The reporting difference was especially stark in patients age 65 and older, where it was estimated that the actual incidence of MDS might actually be close to fourfold higher than what was captured in the database (i.e., 75 vs. 20 per 100,000). Some of the underreporting was likely related to specific criteria for entry into the database: for instance, myeloid malignancies could only be counted once, such that patients presenting with a new diagnosis of secondary AML were usually coded as AML, without mention of the antecedent MDS. Much of the underreporting, however, was likely due to the complexity of diagnosing and classifying MDS, as described above. The rate of reporting may be improving with time, with annual incidence in the SEER database in more recent years estimated at around 20,500 and an age-adjusted incidence of 4.9 per 100,000.[33]

Even the most accurate database would probably underestimate the total global burden of MDS, which is likely present in a substantial percentage of older patients with idiopathic cytopenias who never undergo bone marrow analysis.[34] Although some proportion of this uncaptured population likely has biologically indolent disease that would never require therapy, more thorough cross-sectional studies, particularly in older patients, would help clarify the distinction between this end of the MDS spectrum and more aggressive biology that brings patients to clinical attention.

TABLE 61.1 2016 World Health Organization Classification of the Adult Myelodysplastic Syndromes

MDS with Single Lineage Dysplasia (MDS-SLD)	
Dysplasia	≥10% of cells from a single lineage
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
MDS With Single Lineage Dysplasia and With Ring Sideroblasts (MDS-SLD-RS)	
Dysplasia	Isolated erythroid dysplasia
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	≥15% of erythroid precursors are ring sideroblasts, or if
	SF3B1 mutation present, ≥5% of erythroid precursors are ring sideroblasts
MDS With Isolated Del(5q)	
Dysplasia	Erythroid dysplasia prominent; granulocytic series variable; normal or increased numbers of megakaryocytes with hypolobated nuclei
Blasts	<20% (though usually much less)
Notes	Must include deletion of chromosome 5q inclusive of band 5q31 as sole chromosomal abnormality or with one other abnormality
MDS With Multilineage Dysplasia (MDS-MLD)	
Dysplasia	≥10% of cells from two or more myeloid lineages
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	Peripheral monocyte count must be $<1 \times 10^9$/L; ring sideroblasts may be present, as above for MDS-SLD-RS, in which case it is classified asMDS-MLD-RS
MDS With Excess Blasts (MDS-EB)	
Dysplasia	No specific requirement
Blasts	MDS-EB1: 5%–9% in marrow, <5% in peripheral blood, AND no Auer rods
	MDS-EB-2: 10%–19% in marrow, 5%–19% in peripheral blood, OR Auer rods
Notes	≥20% blasts is now considered AML
Unclassifiable MDS (MDS–U)	
Dysplasia	May be minimal, or not meeting criteria for another subtype
Blasts	<5% in marrow; no Auer rods
Notes	In presence of clonal cytogenetic finding considered diagnostic of MDS

[a] Note: excludes refractory cytopenias of childhood (RCC). MDS/myeloproliferative neoplasms such as chronic myelomonocytic leukemia (CMML), and therapy-related MDS/acute myeloid leukemia (AML).

As referenced above, MDS is by and large a disease of older adults and reflects the inevitable acquisition of genetic mutations by aging hematopoietic progenitor cells. In the United States, the median age at diagnosis is approximately 71 years,[35] and in the absence of a congenital disorder/germline predisposition or exposure to radiation or cytotoxic chemotherapy for another disease, diagnosis prior to the age of 50 is rare.[36] Recent data suggest that a substantial proportion of older adults harbor hematopoietic clones defined by the presence of mutations recurrently found in MDS and AML at a variant allele frequency (VAF) of at least 2%, and that this state of "clonal hematopoiesis of indeterminate potential" (CHIP) progresses to MDS at a rate of 0.5% to 1% per year (see Chapter 19).[37–41] Smaller clones with a VAF < 1% are ubiquitous by middle age.[42,43] CHIP most commonly is driven by mutations in *DNMT3A, TET2*, or *ASXL1*, with high allelic heterogeneity, and pre-disposes to cardiovascular events due to clonal monocytes causing NLRP3 inflammasome-driven inflammation in the endothelium, which results in accelerated atherogenesis.[44,45]

MDS occurs in children much more rarely, at an estimated annual rate of 1 per 1 million.[46] Most cases have excess blasts and evolve to AML over time; other subtypes such as lower-risk MDS including 5q minus syndrome are even less common.[47] Several genetic syndromes confer an increased risk of MDS (see Chapter 30); these include Down syndrome,[48] Fanconi anemia,[49] dyskeratosis congenita and other telomeropathies,[50] Shwachman-Bodian-Diamond syndrome,[51] and germline mutations in *GATA2*,[52] *RUNX1*,[53] *ETV6*,[54] and *DDX41*[55] among others.[39] In patients with Fanconi anemia, GATA2 mutations, or telomeropathies, MDS arising during young adulthood may be the initial presenting sign of inherited conditions that in other patients affect multiple organ systems and result in diagnosis in early childhood.

Most subtypes of MDS appear to be more common in men than women, with SEER data suggesting respective age-adjusted incidences of 6.7 versus 3.9 per 100,000.[56] One exception to this is MDS with isolated del(5q), which most series show to be slightly more common in women.[57] The reason for these sex differences is unclear; some have postulated a protective factor encoded on the X chromosome, or a similar protective factor on the Y chromosome, which is clonally lost in some cases of MDS, as well as in many older healthy men. Others have suggested that the increased incidence in men could be due to differences in occupational exposures, but this has never been clearly demonstrated. In fact, the only toxic chemical exposure definitively proven to cause MDS is benzene,[58] which is now significantly less prevalent in industrial workplaces than it had been in the past. Other environmental exposures, including cigarette smoking, have been suggested to predispose to MDS.[59] Agent Orange, a defoliant used by the US Army in the Vietnam War and frequently diluted with hydrocarbons to facilitate spraying, has been anecdotally linked to MDS risk, but given the lack of ongoing exposure in the population, a definitive causal connection is difficult to prove.[60]

MDS in the United States and Western Europe are epidemiologically similar, but there are differences between these geographical regions and other parts of the world. In Asia[61] and Eastern Europe,[62] for instance, the average age at MDS diagnosis is younger, and the frequency of both severe cytopenias and risk of progression to leukemia may differ.[63] Some of these differences are likely due to variance in environmental exposures. In Japan, for example, broad population-wide exposure to ionizing radiation from the atomic bombings of Hiroshima and Nagasaki in the 1940s continued to influence MDS incidence well into the 1990s.[64] However, the cause of differences in MDS subtypes, such as the low incidence of MDS with ring sideroblasts in Japan compared with the West, remain unclear.

The two exposures most consistently associated with subsequent development of MDS are ionizing radiation and cytotoxic chemotherapy, and MDS arising in these settings, known as therapy-related MDS or therapy-related (treatment-related) MDS (t-MDS), is frequently characterized by TP53 mutations,[65] multiple chromosomal abnormalities including complex karyotypes (most commonly defined as ≥3 clonal chromosomal anomalies),[66] and frequent transformation to treatment-refractory AML.[67] In the United States, radiation is most frequently encountered as treatment for other cancers, and radiation fields that include the hips or pelvis, the most active sites of hematopoiesis in adults, probably pose the greatest risk.[68] Less commonly, exposure to radiation can occur as the result of occupational exposures (e.g., workers at nuclear reactors) or industrial accidents. Among chemotherapeutic agents, there is a substantial difference in the risk of subsequent MDS. In particular, alkylating agents (e.g., cyclophosphamide and melphalan),[69] platinum-based agents,[70] and fludarabine[71] appear to carry the greatest risk, while the risk with other drugs is lower. PolyADP ribose polymerase (PARP) inhibitors also appear to increase the risk of therapy-related MDS, although many people who receive PARP inhibitors have also received other therapies such that the independent contribution of the PARP inhibitor may be unclear.[72] The rapidly progressive AML seen in association with exposure to topoisomerase inhibitors (e.g., doxorubicin, etoposide) is not typically preceded by MDS.[73]

PATHOBIOLOGY

Our understanding of the complex pathobiology underlying MDS has evolved substantially since their first description. MDS is now recognized to arise from the acquisition of sequential mutations in hematopoietic stem cells (HSCs) that either confer clonal advantage, impair normal leukocyte function, or both. In some cases, this cell-autonomous expansion of a malignant clone is complemented by non-cell autonomous alterations in the marrow microenvironment and immune surveillance that allow the clone's expansion. This section details our current understanding of these concepts.

Myelodysplastic Syndromes Cell of Origin

One of the central challenges in understanding the pathogenesis of MDS has been isolating the cell of origin and understanding that cell's mechanisms of self-renewal and propagation, both of which are necessary for the establishment of a malignant clone.[74] The capacity for self-renewal on its face implies that the origin cell is either a hematopoietic stem cell, and thus possesses intrinsic self-renewal capabilities, or is a more differentiated myeloid progenitor that acquired the ability to self-renew. Additional alterations may confer other characteristics associated with MDS, such as enhanced proliferation, resistance to apoptosis, specific types of morphologic dysplasia, or ineffective hematopoiesis and cytopenias, at which point MDS also becomes clinically evident.[75]

The clonal nature of MDS was first established in the 1980s by studies that showed skewed inactivation of glucose-6-phosphate dehydrogenase (G6PD), an X-linked gene, in the hematopoietic cells of female MDS patients heterozygous for G6PD deficiency.[76] More recent studies have used deep sequencing techniques to track the clonal evolution from MDS into AML and have confirmed that in these cases, the pre-existing MDS is as highly clonal as the resulting secondary AML.[77]

Whether MDS is a disorder of stem or early progenitor cells has been more difficult to prove.[78] Xenotransplant experiments using immunophenotypically defined HSPCs (classically CD34$^+$ CD38$^-$ Lin−) from MDS patients have not shown a striking proliferative or self-renewal advantage for the MDS cells compared to normal controls,[79,80] and the degree to which these experiments accurately depict the clonal dynamics of MDS in humans is unclear. More recent studies combining immunophenotypic analysis with deep sequencing of clonal mutations in MDS cells have shown that the mutations appear to originate exclusively in the most primitive, stem-cell-like compartment,[81] and others have shown that differential expansion of specific progenitor compartments may vary between different phenotypes and risk profiles of MDS.[82] These studies have led to the conclusion that MDS is, in fact, a disorder of transformed HSCs.[83] The conceptualization of MDS as a stem cell disorder partly explains why it is so refractory to most attempts at conventional therapy.

Genetic Alterations

Like other cancers, the core hypothesis underlying MDS pathogenesis is that the originating clone of MDS increasingly diverges from normal HSCs, and ultimately undergoes frank malignant transformation, through the sequential accumulation of acquired genetic abnormalities.[84] Improvement in our understanding of how these abnormalities are acquired, how they interact with each other, and their impact on pathways affecting proliferation, self-renewal, and differentiation, has been one of the major advancements in the study of MDS over the last decade.

Several types of genetic abnormalities are found in MDS. The first to be recognized (beginning in the 1970s) were cytogenetic abnormalities on standard karyotyping,[85] which are present in about 50% of patients (see Chapter 57).[86] A second category of cryptic chromosomal aberrations, including microdeletions and copy number-neutral loss of heterozygosity (CN-LOH), are too small to be detected by karyotype but may be found with fluorescence in-situ hybridization (FISH)[87] or single nucleotide polymorphism (SNP) arrays.[88] The most common type of MDS-associated genetic abnormality, mutations in single genes, has been increasingly well-characterized, and clinical tests for recurrent mutations are becoming increasingly available—though not all mutations have equal clinical relevance.[84,89] Finally, epigenomic alterations—global aberrations in histone and chromatin modification—are common in MDS, and are often, though not always, associated with mutations in genes involved in epigenetic regulation.[90]

GERMLINE PREDISPOSITION

Although MDS is largely a disease of older adults, several inherited genetic disorders predispose to its development as well.[91] While most of these disorders are associated with development of bone marrow failure or MDS in childhood, some (including Shwachman-Diamond syndrome,[51] Familial Platelet Disorder-AML due to germline *RUNX1* mutations,[92] and *SAMD9* mutations[93]) can present in young adulthood, and a few (some telomeropathies[50] and germline *DDX41* mutations[55]) most commonly present in middle age or later (see Chapter 30). Similarly, although most are associated with other characteristic non-hematologic features, a few (such as some *GATA2* mutation disorders,[94] *DDX41* mutations, and familial platelet disorder with propensity for AML [FPD-AML]) have only hematologic abnormalities. A partial summary of the most common germline predisposition disorders is given in Table 61.2.

Somatic Mutations

Of the types of genetic abnormalities found in MDS, acquired mutations in individual genes are the most recently recognized (Table 61.3); they are also the most frequent, currently estimated to be present in at least 80% of MDS patients.[84,95] Most mutations are acquired randomly, either spontaneously (e.g., deamination of methylated cytosine to thymine), during DNA replication prior to cell division, or during DNA repair; mutations accumulate with age.[96,97]

One of the central challenges of understanding the genetics of MDS has been determining which mutations contribute to the pathogenesis of the disease and which do not. While HSCs accumulate many mutations over their lifetimes, the majority are of no pathogenic consequence and are thus termed "passenger" mutations. Meanwhile, HSCs acquire nonsynonymous exonic mutations with translational consequences ("coding" mutations) at a rate of about one mutation per decade,[98] though most of these will not affect clonal dynamics or cellular function. Since the incidence of MDS increases with age, HSCs from an average MDS patient might typically contain between 5 and 10 coding mutations, though the actual number varies widely between patients, against a background of hundreds of non-coding or synonymous single nucleotide variations (SNVs). Only a minority of coding mutations, the "drivers," actually contribute to the development of the MDS.[99]

Although the recurrently mutated genes in MDS can be characterized in several ways,[100–104] one of the simplest strategies categorizes them based on their typical position in MDS ontogeny. In this model, mutations that occur early in MDS pathogenesis, such as those in splicing factors, methylation enzymes, and certain epigenetic modifiers, are capable of driving clonal expansion, but their other phenotypic consequences are variable. Mutations that occur later in MDS development may not be capable of driving clonal expansion on their own, but their effects may complement or amplify the originating mutations, and they may be associated with clinical changes, such as worsening of cytopenias. Finally, the acquisition of activating mutations, especially within the RAS pathway, drives transformation to AML. This section is a brief summary of our current understanding of some of the most important genes and pathways that are recurrently deranged in MDS.

TABLE 61.2 Selected Germline Myelodysplastic Syndromes Predisposition Syndromes

Disorder	Cellular Defect	Gene	Inheritance	Features
Fanconi anemia	DNA repair	*FANC* genes (many)	Variable	Other cancers, facial and skeletal dysmorphologies, short stature, other systemic disorders
Diamond-Blackfan anemia	Ribosomal function	Multiple (*RPL* and *RPS* genes, others)	Mostly AD	Short stature, facial dysmorphologies, cardiac/renal abnormalities
Shwachman-Diamond syndrome	Ribosomal function	*SBDS* (most common), *DNAJC21, EFL1*	AR	Short stature, exocrine pancreatic deficiency, immunodeficiency
Telomeropathies	Telomere maintenance	*DKC1, TERT, TERC*, other telomerase complex components	Variable	Dyskeratosis congenita: nail dystrophy, skin pigmentation abnormalities Other: pulmonary fibrosis, cirrhosis, premature graying
FPD-AML	Abnormal RUNX1 function	*RUNX1*	AD	Thrombocytopenia, platelet dysfunction
MonoMAC, Emberger syndrome	Abnormal GATA2 function	*GATA2*	AD	MonoMAC: monocytopenia, hearing loss, warts, atypical mycobacterial infections; Emberger: lymphedema
SAMD9 mutation	Abnormal SAMD9 function	*SAMD9*	AD	Short stature, adrenal hypoplasia, infections
Li-Fraumeni syndrome	*TP53* defects	*TP53*	AD	Other cancers (breast, osteosarcoma, soft tissue sarcoma, CNS, adrenocortical carcinoma, etc.)
DDX41 mutation	Abnormal DDX41 function	*DDX41*	AD	Other hematologic cancers (AML, CML, lymphoma); presents in middle/older age

AD, Autosomal dominant; *AR*, autosomal recessive; *FPD-AML*, familial platelet disorder with propensity for AML.

Originating Mutations

The unifying feature of these mutations is that they occur early in MDS pathogenesis, which can be either inferred by high VAF indicating presence within the majority of cells in an MDS clone, or from analysis of sequential samples from single individuals. The same mutations are also commonly found in clonal hematopoiesis,[39,40,105] an asymptomatic condition in which driver mutations of MDS and AML are found in the blood of individuals with normal blood counts and without known hematologic malignancies, which shows that they are capable of driving clonal expansion as sole lesions.

Some of the common originating MDS mutations, including *TET2, DNMT3A*, and *ASXL1*, do not have significant phenotypic consequences beyond conferring a selective advantage to mutant HSCs. Splicing factor mutations (e.g., *SF3B1, SRSF2, U2AF1*), in contrast, are frequently associated with development of cytopenias and morphologic dysplasia on bone marrow examination. Somatic mutations in *TP53*, which is responsible for integrating the cellular response to DNA damage, constitute a unique category of high-risk MDS that frequently, though not always, develops after exposure to cytotoxic therapy[71,106,107] and is rarely associated with other cooperating mutations.[104,108]

TET2

TET2, which encodes a member of the Ten-Eleven Translocation gene family, is mutated in 20% to 30% of all MDS cases[109] and in 40% to 50% of CMML.[110] The *TET2* protein is a methylcytosine oxygenase responsible for converting 5-methylcytosine (5mC) into 5-hydroxymethylcytosine (5hmC) using iron and α-ketoglutarate (α-KG, produced by IDH1 and IDH2), and for further oxidizing 5hmC to 5-formyl- and 5-carboxycytosine.[111] These reactions contribute to demethylation through base excision repair back to unmodified cytosine.[112] Mutations in *TET2* tend to be inactivating frameshift or nonsense mutations or specific missense substitutions predicted to lead to abrogation of protein function, and many patients are either compound heterozygotes or have UPD at chromosome 4q, leading to effective abrogation of TET2 function.[113] Indeed, patients with *TET2* mutations have been shown to have globally altered methylation profiles.[114]

DNMT3A

The *DNMT3A* gene consists of 29 exons and encodes a 908-amino acid protein that, along with DNMT3B, is one of the two enzymes responsible for de novo CpG methylation independent of replication, whereas a third methyltransferase, DNMT1, is responsible for maintenance of baseline hemi-methylation during active replication.[115] Only *DNMT3A* mutations, however, have been found to occur recurrently in myeloid malignancies, perhaps suggesting differential expression in hematopoietic cells. *DNMT3A* mutations in patients with hematologic malignancies, which include truncating mutations and SNVs in key functional domains, are associated with reduced enzymatic function. For unclear reasons, *DNMT3A* mutations are relatively less common in MDS (5% to 15%) than they are in AML (30% to 50%)[116] or clonal hematopoiesis (60% to 80%).[39,40]

ASXL1

ASXL1 codes for a polycomb chromatin-binding protein and is involved in epigenetic regulation of gene expression.[117] It acts as a coactivator of the retinoic acid receptor and directly interacts with chemical modifiers of histones (e.g., NCOA1, a histone acetyltransferase, and LSD1, a histone demethylase). *ASXL1* mutations occur in about 10% to 29% of total MDS and myeloproliferative neoplasm (MPN) patients[100] and 40% of CMML patients.[118] Pathogenic *ASXL1* mutations are exclusively truncating variants in the C-terminal portion of the protein.[119] In studies of MDS cohorts, investigators have observed that *ASXL1* mutations are rarely associated with *DNTM3A* and *JAK2* mutations[120] but frequently co-occur with *TET2*, *SRSF2*, and *RUNX1* abnormalities.[100,121]

TABLE 61.3 **Genes Somatically Mutated in MDS**

	Gene	Frequency (%)	Notes
Originating	*TET2*	20–30 (MDS) 40–50 (CMML)	Enriched in CMML Mutually exclusive with IDH Often seen in older people without MDS (clonal hematopoiesis)
	DNMT3A	8–13	Often seen in older people without MDS (clonal hematopoiesis)
	ASXL1	10–20 (MDS) 30–40 (CMML)	Enriched in CMML Often seen in older people without MDS (clonal hematopoiesis)
	SF3B1	20–30	Strong association with RS
	SRSF2	10–15 (MDS) 40 (CMML)	Enriched in CMML
	U2AF1	5–12	Association with del(20q)
	TP53	10–12	Association with complex karyotype, therapy-related disease, poor prognosis
	PPM1D	<5	Association with therapy-related disease Not clearly a true driver
Intermediate	*RUNX1*	10–15	Can be somatic or germline
	BCOR	5–10	Frequently associated with RAS pathway mutations
	STAG2	5–10	Cohesin class mutations enriched in high-risk MDS and secondary AML
	EZH2	5–10 (MDS) 20–30 (CMML)	May be functionally involved in some cases of 7q−
	IDH1/2	<5	More frequent in AML
	ATRX	Rare	Associated with acquired thalassemia
Transforming mutations	*NRAS*	5–10	Seen in progression to AML
	KRAS	5–10	Seen in progression to AML
	NF1	<5	Can occasionally be germline
	PTPN11	<5	More common in JMML
	BRAF	Rare	Also seen in hairy cell leukemia

AML, Acute myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *GCPR*, G-coupled protein receptor; *IDH*, isocitrate dehydrogenase; *JMML*, juvenile myelomonocytic leukemia; *MDS*, myelodysplastic syndromes; *MPN*, myeloproliferative neoplasm; *RS*, ring sideroblasts.

SF3B1

SF3B1 encodes the component of the U2 small nuclear riboprotein complex (snRNP) responsible for 3′ branch site recognition and is the most frequently mutated splicing factor gene.[100] *SF3B1* mutations can be found in about 20% to 30% of all MDS patients. They have a particularly strong association with ring sideroblast morphology, with mutations found in >60% to 85% of patients with MDS-MLD-RS, MDS-SLD-RS, or MDS/MPN-RS-T, as well as a substantial proportion of other myeloid neoplasms in which ring sideroblasts can be found.[122,123] The most common mutations are heterozygous missense substitutions that change lysine to glutamate at codon 700 (K700E), with other less common hotspots in the same vicinity such as K666. *SF3B1* mutations tend not to be associated with complex karyotypes or poor-prognosis mutations.[124] They are clinically associated with isolated, transfusion-dependent anemia, preserved WBC and platelet counts, and a lower risk of progression to AML.[125] In cross-sectional studies of MDS patients, *SF3B1* mutations appear to confer a relatively good prognosis,[102] and they are relatively less common in high-risk MDS cohorts, such as those undergoing allogeneic hematopoietic stem cell transplant.[104]

SRSF2

SRSF2 encodes a member of the serine/arginine (SR)-rich family of pre-mRNA splicing factors that interacts with the U2 and U1 components of the spliceosome. After *SF3B1*, it is the second-most commonly mutated splicing factor, with mutations present in 10% to 15% of MDS[126] and 40% of CMML patients.[127] Almost all mutations are heterozygous missense substitutions for proline at codon 95, while a small minority of in-frame insertions or deletions affects the same region. *SRSF2* mutations co-occur with several other mutations, many of which are also frequently found in CMML, including *TET2*, *ASXL1*, *RUNX1*, and *STAG2*.[100] In contradistinction to patients with *SF3B1* mutations, patients with *SRSF2* mutations tend to have more dysplasia in the granulocytic lineage and less in the erythroid lineage, and patients consequently tend to have a less prominent transfusion requirement, more enrichment in the RAEB subtypes, and, at least in some studies, a greater risk of progression to AML.[128]

U2AF1

U2AF1 encodes an auxiliary factor in the U2 spliceosome that is responsible for recognizing the AG splice acceptor dinucleotide at the 3′ end of introns. *U2AF1* mutations occur in about 10% to 15% of patients with MDS.[129] Similar to other commonly mutated splicing factor genes, the two most common mutations are both heterozygous missense substitutions, again implying a dominant negative effect, and both appear to alter sequence specificity of pre-mRNA binding and splicing.[130] The two mutations are in separate zinc finger DNA binding domains, one at codon 34 toward the N terminal of the protein, and one at codon 157 toward the C terminal.

TP53

TP53 mutations, which result in inactivation of the DNA damage response (DDR) pathway,[131] define a unique evolutionary pathway in MDS. *TP53* mutations occur in about 10% to 15% of MDS patients and are universally associated with a poor prognosis.[104,108] *TP53* mutations are often not accompanied by other cooperating point mutations, suggesting that they may be able to drive MDS development as sole lesions. However, they have been shown in cell culture and animal models to be disadvantageous relative to wildtype cells in the absence of chemotherapy or radiation.[132] Consistent with these findings, they are enriched in cases of therapy-related MDS[104,106] and are often associated with complex and monosomal karyotypes that would likely not be tolerated in cells with functioning DDR pathways. They also frequently co-occur with del(5q) and may represent a progression pathway for patients with 5q− syndrome, including those treated with lenalidomide.[133]

PPM1D

PPM1D encodes a phosphatase that negatively regulates multiple components of the DDR pathway, including p53, ATM, ATR, CHK1, and CHK2,[134–136] as well as the MAP kinase pathway[137] and the NFKB pathway.[138] Under normal conditions, its role is to restore homeostasis after periods of cellular stress. Pathogenic *PPM1D* mutations truncate the protein near the C-terminus and confer a gain of phosphatase function,[139–142] thus downregulating the DDR and partially phenocopying *TP53* mutations. *PPM1D* mutations are frequently found in the blood of adults who have previously received cytotoxic therapy.[71,107,143] They have also been found in MDS patients, where they are strongly associated with prior therapy.[144] In MDS, *PPM1D* is frequently co-mutated with *TP53* and does not on its own appear to have a strong correlation either with prognosis or with other phenotypic features, such as complex cytogenetics.[144] It is therefore not clear whether *PPM1D* mutations actually drive MDS development or whether they mark bystander HSC clones that expand in the context of cytotoxic therapy.

Intermediate Mutations

The common feature of these mutations is that, while they are frequent in MDS, they almost never appear as sole lesions, are almost never found in clonal hematopoiesis, and usually appear to have subclonal relationships to founding mutations based on allele fraction. It is thus likely that most of these mutations are incapable of driving clonal expansion on their own but play important cooperative roles in MDS pathogenesis.

EZH2

EZH2 encodes the catalytic subunit of protein repressive complex 2 (PRC2), which promotes the di- and tri-methylation of lysine 27 on histone 3 (H3K27). Locally, methylated H3K27 results in closed chromatin and transcriptional repression, and global H3K27 trimethylation in particular is associated with reduced pluripotency and cellular senescence, suggesting a role for *EZH2* in regulation of cell fate.[145] *EZH2* resides on the long arm of chromosome 7, and its loss has been hypothesized to be at least part of the reason 7q− is a deleterious cytogenetic occurrence in MDS,[146] though not all 7q deletions affect the *EZH2* locus. Mutations in *EZH2* itself are found in 5% to 10% of patients with MDS[102] and 20% to 30% of patients with CMML.[147] Consistent with the model of *EZH2* as a negative regulator of pluripotency and survival, and in contrast to the gain of function mutations in lymphoproliferative neoplasms, *EZH2* mutations in MDS tend either to be inactivating frameshift or nonsense mutations, or missense mutations concentrated in the gene's SET domain, which is critical for DNA binding.[148,149]

RUNX1

RUNX1 (formerly known as *AML1*) is a transcription factor gene commonly mutated in MDS, and its biology is complex. It encodes the alpha subunit of the core binding transcription factor (CBF) and is involved in determining the lineage fate of hematopoietic stem cells.[150] *RUNX1* was initially identified as one of the genes involved in two different common pathogenic translocations: t(8;21), found in AML, and t(12;21), found in ALL.[151,152] Subsequently, germline point mutations in *RUNX1* were identified in autosomal dominant FPD-AML,[53] and later as somatic events in both sporadic AML and MDS.[153] Reflecting the complexity of *RUNX1* biology, mutations occur throughout the gene, can be either monoallelic or biallelic, and can be frameshift insertions or deletions or nonsense or missense substitutions. However, most mutations appear to have an inactivating effect on *RUNX1* function, either by affecting the DNA-binding RUNT domain or by disrupting the C-terminal protein interaction domain.[154] Many of the remaining mutations outside these regions appear to affect RUNX1 interactions with epigenetic regulators like MLL, thereby affecting histone methylation.[155]

BCOR

This gene encodes a corepressor of BCL-6, a transcription factor required for germinal B-cell development. However, it also has a noncanonical role as a component of the PRC1.1 complex, which monoubiquitinates the H2A histone component and leads to epigenetic silencing.[156] Truncating *BCOR* mutations are found in 5% to 10% of MDS cases, likely due to disruption of PRC1.1 function.[100,157,158] They frequently co-occur with TET2 mutations, a combination that in animal models has been shown to induce a rapidly fatal MDS due to derepression of key myeloid and HOXA genes, leading to myeloid skewing and clonal advantage, as well as simultaneous induction of p53 target genes in erythroblasts, which causes dyserythropoiesis and anemia.[159]

ETV6

ETV6 encodes an ets-like transcription factor with mostly repressive activity.[160] It is situated on the short arm of chromosome 12, and its role in hematologic malignancy has been best characterized by its involvement in recurrent translocations, including t(3;12)(q26;p13)[161] and deletions of 12p.[162] In MDS, however, both missense and inactivating frameshift point mutations have been described as well.[163] *ETV6* mutations are relatively rare events in MDS, occurring in at most 5% of cases[100]; recently, familial cases of MDS and AML due to inherited *ETV6* mutations have also been described.[54]

Cohesin Complex Genes

Genes encoding members of the cohesin complex family, including *STAG2*, *SMC3*, *RAD21*, and *SMC1A*, are each mutated in a small minority of MDS cases, but collectively, they can be found in about 10% of MDS.[164] They have multiple physiologic roles, including the promotion of chromosomal stability during mitosis, as well as the generation of chromatin looping structures that enable promoter interactions with distal enhancer elements.[165] Their role in MDS pathogenesis is largely driven by disruption of these epigenetic functions. *STAG2* mutations, which are the most common of this group, appear to have specific interactions with other myeloid transcription factors, including *RUNX1*.[121]

Transforming Mutations

Mutations in tyrosine kinase and growth factor receptor genes are typically associated with pro-proliferative signals and occur in a wide range of myeloid malignancies, including AML (*FLT3*[166]), myeloproliferative neoplasms (*JAK2*[167] and *MPL*[168]), and mast cell disorders (*KIT*[169]). While they do occur in MDS, they are usually late, subclonal events that often mark progression to secondary AML.[170] Activating mutations in *NRAS* are the most frequent tyrosine kinase mutations found in MDS,[171] but still only occur in about 5% of cases and as above tend to begin as subclonal, pro-proliferative events that frequently drive the transition to AML.[172]

Karyotypic Abnormalities

Chromosomal abnormalities, larger-scale genetic aberrations that can be detected on either karyotype or FISH, are also common events in

MDS (see Chapter 70).[173] The most common types of abnormalities in MDS are deletions or duplications of very large chromosomal regions; as opposed to some other hematologic cancers, translocations and inversions are less common. Several of the most common karyotypic abnormalities have been shown to have prognostic value, and one—del(5q)—has enough unique biologic features to be its own subclassification within the WHO criteria.

Del(5q)

Interstitial deletion of the long arm of chromosome 5 (del(5q)) is the most common chromosomal abnormality in MDS,[174] and del(5q) is the only karyotypically-defined subtype recognized by the WHO.[20] Although the specific region affected varies between patients, there are two commonly deleted regions (CDRs), one on 5q31.1 and the other at 5q32–33.3, with most patients having a deletion that includes both CDRs.[175,176] MDS patients in whom del(5q) is the sole karyotypic abnormality often display the "5q-minus syndrome," which is clinically characterized by anemia, normal or elevated platelet count, female predominance,[177] lower risk of transformation to AML, and a striking response to lenalidomide.[178]

The clinical and molecular physiology of 5q− syndrome is complex, and multiple genes lost in the CDRs are responsible for different aspects of the 5q− phenotype. First, haploinsufficiency of RPS14, a ribosomal subunit gene located at 5q31.2, is responsible for the dyserythropoiesis seen in the syndrome,[179] due to p53 expression[180] that is mediated by induction of innate immune signaling.[181] Second, deletion of a key microRNA, miR-145, is responsible for the megakaryocytic component of the phenotype.[182] Separately, haploinsufficiency of CSNK1A1, which is located at 5q32 and encodes casein kinase 1-alpha, is responsible for the sensitivity to lenalidomide, which accelerates the ubiquitination and degradation of remaining casein kinase 1-alpha through a cereblon-dependent process.[183] Importantly, the coordinate loss of RPS14, miR-145, and CSNK1A1 has a greater impact on the del(5q) impact than single loss of any one gene.[184] *TP53* mutations and 17p loss frequently develop in the setting of del(5q),[184] often acting as a resistance mechanism following lenalidomide treatment.

Chromosome 7 Abnormalities

Deletion of one entire copy of chromosome 7 (i.e., monosomy 7) is also characteristic of MDS and portends a poor prognosis.[185] The pathogenesis of chromosome 7 abnormalities is incompletely understood. Several genes recurrently mutated in MDS, including EZH2, *MLL3*,[186] and *CUX1*,[187] lie on 7q, and it has been hypothesized that loss of some or all of chromosome 7 contributes to MDS pathogenesis via a haploinsufficiency mechanism similar to that of del(5q). The evidence for such a mechanism, however, is weak: unlike del(5q), there is no common deleted region on chromosome 7 in which to focus efforts at driver gene discovery.[176,188] It is important to note that in the IPSS-R, del(7q) is considered to be an intermediate-prognosis abnormality distinct from monosomy 7, which is classified as poor prognosis.[189]

Trisomy 8

Trisomy 8 is present in about 5% of MDS patients and can be found in a wide range of other myeloid disorders, including AML, myeloproliferative neoplasms, and aplastic anemia. In MDS, it can often be seen as a late, subclonal event.[190] Although its contribution to pathogenesis is incompletely understood, MDS patients with trisomy 8 appear to upregulate *WT1*, an oncogene that can be mutated in AML (but very rarely in MDS), which appears to behave as a neoantigen that stimulates the expansion of oligoclonal $CD4^+$ and $CD8^+$ T cells.[191] Some evidence suggests that these populations may contribute to impairment of hematopoiesis in MDS patients with trisomy 8,[192] which may explain why some patients with isolated trisomy 8 can have substantial responses to immune suppression with anti-thymocyte globulin (ATG).[191] Trisomy 8 has also been associated with the development of paraneoplastic autoimmune phenomena, such as Behçet disease,[193] again reflective of the immune dysregulation characteristic of this cytogenetic abnormality.

Del(20q)

Del(20q) is an infrequent chromosomal aberration in MDS, occurring in about 2% of patients.[194] Patients with del(20q) frequently have prominent thrombocytopenia, may have concomitant mutations of *U2AF1*, and appear to have an intermediate prognosis,[195] although 20q loss can also be a late event that indicates clonal progression of disease.[196] Although *ASXL1* resides on 20q, it sits outside the CDR.[197]

17p Deletions

Chromosome 17 abnormalities occur most often in MDS in association with complex karyotypes, which is most likely related to the fact that *TP53* resides within the common deleted region on 17p.[198] In MDS, many patients with loss of 17p have an inactivating mutation of their remaining copy of *TP53*, implying that haploinsufficiency is not in and of itself enough to drive pathogenesis,[199] although some common *TP53* hotspot mutations may function as dominant negatives and not require loss of the second allele to drive malignant transformation.[132] As with *TP53* point mutations, loss of 17p is a universally poor prognostic factor in MDS and is frequently seen in cases of therapy-related disease.[69]

Complex and Monosomal Karyotypes

Complex karyotypes, defined by three or more cytogenetic abnormalities within the same clone, are common abnormalities in MDS.[173] About half are associated with *TP53* mutations; conversely, many patients with *TP53* mutations have complex karyotypes.[198] As opposed to 17p abnormalities, which are reflective of the *TP53* loss itself, complex karyotypes may instead be effects of p53 loss and large-scale structural DNA damage that would have triggered p53-mediated apoptosis in normal cells. Monosomal karyotypes, defined by loss of at least two entire chromosomes or one monosomy plus one other abnormality, are also common and also confer a poor prognosis, particularly when associated with monosomy 7 or monosomy 5.[200] When monosomal and complex karyotypes occur together, however, the monosomy does not appear to confer an additional poor prognosis beyond that of the complex karyotype.[201]

Other Karyotypic Abnormalities

A number of other cytogenetic abnormalities have been repeatedly described in MDS, including -Y,[202] del(13q),[70] del(11q), del(12p) or t(12p),[203] del(9q),[194] idic(X)(q13),[194] t(11;16)(q23;p13.3),[204] t(3;21)(q26.2;q22.1),[205] t(1;3)(p36.3;q21),[206] t(2;11)(p21;q23),[204] inv(3)(q21q26.2),[204] and t(6;9)(p23;q34).[207] Most of these do not have specific phenotypes associated with them, but some do confer prognostic information and are included in the IPSS-R. In particular, -Y and del(11q) are designated "very good" prognosis; del(12p), del(20q), isolated del(5q), and normal karyotypes are considered "good"; trisomy 8, del(7q), isochromosome 17(q), trisomy 19, and trisomy 21 are considered "intermediate;" monosomy 7, double deleted (7q), derivative (3q), and complex karyotype with exactly three abnormalities are considered "poor"; and complex karyotypes with more than three abnormalities are considered "very poor."[20]

The Marrow Microenvironment in Myelodysplastic Syndromes

MDS develops not in isolation but within the microenvironment of the bone marrow stroma, also called the "hematopoietic niche" (see Chapter 14).[208] Under normal circumstances, hematopoiesis is in part regulated by paracrine signals released from non-hematopoietic mesenchymal cells,[209] and some of these processes are dysregulated in MDS. For example, some patients with MDS have abnormal circulating levels of cytokines known to affect hematopoiesis, including monocyte colony-stimulating factor (M-CSF), interleukin 1a, and granulocyte–monocyte colony-stimulating factor (GM-CSF),[210] and hematopoietic cells from MDS patients respond abnormally to these cytokines compared to cells from healthy controls.[211] Additionally, hematopoietic progenitor cells transplanted into older mice display a narrower range of clonal expansion than identical cells transplanted into younger mice, suggesting that an aging niche might exert selective pressure on dominant HPC clones.[212] Conditional deletion of the gene encoding dicer1, a microRNA processing enzyme, in osteoprogenitor cells can induce myelodysplasia and secondary AML in mice,[213] and mesenchymal cells of MDS patients display altered expression of DICER and DROSHA, another microRNA-processing enzyme.[214] Finally, introduction of an activating B-catenin mutation in mouse osteoblasts can induce the development of AML through induction of the Notch ligand jagged1, which leads to Notch activation in HSCs.[215]

While these studies show that non-cell autonomous features of the marrow microenvironment can induce myelodysplasia in model systems, it is not clear whether this is a dominant mechanism of MDS initiation in humans. The majority of MDS cases have at least one detectable genetic or karyotypic abnormality,[100,102,144] suggesting that cell-intrinsic dysregulation is usually necessary for disease propagation. Moreover, many of the mutations common in MDS, including those in *TET2*,[45,216] *DNMT3A*,[217] and many of the splicing factor genes,[218] lead to altered inflammatory signaling in terminally differentiated leukocytes. It is therefore likely that at least some microenvironmental dysfunction is a consequence of MDS clones, not a cause.

Immune Dysregulation

In normal human tissues, both the innate and adaptive immune systems play important roles in identifying, isolating, and destroying early clones with malignant potential before they are able to transform into clinically evident cancers. Perturbation of this immune response presumably allows the persistence and propagation of abnormal clones in MDS, but the extent to which this is pathogenically important is not clear.[219]

Several aspects of innate immunity can be abnormal in MDS patients.[220] Some toll-like receptors, including TLR4, are overexpressed on MDS progenitor cells,[221] and increased TLR signaling has been associated with higher degrees of apoptosis and the development of cytopenias. Myeloid-derived suppressor cells are significantly expanded in some patients with MDS, and increased signaling in these cells via interaction with S100A9, an important inflammatory mediator, stimulates inappropriate apoptosis in hematopoietic precursor cells.[222] In fact, activation of the NLRP3 inflammasome may be a convergent mechanism of clonal expansion and pyroptotic cell death that is activated by many of the common drive mutations found in MDS.[218] Coincident with these findings, population-level data suggest that patients with some chronic inflammatory stimulation are at increased risk of developing MDS and AML.[223]

Abnormalities in the adaptive immune system also exist in MDS. These have been particularly well described in hypoplastic variants, which have similarities to aplastic anemia at both the cellular and genetic level, and both can respond to immune suppression.[224] Oligoclonal T-cell receptor gene rearrangements can be found in MDS patients of all subtypes,[225] and clinically detectable abnormalities of NK-cell, B-cell, and T-cell number and function can be detected in a subset of patients as well.[226–228]

Abnormal Apoptosis

Although MDS is typically characterized by normal or increased marrow cellularity, abnormalities of apoptosis are frequently described, particularly in low-risk variants, where increased apoptosis has been hypothesized to contribute to the development of ineffective hematopoiesis.[229] There are two major mammalian apoptosis pathways. The death receptor pathway, also known as the external pathway, is triggered by ligation of tumor necrosis factor (TNF) family members, which leads to the recruitment and activation of caspases at the cell surface.[230] There is ample evidence of abnormalities in this pathway in MDS; for instance, TNF-α levels have been shown to be increased in all MDS subtypes,[231] and other proapoptotic cytokines, including IL-8, transforming growth factor β, interferon-γ, and Fas ligand, have been shown to be elevated as well.[232]

The other major apoptotic pathway, known as the BCL-2 or intrinsic pathway, involves a balance between pro-apoptotic (BAX, BAK, BAD, PUMA, and others) and anti-apoptotic molecules (BCL-2, BCL-XL, MCL-1, and others),[233] and can be abnormal in MDS. For example, ratios of pro-apoptotic (Bax/Bad) to anti-apoptotic (Bcl-2/Bcl-XL) molecules are elevated in patients with lower-risk subtypes, but the ratio reverses in MDS with excess blasts and secondary AML, primarily driven by increased BCL-2 expression.[234] Consistent with this observation, but somewhat paradoxically, inhibition of apoptosis by BCL2 can prevent leukemic transformation in murine models of MDS.[235] Preclinical studies further suggest that inhibition of BCL-2 and other anti-apoptotic molecules may delay progression of disease and may sensitize MDS cells to hypomethylating agents such as azacytidine[236]; clinical trials of BCL-2 inhibitors such as venetoclax in MDS are currently ongoing.

Transformation to Acute Leukemia

Some patients with MDS go undiagnosed until they present with AML. An antecedent unrecognized MDS phase may be suspected on the basis of dysplastic-appearing morphology or long-standing incompletely evaluated cytopenias,[20] but can also be inferred by the presence of MDS-associated mutations, including *SF3B1*, *SRSF2*, *U2AF1*, *ZRSR2*, *ASXL1*, *EZH2*, *BCOR*, or *STAG2*.[237] Absence of these mutations does not imply the converse conclusion that the AML arose de novo; while *NPM1* mutations appear to be restricted to de novo AML, mutations in *DNMT3A*, *TET2*, and *IDH1/2* are not ontogeny-specific. *TP53*-mutated AML comprises its own category and is associated with prior chemotherapy and complex karyotypes.[106]

In most cases, progression of MDS to AML involves the acquisition of pro-proliferative mutations, which tend to be late, subclonal events.[238] As discussed above, patients who develop secondary AML from an antecedent MDS tend to have a poorer prognosis, with both a lower rate of complete remission and a poorer overall survival, independent of remission, than patients with de novo AML.[237,239] In unselected populations, some of this difference in outcome can be explained by demographic characteristics associated with secondary AML, including older age and increased number of comorbidities, mirroring the characteristics of the MDS population. However, patients with secondary AML have inferior outcomes even compared to age-matched controls with de novo AML,[237] reflective of the refractory nature of the antecedent MDS. Overcoming the intrinsic resistance to therapy common to most patients with MDS remains one of the central challenges of treating the disease.

CLINICAL MANIFESTATIONS

Compared to other hematologic neoplasms, the clinical features of MDS are often underemphasized relative to laboratory aspects of the disease. This is due in part to the fact that the major common physiologic defect, ineffective hematopoiesis, usually leads to nonspecific signs or symptoms, such as fatigue or exercise intolerance.

Nevertheless, it is important to understand these features within the context of the disease's pathogenesis and management.

Some patients with MDS have distinct clinical phenotypes that are largely related to genetics or specific pathologic features. MDS can also coexist with other hematologic malignancies, including multiple myeloma,[240] hairy cell leukemia,[241] chronic lymphocytic leukemia (CLL),[242] non-Hodgkin lymphoma,[243] and large granular lymphocyte leukemia.[244]

Signs and Symptoms

Although some patients with MDS profess to being asymptomatic, fatigue is extremely common, as is a sense of general malaise.[245] Rarely, patients may complain of diffuse arthralgias or bone pain. Smaller proportions of patients may present with severe or recurrent infections as a result of immune defects, most commonly neutropenia or granulocyte dysfunction.[246] Bleeding or easy bruising as a result of thrombocytopenia or qualitative platelet defects also bring some patients with MDS to medical attention.[247] When present, fever is most commonly a sign of infection, though a small number of patients may have low-grade fevers in the absence of a discernible infection. Splenomegaly or hepatomegaly are rare in MDS and should prompt consideration of either an alternate diagnosis or an MDS/MPN overlap syndrome, such as CMML, which is defined by peripheral monocytosis and exclusion of other neoplasms or reactive conditions that can cause monocytosis.

Dermatologic Manifestations

Although dermatologic manifestations of MDS are uncommon,[248] a few deserve specific mention. Neutrophilic dermatosis (Sweet syndrome; Fig. 61.2) is characterized by painful plaques on the face, neck, trunk or extremities, often in association with fever and diffuse arthralgias.[249] While neutrophilic dermatosis can be seen in any subclass of MDS, it is classically associated with an impending transformation to AML. It frequently responds to steroids or dapsone therapy, but may recur as steroids are tapered.[250]

Pyoderma gangrenosum (PG; Fig. 61.3) is an ulcerative, necrotic lesion that most frequently develops on the extremities, and is occasionally associated with MDS.[251] Histologically, it is characterized by neutrophilic infiltrates; clinically, it may be associated with pathergy where minor trauma such as intravenous catheter insertion leads to the development of skin lesions or ulcers that may be resistant to healing. A high index of suspicion is necessary to distinguish it from necrotizing infections since treatment of PG involves systemic steroids and surgical debridement is contraindicated.

Other dermatologic manifestations of MDS include monocytic infiltrates, classically of the gingiva and other mucosal surfaces, a process most frequently seen in CMML[252]; the development of a chloroma or granulocytic sarcoma, which by definition indicates progression to AML; and petechial lesions, which most frequently develop on the lower extremities and are associated with severe thrombocytopenia.

Autoimmune Manifestations

Some patients with MDS may have rheumatologic features to their disease, which may in part arise from immune dysregulation that occurs during disease pathogenesis.[253] In a few patients, these may be the presenting complaint. Such manifestations can include episodes of seronegative oligoarthritis or polyarthritis,[254] cutaneous vasculitis,[255] inflammatory myositis,[256] lupus-like syndromes, or autoimmune peripheral neuropathies. Other autoimmune phenomena have also been reported, including mucocutaneous ulcerations similar to Behçet disease, iritis, inflammatory bowel disease, and pure red cell aplasia. Many of these conditions respond to the initiation of immunosuppressive agents such as corticosteroids or T-cell directed therapies.[257]

LABORATORY MANIFESTATIONS

Erythroid Lineage

Most patients with MDS present with some degree of anemia, which contributes to fatigue, the most common presenting complaint.[258] The anemia is often macrocytic, and the peripheral blood smears of MDS patients frequently show a variety of abnormal forms, including oval macrocytes, and less commonly dacrocytes, elliptocytes, or acanthocytes.

Anemia in MDS is usually due to ineffective hematopoiesis. Consequently, the serum erythropoietin (EPO) level is typically elevated, though in many elderly patients it is still lower than would be expected for the degree of anemia, in some cases because of subclinical renal insufficiency.[259] Ineffective hematopoiesis causes abnormal iron utilization in a substantial number of patients, many of whom have evidence of iron overload based on ferritin or transferrin saturation even in the absence of transfusions.[260] Studies have shown other abnormalities of erythrocytes as well, including increased levels of fetal hemoglobin,[261] aberrant surface antigens,[262] increased osmotic fragility, and low levels of pyruvate kinase,[263] although none of these are routinely assessed in clinical practice. Hemolysis is rarely observed.

Morphologic changes in the erythroid lineage on bone marrow examination can vary widely from patient to patient. Many patients have megaloblastoid erythroid precursors that contain multiple nuclei or asynchronous maturation of the nucleus and cytoplasm (Fig. 61.4). It is this asynchrony, with continued membrane synthesis in the absence of normal nuclear maturation, which is thought to give rise to the macrocytosis displayed by most patients.

Ring sideroblasts (see Fig. 61.4), erythroid precursors containing iron-laden mitochondria, are another relatively common finding.[264] These are defined by the presence of at least five granules that are positive with the Prussian Blue reaction and surround at least one third of the circumference of the cell nucleus. Ring sideroblasts are not in and of themselves diagnostic of MDS, and can be seen in a number of other disorders including congenital sideroblastic anemias, anti-tuberculosis drugs, and nutritional deficiencies, but their presence in association with other dysplastic changes is highly specific for MDS and, as described above, is tightly linked to acquired *SF3B1* mutations.[122] Ring sideroblasts may be seen in all subtypes of MDS; the specific designation of MDS-SLD-RS or MDS-MLD-RS is made when ring sideroblasts comprise at least 15% of the erythroid precursors and blasts are not increased, or when ring sideroblasts are at least 5% of red cell precursors and an *SF3B1* mutation is present.

In a normal bone marrow, myeloid precursors typically outnumber erythroid precursors by a ratio of 2 to 4 to 1. A special case arises in cases of MDS in which this normal ratio is skewed toward the erythroid lineage, that is, 50% or more of the total cellularity is erythroid. If in this case 30% or more of the remaining cellularity is comprised of myeloblasts, the case may be diagnosed as erythroleukemia (WHO AML, not otherwise specified, subtype acute erythroid leukemia, erythroid/myeloid type; formerly FAB AML-M6A).[20]

Acquired hemoglobin H disease is a rare but well-described development in MDS that is associated with acquired mutations of *ATRX*,[265] a gene encoding a chromatin-remodeling protein. *ATRX* functional loss results in downregulation of globin synthesis in the alpha cluster (the genes themselves remain intact) but not the beta globin cluster. Patients with acquired *ATRX* mutations have clinical features resembling alpha thalassemia, including microcytosis, anisocytosis, poikilocytosis, target cells, schistocytes, dacrocytes, and beta-chain tetramers on crystal violet staining.[266] As opposed to the macrocytosis seen in most MDS patients, those with acquired *ATRX* mutations are typically profoundly microcytic, again similar to thalassemia.

Myeloid Lineage

About one-half of patients with MDS are neutropenic at the time of diagnosis, and more will become neutropenic with time.[267] Many also have defective neutrophil function irrespective of the absolute neutrophil count (ANC), and patients with MDS have been shown to have inadequate inflammatory responses to infections. Many have diminished production of hematopoietic growth factors like G-CSF and GM-CSF, and their neutrophils often have reduced phagocytic, chemotactic, or bactericidal capabilities.[268–270]

The granulocytes of MDS patients also display frequent morphologic abnormalities (Fig. 61.5). In the marrow, either myeloid hyperplasia or hypoplasia can occur, and there is often a prominent left shift toward immature forms. Myeloid precursors often display asynchronous maturation of the nucleus and cytoplasm. In promyelocytes this can manifest as an early hypergranulation coupled with reticulated nuclei and a prominent Golgi apparatus, but more mature myeloid forms are usually hypogranulated and hypolobated.

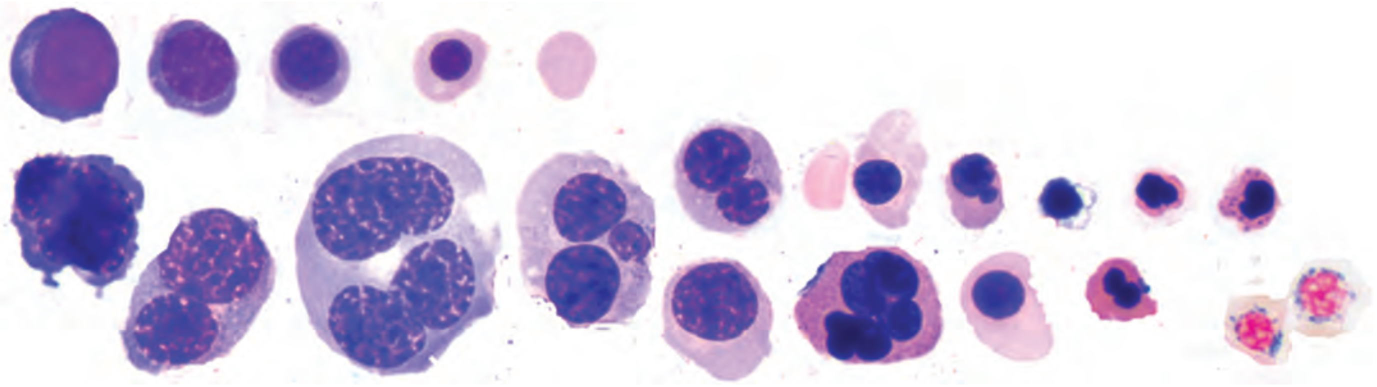

Figure 61.4 ERYTHROID DYSPLASIA. Examples of dysplastic erythroid precursors *(bottom)* compared to those with normal morphology in the sequence of erythroid maturation *(top)*. The dysplastic forms include (*left* to *right*) abnormal immature forms with multinucleation; maturing forms with multinucleation and nuclear-to-cytoplasmic dyssynchrony; and more mature forms with megaloblastoid change, nuclear budding, cloverleaf forms, cytoplasmic vacuolization, and cytoplasmic stippling. Ringed sideroblasts *(far right)* also are evidence of erythroid dysplasia. Photomicrographs are from patients with refractory cytopenia with multilineage dysplasia and ringed sideroblasts.

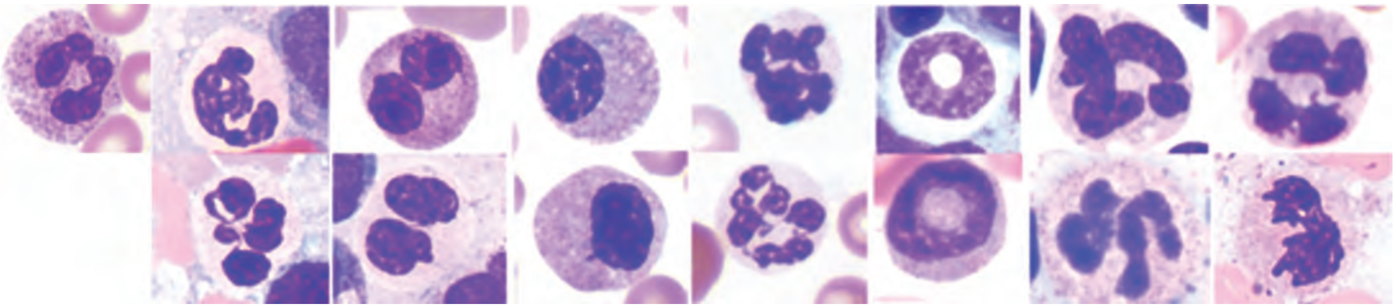

Figure 61.5 GRANULOCYTIC DYSPLASIA. Granulocytic dysplasia is most evident in mature neutrophils and can be contrasted to features of normal forms *(far left, top)*, which are usually still present as a subpopulation of the total cells in most cases. Granulocytic dysplasia is characterized by *(left to right, starting at second column)* reduced cytoplasmic granulation, nuclear hypolobation (resulting in the binuclear or single-lobed pseudo–Pelger-Huët forms), hypersegmentation, ringed forms ("rodent cells"), cells with nuclear twinning, and cells with excessive nuclear excrescences. Photomicrographs are from a number of cases of refractory cytopenia with multilineage dysplasia and refractory anemia with excess blasts.

The myeloid series may also be abnormally localized within the marrow: rather than differentiating in an organized fashion inward from the endosteum, immature cells often cluster centrally in a morphologic process known as abnormal localization of immature precursors (ALIP). ALIP has been shown to occur in most cases of MDS-EB and in about one-third of cases in which the blast percentage is less than 5%.[271] In these latter cases, ALIP may be an independent risk factor for subsequent development of AML.[272]

Morphologic characterization of the myeloid series is particularly important with regard to the blast count, since ≥20% myeloblasts is characterized as AML using the WHO classification, and ≥5% qualifies as MDS-EB. Even patients with lower blast proportions, however, still have an increased risk of developing AML, and some have proposed designating any MDS patient with more than 2% marrow blasts as having "oligoblastic leukemia."[273]

In the blood, morphologic abnormalities include pseudo Pelger-Huët cells, which have condensed chromatin and bilobed nuclei resembling an old-fashioned pince-nez (true Pelger-Huët cells are a benign congenital abnormality). Granulocytes may display other nuclear abnormalities as well, including hypersegmentation reminiscent of vitamin B_{12} deficiency, or aberrant ring shapes. The hypogranulation visible in the marrow typically persists in the peripheral blood, and the left shift typical of MDS marrows is often, though not always, present to some degree in the blood as well.

Despite these quantitative and qualitative defects in leukocytes, only a minority of MDS patients have problems with recurrent infections.[274] When infections do occur, they tend to be bacterial and often arise from the lower respiratory tract, skin, and mucous membranes. Patients without absolute neutropenia may still develop recurrent infections as a consequence of abnormal neutrophil function. Even though only some patients have recurrent infections, an infection is the most common cause of MDS-associated death.

Megakaryocytic Lineage

Thrombocytopenia is present in 25% to 50% of MDS patients at the time of presentation,[267] and some patients also have functional platelet defects, even if the platelet count is normal.[275] Laboratory abnormalities include prolonged bleeding times, defective granulation, and abnormal platelet aggregation indices mediated by hypofunctional platelet glycoprotein IIb/IIIa, leading to a defect similar to Glanzmann syndrome.[276,277] These defects can occasionally manifest as spontaneous bleeding, or can be unmasked after trauma or surgery.

Thrombocytosis, by contrast, is relatively unusual in patients with MDS, except in those with MDS/MPN overlap syndromes or 5q− syndrome.[278] *JAK2* mutations, in particular, are associated with thrombocytosis, and are enriched in MDS/MPN overlap cases.

In the marrow, megakaryocytes are most commonly present in normal or increased numbers. A number of morphologic abnormalities can be observed, including abnormally small forms (micromegakaryocytes), hypersegmentation, and nuclear hypolobation (Fig. 61.6).[279,280] Megakaryocytes may also be abnormally distributed in clusters scattered throughout the marrow in MDS, rather than their normal parasinusoidal positioning.

Lymphoid Lineage

Abnormalities in the lymphoid lineage have been described in subsets of patients with MDS. Some patients have been shown to have global decreases in NK cells,[226] deficient receptor localization on B cells,[228] or abnormal T-cell responses to mitogenic stimuli.[227] Certain types of immune functions, however, appear to be preserved, such as antibody-dependent cellular cytotoxicity.[281]

The mechanism by which these abnormalities develop in MDS is unclear. One hypothesis proposes that they could be indirectly reflective of shared somatic defects in a multipotent lymphoid-myeloid progenitor, which is possible given that most driver mutations in MDS patients are present in the LT-HSC compartment and can therefore be passed both to myeloid and lymphoid cells.[81] Alternatively, a number of immune functions, including both B-cell and T-cell diversity, diminish as a function of normal aging,[282,283] and in this context, deficiencies of immune function could develop as a consequence of lymphoid cells arising from and interacting with an abnormally aged hematopoietic niche.

Other Objective Findings

Patients with MDS may have a variety of other laboratory abnormalities as a consequence of their disease. Ineffective erythropoiesis may lead to inappropriate iron deposition, resulting in abnormally elevated ferritin and transferrin saturation, which may be exacerbated by congenital variants in iron processing.[284] Nonspecific markers of cellular turnover, such as elevations in lactate dehydrogenase,[285] uric acid, and phosphate, may also be seen. Reflective of underlying immune dysregulation, some patients may have abnormalities of immunoglobulins, including hypogammaglobulinemia, polyclonal hypergammaglobulinemia, or monoclonal gammopathies.[286,287] Whether this latter phenomenon is directly related to MDS or to an unrelated, early plasma cell dyscrasia (given that most patients with MDS are elderly, and the risk of monoclonal gammopathy increases with age) has not been definitively established.

Specific Clinical Syndromes

Although MDS is a heterogeneous disorder, it includes a number of specific entities, either defined by cytogenetics, pathologic findings, or clinical features, which possess distinctive clinical features or biologic behaviors. Some of these are discussed in more detail below.

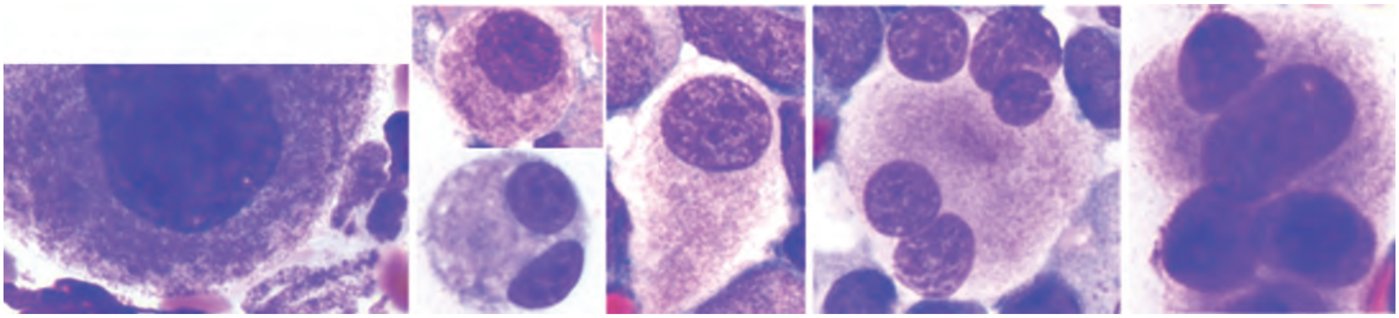

Figure 61.6 MEGAKARYOCYTIC DYSPLASIA. Dysmegakaryopoiesis is most obvious with the presence of micromegakaryocytes and abnormal larger forms *(panels 2–5)*. These are compared with a normal megakaryocyte at same magnification *(panel 1, far left)*. Micromegakaryocytes have single, two, or four small nuclei, which indicate a low-ploidy level. Normal low-ploidy megakaryocytes can be seen in the bone marrow, but these are immature forms and do not have mature granular cytoplasm with platelet material, as do the micromegakaryocytes. Larger dysplastic megakaryocytes have multiple, small, widely spaced nuclei. Photomicrographs are from a number of cases of refractory anemia with excess blasts and refractory cytopenia with multilineage dysplasia.

The 5q– Syndrome

Patients with isolated loss of the long arm of chromosome 5 (so-called del(5q) or 5q minus syndrome) are a unique group with a pathobiology that is described in more detail above. Clinically, 5q– syndrome is characterized by a predominant anemia with normal or elevated platelet counts, and a relatively indolent course with progression to AML in fewer than 25% of cases.[288,289] For unclear reasons, this syndrome is more common in women, who comprise 60% to 70% of cases in most series. The anemia in lower-risk del5q MDS is usually responsive to lenalidomide,[178] which is discussed in more detail in the Treatment section below. Those patients who become refractory to lenalidomide typically are transfusion dependent, and management of iron overload then becomes increasingly important. Many such patients also acquire abnormalities in *TP53*.

The designation of 5q– syndrome applies only to patients with the characteristic morphology and in whom loss of 5q is the only cytogenetic abnormality (Fig. 61.7A–C). Patients in whom 5q– is only one of several cytogenetic aberrations tend to have a poorer prognosis, with a more rapid progression to AML. As referenced above, loss of 5q often occurs in tandem with *TP53* mutations (or loss of 17p), another poor-prognosis combination.[133]

Hypocellular Myelodysplastic Syndromes

Most patients with MDS have hypercellular or normocellular marrows, adjusted for age. Hypocellular marrows, in contrast, are found in fewer than 15% of patients (Fig. 61.8A).[224] These patients have substantial overlap, both morphologically and clinically, with other hypoplastic syndromes, including aplastic anemia,[290] PNH,[291] and T-cell large granular lymphocyte leukemia.[244,292] While extensive dysplasia favors MDS (see Fig. 61.8B), distinction between these entities can sometimes be difficult, as patients with MDS may occasionally have PNH or LGL clones detectable by flow cytometry, though these are usually small and transient. Some of the resemblance may in fact reflect a shared pathogenesis; for instance, studies have shown that a sizable minority of aplastic anemia cases harbor clonal somatic mutations in genes recurrently mutated in MDS, including *ASXL1* and *DNMT3A*,[293] and that these patients have an inferior prognosis and lower likelihood of response to immunosuppressive therapy compared to patients with mutations in *PIGA* and *BCOR*.[294] It is therefore possible that these studies are defining distinct disease processes within a homogeneous-appearing morphology, with *ASXL1* and *DNMT3A* mutations defining disease more similar to MDS, and *BCOR* and *PIGA* mutations defining disease more akin to true, immune-mediated aplasia. Finding somatic mutations characteristic of the alternative diagnoses (for instance, telomerase complex mutations in aplastic anemia,[50] or *STAT3* mutations in LGL[295]) may clarify the picture as well.

Myelodysplastic Syndromes/Myeloproliferative Neoplasm Overlap Syndromes and Myelodysplastic Syndromes With Fibrosis

Although previously included as a subtype of MDS, disorders with overlapping features of both MDS and MPN are no longer included

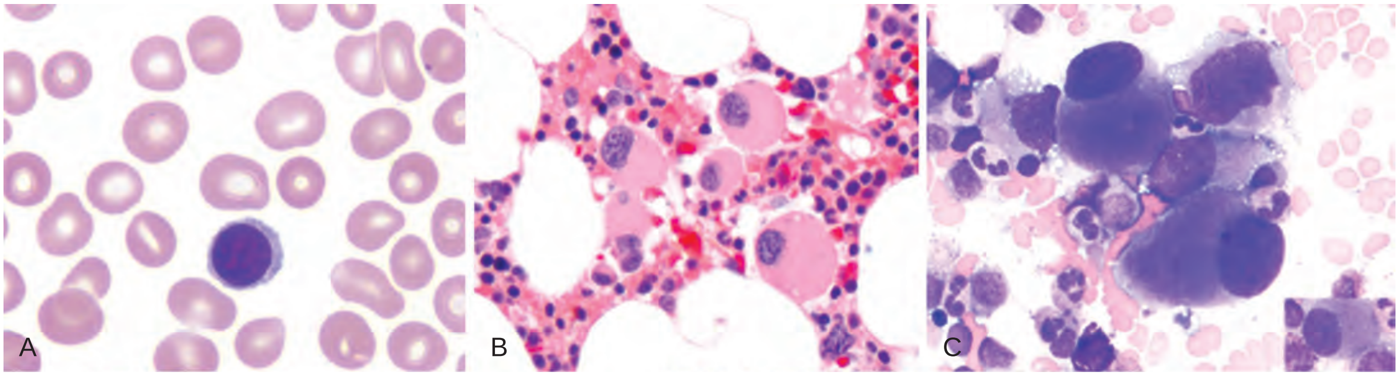

Figure 61.7 THE 5Q– SYNDROME. The 5q– syndrome has specific morphologic correlates. There is a macrocytic anemia (A) and a cellular bone marrow characterized by increased small monolobated megakaryocytes (B) and (C). The megakaryocyte nuclei have little segmentation and are fairly round. Although some true micromegakaryocytes may be present (C, *inset*, same magnification), the typical monolobated forms are not as tiny as the micromegakaryocytes.

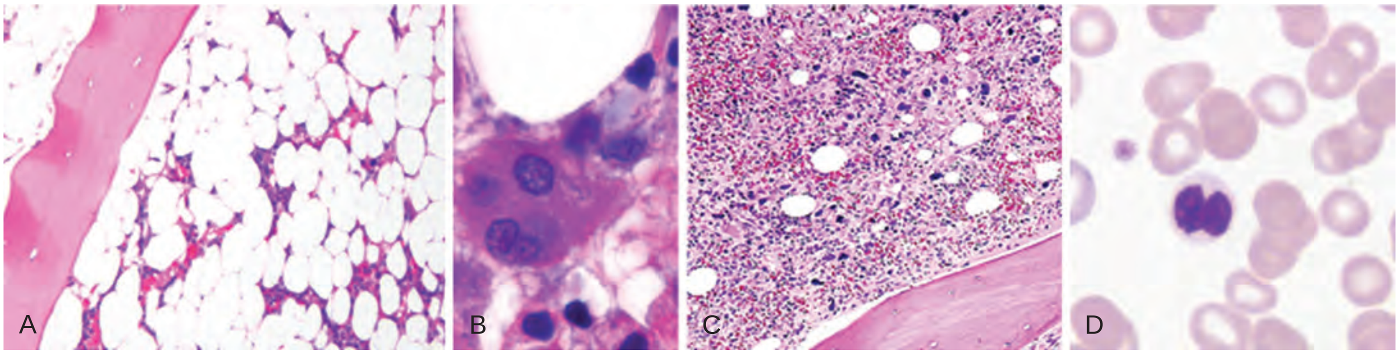

Figure 61.8 HYPOCELLULAR MYELODYSPLASTIC SYNDROME AND MYELODYSPLASTIC SYNDROME WITH FIBROSIS. Hypocellular myelodysplastic syndrome (A and B) can present a diagnostic problem and can be difficult to differentiate from aplastic anemia. Dysplasia may be difficult to evaluate if the smears are paucicellular. The finding of dysplastic megakaryocytes (note small widely separated nuclei, C) on the biopsy sample can be helpful. Myelodysplastic syndrome with fibrosis (D) can be difficult to differentiate from myeloproliferative neoplasms (MPNs). However, the lack of large megakaryocytes, which typically are see in the MPNs along with presence of dysplasia in the circulating neutrophils are useful clues to the correct diagnosis.

in the WHO classification system and are now considered a distinct category. MDS/MPN overlap entities, which include CMML, juvenile myelomonocytic leukemia, atypical chronic myeloid leukemia, MDS/MPN with ring sideroblasts and thrombocytosis (in which *JAK2* or *MPL* and *SF3B1* mutations usually co-exist), and unclassifiable cases, are discussed in more detail elsewhere (see Chapter 70 and 71). CMML can present as MDS with cytopenias but with absolute monocytosis, or with leukocytosis and WBC > 13×10^9/L ("proliferative CMML") driven by aberrant GM-CSF signaling. The monocytes in CMML with have a classical immunophenotype ($CD14^{++}/CD16^{-}$) and precursor states exist akin to CHIP.[296] The mutation profile in CMML is enriched for somatic mutations in *SRSF2, CBL, ASXL1, SETBP1*, and Ras pathway members, compared to MDS without proliferative features.[297,298]

Mildly increased marrow reticulin is common in MDS but marked fibrosis (see Fig. 61.8C) rarely occurs in cases of MDS without myeloproliferative features. When it does occur, it can be difficult to distinguish these cases from MPN.[299] Extensive dysplasia (see Fig. 61.8D) favors MDS.

Therapy-Related Myelodysplastic Syndromes

T-MDS is a well-recognized consequence of cytotoxic chemotherapy or radiotherapy for other cancers, but the overall incidence varies depending on the type of cancer and type of therapy.[300,301] Therapy-related MDS has been best characterized in patients with a prior history of breast cancer,[68,302] lymphoma,[303,304] or myeloma,[305] where the overall incidence is usually reported at around 1%. On the other hand, it is rare following treatment for other types of tumors, such as gastrointestinal and genitourinary cancers. This difference is largely attributed to differences in the types and intensities of chemotherapeutic agents used to treat different tumor types. In particular, high doses of alkylating agents, such as cyclophosphamide, melphalan, chlorambucil, or busulfan, have been recurrently associated with classical t-MDS,[306] as has extensive radiation therapy.[307]

T-MDS was initially thought to be driven by the acquisition of large-scale chromosomal damage induced by the cytotoxic therapy, given both the mechanism of alkylators (which induce double-stranded DNA breaks) and the fact that many patients with t-MDS have complex karyotypes. This model of DNA damage as the initiating event, however, was undercut by analysis showing that cytogenetic abnormalities present in the bone marrow of patients who developed therapy-related MDS after autologous transplant for lymphoma could be found in specimens banked at the time of the transplant, years before the development of t-MDS.[308] Subsequent analysis of a small group of patients with therapy-related AML harboring *TP53* mutations showed that clones harboring the mutations preceded the development of leukemia by years, and in some cases could be detected prior to the original initiation of chemotherapy.[106] Additional studies have confirmed that patients with detectable clonal hematopoiesis at the time of chemotherapy treatment are at increased risk of developing t-MDS due to selection of chemoresistant clones, especially those harboring *TP53* mutations, by cytotoxic therapy.[71,107,309,310] These findings suggest that most cases of t-MDS are driven by the expansion of pre-existing mutant HSC clones that gain a selective advantage upon exposure to cytotoxic therapy, rather than accumulation of DNA damage caused by the therapy itself.

Therapy-related MDS has relatively distinct clinical behavior. It is characterized by a latency of years and recurrent large-scale chromosomal abnormalities, especially of chromosomes 5 and 7 or 11q23. Complex karyotypes are also common.[311] These karyotypic abnormalities, which occur in only about 10% to 15% of patients with de novo MDS, are present in more than half of patients with t-MDS. They have a more aggressive clinical course than patients with de novo disease, with more frequent progression to acute leukemia. They also respond poorly to all classes of treatment, and relapse is common even after allogeneic stem cell transplant.[144,237,312] These clinical associations are driven by the unique biology of t-MDS, including the enrichment of *TP53* mutations and adverse karyotypes, and not by the prior cytotoxic therapy on its own. Patients with clinically defined therapy-related disease who lack these abnormalities have a prognosis more similar to de novo MDS.[144,237]

DIFFERENTIAL DIAGNOSIS

In the absence of clonal markers or excess blasts, MDS is a diagnosis of exclusion (Table 61.4), requiring the exclusion of other potential contributors to cytopenias and dysplasia.[3] Since cytopenias are the most common presenting clinical feature and cytopenias have many potential causes, the differential diagnosis is broad and includes numerous other entities covered in more detail elsewhere in this text. All patients suspected of having MDS should undergo a bone marrow aspirate and biopsy, since the diagnostic criteria are almost entirely pathologic and marrow findings are critical for risk stratification and treatment planning.

TABLE 61.4 **Diagnostic Criteria for Myelodysplastic Syndromes**

A. Presence of at Least One Unexplained Cytopenia:		
Hemoglobin <11 g/dL, *or*		
Absolute neutrophil count <1.5 × 10^9/L, *or*		
Platelet count <100 × 10^9/L		
plus **B. Presence of One or More MDS-Qualifying Criteria:**		
>10% dysplasia in one or more hematopoietic lineage without another explanation, *or*		
5%–19% blasts in bone marrow, *or*		
An MDS-associated cytogenetic abnormality, such as:		
t(1;3)(p36.3;q21.1)	t(2;11)(p21;q23)	inv(3)(q21;q26.2)
t(3;21)(q26.2;q22.1)	−5 or del(5q)	t(6;9)(p23;q34)
−7 or del(7q)		del(9q)
del(11q)	t(11;16)(q23;p13.3)	del(12p) or t(12p)
	i(17q) or del(17p)	idic(X)(q13)
plus **C. Exclusion of Alternative Diagnoses**		
AML (i.e., <20% blasts, and no t(8;21), inv(16), t(16;16), t(15;17), or erythroleukemia) or *ALL*		
Other hematologic diseases (aplastic anemia, PNH, LGL leukemia, lymphoma, myelofibrosis and other MPN)		
Viral infections (HIV, EBV, parvovirus)		
Nutritional deficiencies (iron, copper, B_{12}, folate)		
Medications (methotrexate, azathioprine, isoniazid, cytotoxic chemotherapy)		
Alcohol or other toxins		
Autoimmune diseases (SLE, Felty syndrome, ITP, autoimmune hemolytic anemia)		
Congenital disorders (Diamond-Blackfan anemia, Shwachman-Diamond syndrome, Fanconi anemia, and others)		

[a] Diagnosis can be made earlier than 6 months if no other cause is apparent for cytopenias, or there are excess blasts or an MDS-defining cytogenetic abnormality.

ALL, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *EBV*, Epstein-Barr virus; *HIV*, human immunodeficiency virus; *ITP*, immune thrombocytopenic purpura; *LGL*, large granular lymphocyte leukemia; *MDS*, myelodysplastic syndromes; *MPN*, myeloproliferative neoplasm; *PNH*, paroxysmal nocturnal hemoglobinuria; *SLE*, systemic lupus erythematosus.

Several nutritional deficiencies can cause cytopenias and morphology similar to MDS (see chapter on nutritional deficiencies). Folate deficiency can cause macrocytosis and, in extreme cases, megaloblastic morphology in the marrow.[313] Vitamin B_{12} (cobalamin) deficiency is a more classic cause of megaloblastic changes, and patients with severe B_{12} deficiency can have bizarre morphology with an abundance of early forms that can occasionally be confused with evolving AML, especially erythroleukemia.[314] Since the hematologic changes of B_{12} deficiency can occur in the absence of classic neurologic symptoms, B_{12} and folate levels should be checked on all patients in whom a potential diagnosis of MDS is being entertained, and methylmalonic acid and homocysteine levels may help clarify whether deficiency is truly present in cases with borderline levels.[315]

Copper deficiency is less common than B_{12}/folate deficiency but can also be mistaken for MDS. It classically arises in patients who have had gastrectomies or certain forms of gastric bypass surgery, particularly biliopancreatic diversion,[316] but is uncommon in newer forms of gastric bypass, including gastric sleeve procedures and Roux-en-Y procedures. It can also develop in patients with malabsorption syndromes such as uncontrolled celiac disease or those taking high doses of zinc, which competes with copper for absorption in the small bowel.[317] Clinically, patients with copper deficiency develop an anemia that can be normocytic or macrocytic and can occasionally be profound. Mild neutropenia can also be seen, while clinically significant thrombocytopenia is rare.[318] Such patients can also develop neurologic symptoms similar to those seen in B_{12} deficiency, including peripheral neuropathy and in advanced cases myelopathy, demyelination, and rarely optic neuritis.[319] In the marrow, copper deficiency is classically associated with ring sideroblasts and erythroid and neutrophil vacuolization.[320]

Alcohol is a marrow toxin and a common cause of hematologic abnormalities, especially macrocytic anemia.[321] Bone marrow examination often reveals ring sideroblasts, and sometimes megaloblastic morphology, but frank dysplasia that would suggest MDS is uncommon.[322] Patients with borderline marrow findings who consume alcohol heavily should be advised to completely abstain from drinking (such advice is sometimes heeded), with a repeat marrow examination in 2 to 3 months if they are abstinent and cytopenias persist.

Other drugs and toxins have also been associated with dysplastic changes in the marrow. Well-described offenders include valproic acid,[323] mycophenolate mofetil,[324] ganciclovir,[325] alemtuzumab,[326] and the antimetabolites mercaptopurine and methotrexate.[327] These tend to cause macrocytic anemias and can also cause neutropenia and thrombocytopenia. On the other hand, isoniazid[328] and chloramphenicol,[329] and to a lesser extent cycloserine[330] and pyrazinamide,[331] have been associated with modest sideroblastic anemia. The anemia associated with isoniazid, in particular, can often be reversed with high doses of vitamin B_6 (pyridoxine).[332] Chloramphenicol can also cause an idiosyncratic pancytopenia distinguished by prominent vacuolization of erythroid precursors.[333]

HIV infection has specifically been associated with trilineage dysplasia that is most predominant in the erythroid line.[334] The erythroid hematopoiesis almost always is megaloblastic, and reticulin fibrosis can be seen. The marrows also often have polyclonal plasma cell expansion and lymphoid aggregates, and sometimes granulomas. The differential diagnosis of erythrodysplasia in patients with HIV infection includes the influence of medications, opportunistic infections, or a direct effect of HIV on the hematopoietic progenitor cells.[335]

Other primary hematologic disorders are also on the differential diagnosis with MDS. Hypoplastic MDS, for example, can be difficult to distinguish from aplastic anemia, as described above (see Chapter 31).[336] Similarly, some patients with MDS may have a significant degree of co-existing fibrosis, which can complicate the distinction from MPN (see Chapter 71).[337]

Some patients have cytopenias for which no cause is apparent despite extensive evaluation, including marrow aspiration and biopsy.[338] These patients with "idiopathic cytopenias of undetermined significance" (ICUS) can progress to MDS; the cytopenias may also be due to a non-clonal cause (e.g., immunologically mediated) and may be non-progressive, giving ICUS a variable natural history.[25,339] Detection of a somatic mutation in these patients—so-called "clonal cytopenias of undetermined significance" (CCUS)—is associated with a higher likelihood of progression to overt WHO-defined MDS or AML, especially if the multiple mutations are present at a high VAF and there are red cell abnormalities such as broad RDW.[340,341]

PROGNOSIS

As discussed throughout this chapter, MDS is heterogeneous in both morphology and clinical course. Patients with MDS typically have at least one persistent otherwise unexplained cytopenia (hemoglobin less than 11 g/dL, ANC < 1500/mm^3, or platelet count less than 100,000/mm^3), plus one of the following: (1) ≥5% blasts in the bone marrow, (2) any of several chromosomal abnormalities that are found recurrently in MDS; (3) a meaningful degree of dysplasia, usually 10% or more, detectable in at least one cell lineage on bone marrow examination, or (4) other evidence of clonal hematopoiesis.[20] In the past this latter category has usually comprised either karyotype or FISH results demonstrating chromosomal abnormalities missed by conventional karyotype, but evidence of clonal hematopoiesis based on detection of recurrent somatic mutations may need to be considered as well. However, given that at least 10% of the population aged 70 or older harbor point mutations in genes associated with myeloid malignancies,[39] detection of such a mutation in the absence of other diagnostic criteria cannot be considered equivalent to MDS. Patients with unexplained cytopenias who have clonal mutations have a considerably higher likelihood of developing MDS meeting WHO criteria or another myeloid neoplasm compared to those who lack clonal mutations, especially if multiple mutations or splicing mutations are present, or the clonal burden is high.[340]

As described above, the WHO criteria divide adult MDS into several general categories. Practitioners should note that these criteria have several limitations, the most obvious being the complexity of the criteria themselves, which can make them cumbersome to use. Second, as described above, there are a number of conditions that can mimic aspects of MDS, and the diagnostic criteria assume these diagnostic possibilities have been eliminated. Third, morphologic criteria are still based around arbitrary percentages of dysplasia and blasts, which can be interpreted differently by different pathologists or may be vulnerable to sampling variations.[342,343] Finally, although WHO criteria incorporate cytogenetics to a limited extent, the criteria have not yet been updated to include types of newer genetic results that have been shown to have diagnostic value, and it is likely that incorporating some of these features will improve diagnostic clarity.

IPSS and IPSS-R

Although the WHO classification system (and the FAB system before it) is the accepted standard for diagnosing MDS, WHO criteria confer limited prognostic information, so other systems have been developed expressly for this purpose. The most widely used has been the International Prognostic Scoring System (IPSS, Table 61.5)[344] and its newer revised iteration, the IPSS-R (Table 61.6).[345] The original IPSS was first published in 1997 and was derived by analyzing baseline characteristics in over 800 newly diagnosed MDS patients from all diagnostic categories who received supportive care. Patients were scored based on three characteristics: the percentage of blasts in the marrow, the presence of specific cytogenetic abnormalities, and the number of cytopenias in the blood. Patients were then stratified based on total score into four risk groups (low, intermediate-1, intermediate-2, and high) that were shown to have prognostic value, both in estimating the chance of progressing to AML and in estimating the duration of overall survival. The original IPSS excluded patients with therapy-related MDS, patients with proliferative CMML, and patients who underwent AHCT.

The original IPSS had several limitations that ultimately necessitated its revision. First, it was formulated four years prior to the adoption of the first iteration of WHO classification criteria, and some of the changes in those criteria (for instance, changing the cutoff for AML from 30% blasts to 20% blasts) invalidated certain aspects

TABLE 61.5 1997 International Prognostic Scoring System for Myelodysplastic Syndromes

Variable	Score			
	0	0.5	1	1.5
Marrow blasts (%)	<5	5–10	—	11–20
Karyotype	Good	Intermediate	Poor	—
Cytopenias	0–1	2–3	—	—

Survival Based on IPSS (percent alive at milestone timepoint without disease-modifying therapy)

IPSS Risk Group	No. Patients	2 Years	5 Years	10 Years	15 Years
Low	267 (33%)	85	55	28	20
Intermediate-1	314 (38%	70	35	17	12
Intermediate-2	179 (22%)	30	8	<1%	<1%
High	56 (7%)	5	<1%	<1%	<1%

IPSS, International Prognostic Scoring System.

TABLE 61.6 2012 Revised International Prognostic Scoring System for Myelodysplastic Syndromes

Cytogenetic Risk	Included Karyotypic Abnormalities
Very good	del(11q), −Y
Good	Normal, del(20q), del(5q) alone or +1 other abnormality, del(12p)
Intermediate	+8, del(7q), i(17q), +19, +21 Any other single or double abnormality Two or more independent clones
Poor	der(3q), −7, double with del(7q), complex with exactly 3 abnormalities
Very poor	Complex with >3 abnormalities

IPSS-R Scoring Table

Parameter	Category/Score				
Cytogenetic risk	Very good 0 points	Good 1	Intermediate 2	Poor 3	Very poor 4
Marrow blasts (%)	≤2 0 points	3–4 1	5–10 2	10–19 3	—
Hemoglobin (g/dL)	≥10.0 0 points	8.0–9.9 1	<8.0 1.5	—	—
Platelet count ($\times 10^9$/L)	≥100 0 points	50–99 0.5	<50 1	—	—
Neutrophil Count ($\times 10^9$/L)	≥0.8 0 points	<0.8 0.5	-	-	-

IPSS-R Risk Groups and Predicted Outcomes

IPSS-R Risk Group	Total Score	% of Patients	Median Survival (Years)	25% With AML (Years)
Very low	≤1.5	19	8.8	NR
Low	2–3	38	5.3	10.8
Intermediate	3.5–4.5	20	3	3.2
High	5–6	13	1.6	1.4
Very high	>6	10	0.8	0.73

AML, Acute myeloid leukemia; *IPSS-R*, Revised International Prognostic Scoring System.

of the IPSS. Furthermore, broad application of the criteria to larger populations of MDS patients began to reveal that the original IPSS gave insufficient weight to some important clinical features, particularly the presence of severe cytopenias and complex karyotype. The IPSS was only validated in de novo disease, not t-MDS, and only in patients treated with supportive care alone. In response to some of these evident limitations, several alternative prognostic systems were proposed, but none were widely adopted.[346–348]

The IPSS-R, introduced in 2012, revised the MDS blast cutoff to 20% and assigned points for severity of cytopenias. Furthermore, it incorporated a broader range of cytogenetic abnormalities than the original IPSS, rebalanced karyotype importance versus blast proportion, and stratified patients into five risk categories instead of four. The resulting system thus incorporates more informative biology and offers better refinement of prognosis than its predecessor.[349,350]

The median survival times estimated by the IPSS and IPSS-R are largely reflective of natural history since they were originally derived in patients who did not receive any therapy for their MDS. However, IPSS-R stratifications have been shown to retain relevance when applied to treated populations, including risk stratification of patients receiving hypomethylating agents[351] and those who undergo allogeneic transplant.[352]

Nevertheless, the IPSS-R still has limitations. It does not incorporate some laboratory findings, such as the LDH and the serum ferritin, that have been shown to have independent prognostic value in dedicated studies.[353–355] It does not capture the kinetics of disease or comorbid conditions.[356] Additionally, similar to the WHO classification criteria, IPSS-R does not include any mutational data other than cytogenetics.

A molecular classification system, IPSS-RM, has been in development for more than 5 years. A European consortium evaluated more than 2,000 cases and identified 8 distinct mutation clusters with variant prognosis.[357] Currently there is a high degree of variability in how clinicians use molecular profiling in evaluating patients with suspected MDS,[358] and the availability of sequencing in different practice settings. The complexity of developing a molecular classification system appropriate for clinical use is underscored by the heterogeneity of co-mutation patterns, clonal architecture, and clone size associated with even a single allele.[359]

Other Risk Stratification Systems

The limitations of the IPSS prompted attempts at more refined risk stratification using alternative models. Few of these have gained much traction in clinical practice but retain value for use in clinical trials and retrospective studies. For instance, a need for better stratification of lower-risk patients (i.e., IPSS-low or Int-1) led to the creation of a Lower-Risk Prognostic Scoring System (LR-PSS) by the MD Anderson group.[346] The LR-PSS uses criteria similar to the IPSS but sets lower thresholds for point assignment (e.g., 2 points for a platelet count <50 × 10^9/L and 1 point for bone marrow blasts ≥4%). Subsequent studies have confirmed the LR-PSS's ability to risk stratify patients, with those in the highest risk group having the greatest risk of developing AML, and the poorest overall survival.[360]

Other attempts to improve prognostic systems have included attempts to incorporate formal measures of comorbidity into the IPSS,[361] and an attempt to combine the WHO classification system with the IPSS that has been dubbed the WPSS.[362] This latter system was formulated prior to the introduction of the IPSS-R.[363]

TREATMENT OF PATIENTS WITH MYELODYSPLASTIC SYNDROMES

Treating patients with MDS presents a number of challenges. First, MDS patients are often elderly and frequently have serious comorbid conditions, poor performance status, or frailty. Second, the heterogeneous nature of MDS means that treatments appropriate for some patients may be unhelpful for others. Third, a number of biologic factors, including the disease's origin in a quiescent stem cell, make MDS highly refractory to most conventional treatments like intensive cytotoxic chemotherapy, which many MDS patients are not healthy enough to receive anyway. Hematopoietic cell transplantation (HCT) remains the only potentially curative therapy for MDS but is unavailable to many due to age and comorbidities, and even for those who undergo it, relapse is common.

Despite these challenges, most patients with MDS should be offered some form of therapy. For elderly patients or those with serious comorbid conditions who are too unwell to undergo active treatment, this may consist primarily of supportive care and possibly hospice referral. Other patients with lower-risk disease may benefit from a period of observation, or judicious use of transfusion and growth factor support, balanced in carefully selected cases with chelation therapy to prevent or ameliorate iron overload. Patients with higher-risk disease may derive benefit from treatment with hypomethylating agents or other conventional therapies, and those patients with higher-risk disease who meet other selection criteria should be referred for consideration of HCT. Finally, patients should whenever possible be encouraged to participate in clinical trials to the extent that this remains consistent with their personal goals of care.

Once the decision to pursue active treatment has been made, there are at least three major points to consider. One is the choice of initial treatment modality, which is guided in large part by risk stratification (Fig. 61.9). This should typically start by computation of the IPSS-R, but IPSS-R score should not be the sole consideration in choosing therapy; for instance, a very young patient with IPSS-R lower-risk MDS that has evolved quickly and has higher-risk molecular genetic features may still warrant consideration of HCT (see Chapter 104), while an elderly patient with higher-risk disease may nevertheless opt not to pursue treatment with a hypomethylating agent after discussion of the risks and potential benefits. Second, there are a number of special cases for which there is no clear consensus about the single best treatment strategy; these include patients with lower-risk disease who have a dominant cytopenia other than anemia and patients with high-risk disease who have progressed on a hypomethylating agent but are not candidates for transplant.

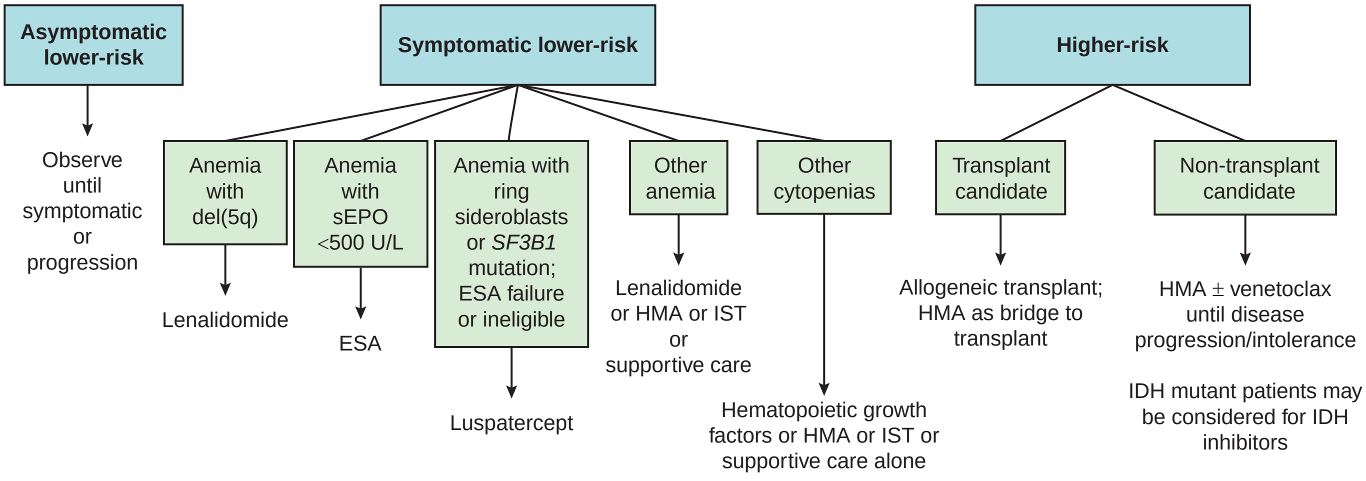
Finally, since therapies other than HCT are rarely if ever curative, defining what constitutes a meaningful response to therapy can be a nontrivial endeavor. Objective criteria for response were proposed by an IWG in 2000 and revised in 2006 and again in 2018,[364] and include improvements in cytopenias, reduction of the number of metaphases with abnormal karyotypes, and reduction in the percentage of the marrow involved by blasts.[365] However, improvements in these objective variables may not always coincide with the ways patients perceive changes in their quality of life[366,367] or MDS-related symptoms,[3] and these perceptions may be more likely to impact patients' decisions to continue or discontinue active therapy for their disease.

Lower-Risk Disease

Many patients with lower-risk MDS do not require active treatment directed at the underlying disease process, but this does not mean they require no care at all. In fact, providing appropriate supportive care is an important undertaking that can at times be complex and time-consuming, and requires a detailed understanding of the evidence behind the available supportive measures.[368]

Management of Anemia

Because most MDS patients become anemic at some point during their disease, appropriate management of anemia is important.[369] Most patients with MDS will require packed RBC transfusions during



Asymptomatic lower-risk
Symptomatic lower-risk
Higher-risk
Observe until symptomatic or progression
Anemia with del(5q)
Anemia with sEPO <500 U/L
Anemia with ring sideroblasts or *SF3B1* mutation; ESA failure or ineligible
Other anemia
Other cytopenias
Transplant candidate
Non-transplant candidate
Lenalidomide
ESA
Luspatercept
Lenalidomide or HMA or IST or supportive care
Hematopoietic growth factors or HMA or IST or supportive care alone
Allogeneic transplant; HMA as bridge to transplant
HMA ± venetoclax until disease progression/intolerance
IDH mutant patients may be considered for IDH inhibitors

*Consider **clinical trial enrollment** for all patients*
***Supportive care** (e.g., transfusions and antimicrobials as needed) for all patients*
***Chelation therapy** for selected lower-risk RBC transfusion-dependent patients*
***Risk stratification** using IPSS-R supplemented by molecular testing*

Figure 61.9 TREATMENT FOR MYELODYSPLASTIC SYNDROMES IS INDIVIDUALIZED TO THE PATIENT'S RISK STATUS, SYMPTOMS, AGE, AND MEDICAL HISTORY. Asymptomatic patients can be observed since there is no clear benefit from early therapy. For higher-risk patients, the key decision is whether to proceed with transplantation; for non-transplant candidates, DNA hypomethylating agents are the treatment of choice. Increasingly, other agents are being added to DNA hypomethylating agents. Lower-risk patients with anemia may be candidates for lenalidomide (if del5q), erythropoiesis stimulating agents (if serum erythropoietin <500 U/L), or luspatercept (if ring sideroblasts or *SF3B1* mutation present). There is no standard therapy for other cytopenia patterns. More detail is given in the text. *EPO*, Erythropoietin; *ESA*, erythropoiesis stimulating agents; *HMA*, hypomethylating agent; *IPSS*, International Prognostic Scoring System; *IPSS-R*, Revised IPSS; *IST*, immunosuppressive therapy; *MDS*, myelodysplastic syndromes.

the course of their disease. To minimize the risks associated with repetitive transfusion, it is usually appropriate to reserve transfusion until the hemoglobin is below 8 to 9 mg/dL or the patient has symptoms referable to anemia. More restrictive transfusion strategies, such as those suggested by studies in inpatient or critical care settings,[370,371] may be appropriate in younger, healthy patients, while some older patients, particularly those with significant comorbid cardiac disease, may benefit from more liberal strategies targeting a hemoglobin of 9 to 10 mg/dL.[372,373] If the patient is an HCT candidate, irradiated blood is essential.[374] Since many patients with MDS will receive hundreds of units of PRBCs over the course of their disease, prevention and appropriate management of iron overload can be important.[375,376]

Transfusion dependency is a negative predictor of outcome in MDS.[377] While transfusion requirement may to some extent be a marker of more severe hematopoietic insufficiency and worse disease not captured by other prognostic markers, the poor outcomes may also be a reflection of the adverse effects of repetitive transfusion, including accumulation of toxic iron species, immune modulation, and a risk of infection.[378] Given these facts, the administration of erythropoiesis-stimulating agents (ESAs) has been heavily investigated in MDS in an attempt to spare patients from unnecessary transfusions.

Dozens of studies of ESAs have been conducted in MDS, and 20% to 50% of patients experience meaningful, sustained improvements in their hemoglobin level in response to ESA supplementation.[379–384] Predictors of response include lower pre-treatment serum EPO levels (<500 U/L, but especially <100 U/L),[385] lower IPSS scores,[386] normal blast counts, normal or low-risk cytogenetics,[387] and lower serum and marrow levels of inflammatory cytokines.[388] The serum EPO level should be evaluated in the context of the degree of anemia; a trial of an ESA is usually reasonable in patients with EPO levels up to 200 to 300 U/L, which, while elevated compared to normal, is still lower than would be predicted for most MDS patients' degree of anemia. Patients with EPO levels over 500 U/L, on the other hand, are unlikely to respond to any dose or duration of ESA.

There are two major formulations of ESA available in the United States. Epoetin alfa, the shorter-acting of the two, can either be given at a dose of 150 to 300 U/kg three times weekly, or in a fixed dose of 40,000 to 60,000 units once weekly.[382] Higher doses above 60,000 U/weekly have not proven to be more effective.[389] Darbepoetin alfa is longer acting due to an altered glycosylation pattern, and is typically given in doses of 200 to 300 μg every 2 weeks or 500 μg once every 3 weeks.[390] Retrospective comparisons of the two agents have not shown a significant difference in efficacy.[391] Other ESA formulations are available outside the US, such as epoetin zeta. Bioequivalent forms of ESAs are also available in many countries.

Although there is some increase in the proportion of responding patients with longer duration of ESA therapy,[392] in practical terms, a trial of 8 to 12 weeks is reasonable. Prior to starting therapy, other causes of anemia should be ruled out. In particular, response can be suboptimal if patients are absolutely or even relatively iron deficient, and oral or parenteral iron supplementation may be reasonable in patients with ferritin levels at the lower end of the normal range.

One limitation of the numerous studies of ESAs in MDS patients is the lack of a consistent definition of response since most studies predated uniform IWG criteria. Some studies define this based on a hemoglobin increase (usually improvement by 1 to 2 g/dL),[393,394] while others have defined response by transfusion reduction or quality of life metrics.[395] In practice, any of these improvements could be a reasonable criterion for continuation of therapy. Supplementation with ESA has not been shown to alter the rate of progression to acute leukemia, and probably has a minimal influence on survival.[396] Additionally, several studies have shown an improvement in response in patients supplemented with a combination of ESA and G-CSF, especially in MDS-SLD-RS, likely due to pleiotropic effects of both growth factors on hematopoietic progenitors.[397]

ESAs are no longer routinely used for management of anemia in solid tumor patients, where studies have shown them to be associated with an increased risk of poor outcomes.[398] Similar findings have also been noted in patients without cancer receiving ESAs for anemia associated with renal failure.[399] Such a risk has not consistently been shown in MDS, although most studies published to date have not had long follow-up periods. The risk of thromboembolism has largely been correlated with the degree of improvement in hemoglobin, with patients targeted to hemoglobin over 12 mg/dL at greatest risk. Given this, the consensus recommendation in MDS is to initiate an ESA at hemoglobin <10 g/dL and target a level between 11 and 12 g/dL.[400]

Luspatercept, a fusion antibody that is an activin receptor IIB ligand trap, binds to members of the transforming growth factor β family that inhibit erythropoiesis in MDS and can release developing erythroid precursor cells from a differentiation block. Luspatercept improves anemia in patients with MDS and ring sideroblasts who are either not ESA treatment candidates due to high serum EPO level or who have been failed by an ESA, and was approved by the US FDA in April 2020.[401] In a randomized, placebo-controlled trial, about 40% of patients treated with subcutaneous luspatercept at a starting dose of 1.0 mg/kg every 21 days (and escalating to 1.75 mg/kg if needed) had an 8-week transfusion free period compared to 15.8% in the placebo arm.[402] The most common adverse events include fatigue. The effectiveness of luspatercept in other subtypes of MDS besides those with ring sideroblasts is an ongoing area of investigation.

A small proportion of anemic patients will benefit from treatment with androgens such as danazol or testosterone.[403] A history of prostate cancer is usually a contraindication, and hepatotoxicity should be monitored.

Management of Neutropenia and Infections

As referenced above, patients with MDS often become neutropenic but also appear to have other qualitative immune defects that are not accurately represented by the ANC,[404,405] and infection is the leading cause of death in MDS.[246] Despite this, supplementation with either G-CSF (filgrastim) or GM-CSF (sargramostim) and their bioequivalents has not been shown to improve outcomes in MDS patients.[406–408] Nevertheless, it is reasonable to consider a trial of growth factor (usually G-CSF, due to less frequent adverse effects) in lower-risk IPSS patients with severe neutropenia, typically defined as an ANC < 200 to 500/mm^3. Supplementation in higher-risk patients, particularly those with any degree of excess blasts, is not usually recommended in the absence of chemotherapy, due to lingering concerns about promoting expansion of leukemic clones.[409]

Appropriate antimicrobial use is an important component in the care of MDS patients. Patients should be counseled to seek medical attention for any fever greater than 100.4°F (38.4°C), and those who are neutropenic should be started on broad-spectrum parenteral antibiotics while an appropriate search for infection is undertaken. A thorough discussion of treating febrile neutropenia can be found elsewhere in the text, but should begin with an antibiotic that covers a broad spectrum of gram-negative organisms including *Pseudomonas* species.[410] Although there is no clear benefit of prophylactic antibiotics, they may be appropriate for selected patients who demonstrate a pattern of recurrent infections. There is less consensus about prophylactic antivirals[411] or antifungal medications,[412] and the efficacy of the latter depends on local microbiological isolates and epidemiological patterns.

Management of Thrombocytopenia and Bleeding

Modest thrombocytopenia is common across many subtypes of MDS, while severe depression of platelet counts is more frequently seen in patients with higher-risk IPSS scores or those undergoing active treatment with hypomethylating agents or chemotherapy. Overall, bleeding is the second most common cause of non-leukemic death in MDS patients.[413] Conventional wisdom and observational studies indicate that the risk of bleeding with trauma begins to increase at a platelet count near 50×10^9 cells/L and that of spontaneous hemorrhage does not increase significantly until the count is below 10 to 20×10^9 cells/L. However, these cutoffs may underestimate the bleeding risk in MDS patients, many of whom have qualitative defects in platelet function that are not captured by the platelet count. A number of retrospective studies have evaluated the significance of thrombocytopenia in MDS, all of which have found that thrombocytopenia confers a poor prognosis due both to the risk of bleeding and, in some cases, an elevated risk of transformation to AML.[414,415]

As with red blood cells, management of thrombocytopenia can either involve transfusions or use of growth factors. Many institutions use a standard transfusion threshold of 10 × 10^9 cells/L,[416] but as discussed above, a higher goal may be appropriate in selected patients who show a predilection for bleeding. In general, patients should be transfused prophylactically rather than waiting for bleeding to occur. Although there are few large studies comparing transfusion strategies specifically for MDS patients, a study of patients with other hematologic malignancies showed that for most patients (including those with AML), a prophylactic strategy using a trigger of 10 × 10^9 cells/L led to fewer significant hemorrhages than a therapeutic strategy in which patients were transfused only when bleeding.[417]

Thrombopoietin analogs, which are widely used for refractory immune thrombocytopenia purpura (ITP),[418] are not approved by any regulatory agencies for use in MDS. Formulations approved in ITP include romiplostim, a "peptibody" consisting of 14 amino acid peptides that bind the extracytoplasmic domain of the thrombopoietin receptor fused to an IgG1 heavy chain, and eltrombopag, a small molecule without TPO homology that nevertheless binds and activates the TPO receptor.[419] Romiplostim is administered as intermittent subcutaneous injections, whereas eltrombopag is an oral formulation that is taken daily.

Both thrombopoietin analogs have shown efficacy in terms of reducing platelet transfusions and clinically significant bleeding events and increasing platelet counts in early-phase trials in MDS.[420–422] In patients with IPSS low or intermediate-1 risk MDS who had platelet counts less than 50 × 10^9/L, romiplostim consistently led to significant improvements in platelet count, which were durable in about half of patients.[423] Modest improvements were also seen in a trial of eltrombopag.[424]

However, concerns have been raised about the safety of TPO agonists in patients with MDS. First, a number of studies in ITP have shown an increase in marrow reticulin fibrosis in some patients.[425] While the absolute risk of fibrosis has not been determined, and fibrosis has been moderate in most patients, it is possible that the abnormal marrow microenvironment of MDS patients might encourage reticulin deposition.[426] Second, there is concern about increased blast proliferation in the presence of TPO agonists, since some blasts have functional TPO receptors. A randomized controlled trial of romiplostim versus placebo was stopped early by the study's safety monitoring committee due to interim analysis suggesting a higher rate of progression to AML in the romiplostim arm.[427] At the time the study was stopped, 10 of 167 patients in the romiplostim group had progressed to AML, compared to 2 of 83 in the placebo group. Since the study accrual was incomplete at the time the study was stopped, the risk of disease progression could not be definitively assessed and the AML progression rate eventually nearly equalized; nevertheless, the manufacturer added a warning of risk of MDS progression to romiplostim's label. In a controlled trial of eltrombopag, there was also a modest increase in disease progression with active therapy.[428] Therefore romiplostim or eltrombopag cannot be recommended for routine treatment of MDS-associated thrombocytopenia outside a clinical trial, although patients with refractory bleeding who fail to respond to platelet transfusions could consider trying one of these agents palliatively.

Other agents approved for thrombocytopenia such avatrombopag, lusutrombopag, or the Syk inhibitor fostamatinib have not been studied in MDS patients. The use of antifibrinolytic agents (tranexamic acid or aminocaproic acid) may be helpful in patients with refractory bleeding, especially those who have platelet alloimmunization.[429]

Management of Iron Overload (Transfusional Hemosiderosis)

Although it is clear that MDS patients who undergo repeated blood transfusions have an increased risk of developing iron overload,[377] the importance of this relative to other disease-related risks, and how to assess and respond to it, remains a matter of debate.[378] MDS is distinct from pediatric illnesses associated with iron overload, in which the benefit of chelation has been well established,[430] in that many MDS patients will not live long enough for the clinical impact of end-organ iron deposition to be realized, and there are competing risks in MDS patients including neutropenic sepsis and leukemia progression that are not present in thalassemia or sickle cell anemia. Registry data suggest that patients with higher transfusion requirements have a greater risk of complications,[431,432] but registry data cannot prove the direction of the relationship—that is, whether the transfusions lead to complications or whether the need for transfusion is simply a marker of more severe disease or underlying comorbidities. Other retrospective studies have provided circumstantial evidence for deleterious effects of iron overload. For instance, one study has shown a higher rate of death from heart failure among MDS patients,[433] and another has shown increased rates of heart and liver failure among MDS patients with high lifetime numbers of transfusions[434]—but these observations again cannot prove causality.

There are two major formulations of chelating agent available in the United States, deferoxamine and deferasirox.[435] (A third agent, deferiprone/L1, is approved for thalassemia patients via a restricted distribution program, and is not often used in MDS because of idiosyncratic neutropenia.) Deferoxamine is administered as a continuous subcutaneous or intravenous infusion, a cumbersome mechanism that has limited its applicability in widespread practice. Deferasirox, an oral formulation, is more convenient so is much more widely used, but is quite costly.

Deferasirox is typically started at 20 mg/kg once daily and escalated to 30 to 40 mg/kg/day using the original formulation and started at 14 mg/kg once daily for a revised formulation with a different lactose-free binder. Although deferasirox has been shown to rapidly mobilize stored iron and reduce labile plasma iron species, it is frequently discontinued either as a result of disease progression or due to side effects, which include GI distress, renal impairment, and rash.

There are data from retrospective studies showing better outcomes for patients who undergo iron chelation, but all of these are subject to patient selection bias. In one study, a Canadian review of 178 patients, only 18 received chelation therapy, suggesting that these patients were carefully selected and destined to have a better outcome anyway.[436] In another, a French study of 97 patients in whom 46% received chelation, the regimen and duration of chelation therapy varied considerably, and no baseline assessment of iron stores was performed.[437] A recent meta-analysis of iron chelation studies in MDS found that use of chelation therapy was associated with an increase in length of survival (overall 61.2 months longer for patients receiving chelation),[438] but since the analysis included only retrospective studies, it is possible that these numbers are again largely reflective of selection bias, with healthier or younger patients more likely to receive chelation therapy than those who were older or sicker.

In a single-arm cohort study of 1744 patients treated with deferasirox, including a prespecified MDS subgroup of 341 patients, median ferritin levels decreased significantly compared to baseline regardless of whether patients were chelation-naïve or not, as did the median alanine aminotransferase (ALT), which was tracked as a marker of hepatic toxicity from iron overload.[439] On the other hand, 48.7% of the MDS patients discontinued treatment within one year of initiation due to side effects. Since there was no control arm and the study period was short, no conclusions could be drawn about the impact of chelation on more meaningful clinical outcomes. Other studies have shown improvements in hematopoiesis in patients started on chelation therapy,[430,431] but these observations were not tied to longer-term outcomes either.

A phase III study, TELESTO, randomized patients with lower-risk MDS who had received 15 to 75 RBC units and had elevated ferritin but preserved organ function to receive either deferasirox or placebo.[440,441] The original accrual goal was 630 patients, but because of narrow entry criteria and clinicians' lack of perceived equipoise about the benefit and risks of chelation therapy, only 210 patients were enrolled, which precluded an assessment of overall survival.

The trial did show benefit with chelation in a complex composite endpoint including elevation of liver tests, infection, congestive heart failure exacerbation, and death, but elevated creatinine was observed in many patients.

Despite the limitations of the available data, there are several published consensus opinion guidelines regarding the use of chelation therapy in MDS.[260,442] Although they differ with respect to their specific recommendations, most operate on similar principles: the patients best suited to iron chelation therapy are either those with lower-risk disease who face a long period of transfusion dependency, or those who could potentially be eligible for HCT, since in the transplant setting numerous studies have shown that a high serum ferritin level is associated with inferior outcomes.[443] A third category of patients comprises those with suspected end-organ damage as a result of iron overload. Some of the guidelines recommend waiting to start chelation therapy until the ferritin is greater than 1000 µg/L or the patient has had more than 20 to 30 lifetime transfusions, but they also note that neither of these criteria is supported by high-level evidence. Serum ferritin is problematic since it is subject to variability based on inflammatory state and is an imperfect marker of total body iron burden. For quantitative assessment of hepatic iron overload, T2*-weighted MRI of the liver or other organs has supplanted biopsy as the preferred method of validation.[444]

Other Therapies for Lower-Risk Disease

The literature is replete with attempts to treat patients with lower-risk MDS with a variety of different drugs, especially so-called "differentiating agents" such as retinoic acid or arsenic trioxide (ATO). With the exception of lenalidomide for 5q− syndrome, most of these have been inconsistently effective at best.

Lenalidomide

As described above, lenalidomide is a derivative of thalidomide that is uniquely effective in reversing the severe anemia associated with isolated del(5q). This was previously thought to be related to poorly characterized immunomodulatory effects (as implied by "Imid," the name given to the class of thalidomide derivatives).[445] However, more recent work has shown that lenalidomide actually exerts its effect in 5q− syndrome by mediating the binding of the E3 ubiquitin ligase component cereblon, which is responsible for modulating substrate specificity, to casein kinase 1α, thus triggering casein kinase's proteasomal degradation.[183] Casein kinase 1α is an essential kinase whose gene, *CSNK1A1*, lies within the minimally deleted region on 5q.[175] In normal cells, treatment with lenalidomide is insufficient to deplete casein kinase 1α to lethal levels, but the haploinsufficiency of *CSNK1A1* induced by loss of 5q renders 5q− cells sensitive to the drug through a p53-dependent mechanism and allows for repopulation of the marrow by wildtype hematopoietic progenitors. This activity appears to be unique to lenalidomide and is not shared, for instance, by thalidomide. Resistance eventually develops in most cases, often through inactivating mutations in *TP53*.[446]

Lenalidomide's efficacy was first observed in MDS-001, a phase I study of 32 patients with symptomatic anemia who had not responded to ESAs.[447] Twenty of the 32 patients became independent of transfusion for some period of time, including 10 of 12 patents with del(5q). Of the responders, those with del(5q) had a significantly longer duration of response. This prompted further study of lenalidomide specifically in del(5q) patients in MDS-003, a phase II study in which 76% of 148 enrolled patients had an improvement in anemia and 67% achieved transfusion independence, with a median improvement in hemoglobin near 5 mg/dL.[178] A second phase II trial, MDS-002, showed that lenalidomide was also effective in a substantially smaller subset of patients without del(5q), with an overall response rate of 43% and a transfusion independence rate of 26%.[448] The factors that determine lenalidomide responsiveness in non-del(5q) MDS have not been determined.

The most conclusive evidence of lenalidomide's efficacy in del(5q) comes from the phase III MDS-004 trial, a randomized, double-blinded study in which patients were randomized 1:1:1 to receive lenalidomide 10 mg/day on days 1 to 21 of a 28-day-cycle, lenalidomide 5 mg/day on days 1 to 28, or placebo on days 1 to 28.[449] Those without an erythroid response at 16 weeks were unblinded and became eligible for open-label treatment. At the conclusion of the study, significantly more patients in both lenalidomide groups had achieved transfusion independence for at least 26 weeks than those in the placebo group (56% in the 10-mg group vs. 43% in the 5-mg group vs. 5.9% in the placebo group), with those in the 10-mg group having a longer median duration of response (82.9 weeks) than those in the 5-mg group (41.3 weeks). Treatment with lenalidomide also appeared to lower the risk of transformation to AML; at a median follow-up of around 3 years, 36% of patients who had received placebo only and 30% who had started with placebo and crossed over to lenalidomide had developed AML, compared to 23% in the 5-mg group and 22% in the 10-mg group, though the crossover model prevented an assessment of statistical significance.

Given recent progress in understanding of lenalidomide's mechanism of action, it is perhaps unsurprising that it demonstrates considerably lower efficacy in MDS patients who do not have del(5q). In these patients, studies including the MDS-005 randomized trial have consistently shown an overall response rate of about 25%, which on average lasts less than a year.[450] It is not known whether the patients with non-del5q MDS who respond have abnormalities of casein kinase 1-α, or whether their sensitivity to lenalidomide occurs via a different mechanism. ESA increases the response rate to lenalidomide.

Lenalidomide is generally well tolerated, but the most common side effects are neutropenia and thrombocytopenia, which are most common in the first month of treatment and which have some correlation to treatment response.[451] Rash is another recurrent adverse event. Pretreatment thrombocytopenia, a feature atypical of 5q− syndrome, appears to negatively correlate with response and perhaps serves as a phenotypic proxy for cooperating genetic events that blunt the molecular sensitivity to the drug.[133] While thromboembolism has been observed in studies of lenalidomide in patients with myeloma, this effect largely seems to be confined to co-administration of lenalidomide and dexamethasone.[452]

Low-Dose Cytarabine and DNA Hypomethylating Agents

Cytarabine (cytosine arabinoside or Ara-C) is a nucleoside analog that is widely used in the treatment of a number of hematologic malignancies. In MDS, its use in both lower- and higher-risk patients dates to the 1980s.[453,454] The typical dosing schedule is 5 to 20 mg/m^2/day via subcutaneous injection (daily or twice daily) or continuous IV infusion. Although 10% to 20% of patients with MDS have some degree of hematologic or blast cytoreductive response during Ara-C therapy, these tend to last only a few months, and treatment has not been shown to improve survival or reduce the rate of transformation to AML.

One of the drawbacks to treatment with cytarabine or any other conventional chemotherapeutic agent is that they cause cytopenias as a primary side effect, and since cytopenias are a central problem in most MDS patients, the agents rapidly become limited in utility.[455] The worsening of cytopenias is likely one of the primary reasons for the lack of survival benefit for cytarabine in MDS.

Reduced schedules of 5-azacytidine and decitabine have been used in lower-risk MDS patients, with complete response rates exceeding 30%.[456] These agents are described further below in the discussion of treatment of higher-risk patients, where they see much greater use.

Anti-Tumor Necrosis Factor Therapy

The observation that MDS patients often have elevated levels of inflammatory cytokines and increased rates of apoptosis led to the postulate that blockade of these pathways might ameliorate the ineffective hematopoiesis found in many patients with MDS. Etanercept, a soluble TNFα inhibitor, has been analyzed in two small pilot studies of MDS patients, with mixed results: cytopenias improved in one trial,[457] whereas no effect was seen in the other.[458] The drug has also been combined with both ATG[459] and 5-azacytidine,[460] but in neither case was it clear that the addition made a difference. A separate case report described sustained erythroid responses in two patients treated with infliximab, a monoclonal anti-TNF antibody.[461] TNFα and other inflammatory mediators may play a greater role in some subsets of MDS than others.[462]

Immunosuppressive Therapy

Corticosteroid therapy was once a mainstay of treatment for MDS, but despite reported response rates in the range of 10% to 20%,[463] the complications of long-term steroid use in this population were found to outweigh the benefits. Nevertheless, immunosuppressive therapy may be reasonable for certain subsets of MDS patients in whom autoreactive T-lymphocytes contribute to the inhibition of effective hematopoiesis. Patients with hypoplastic MDS, in particular, have been thought to be good candidates for treatment with ATG or other parallel approaches, but studies have not consistently shown that marrow cellularity predicts response to anti-T-cell therapy in MDS.[464] Other studies have shown that patients with underlying PNH clones, which can be assessed by flow cytometry for PIG-anchored glycoproteins CD55 and CD59, may also respond to ATG.[465]

Retrospective analysis of data from the International Myelodysplasia Risk Assessment Workshop (IMRAW) showed that treatment with immunosuppression was associated with an improvement in overall survival (8.1 vs. 5.2 years, $P < .001$) and a lower risk of leukemic transformation, but these results could have been subject to selection bias since fewer patients with higher-risk disease are treated up front with immunosuppression. On the other hand, a randomized study comparing ATG plus cyclosporine to best supportive care suggested a slight improvement in hematologic response in the ATG + CsA group, but there was no difference in disease-free or overall survival.[466] Subgroup analysis suggested that patients with hypocellular marrows were more likely to respond to immunosuppression, again hinting at biologic similarities to aplastic anemia. In studies making careful distinction between MDS and aplastic anemia, however, mortality with ATG treatment was higher in MDS than in AA.[290] In the largest multicenter retrospective review, marrow hypocellularity (<20% cellular) was associated with better response to IST therapy, and the use of horse ATG was associated with better outcomes than with rabbit ATG or cyclosporine.[467]

Alemtuzumab, a monoclonal antibody against anti-CD52, has activity in highly selected subsets of MDS patients. In particular, one small phase I/II study of patients yielded a 77% overall response rate among patients with IPSS intermediate-1 disease.[468] Some patients with cytogenetic abnormalities normalized their karyotype, and the rate of complete response appeared to increase with time in those patients who were not lost to follow-up. However, alemtuzumab is severely immunosuppressive and difficult to obtain, and the study was hampered by a high rate of attrition. The biologic basis for the high response rate in this single study remains unclear.

Manipulating the Microenvironment: Vascular Endothelial Growth Factor and Other Targets

Observations of increased microvessel density in the bone marrow of MDS patients[469] led to interest in targeting vascular growth factors and other molecules associated with the marrow microenvironment, but results have been disappointing. For instance, a phase II trial of bevacizumab, a monoclonal antibody directed against vascular endothelial growth factor (VEGF), showed a decrease in VEGF levels and a significant reduction in microvascular density, but only one of 21 patients had any type of hematologic response.[470] Similarly, a phase II study of vatalanib, an oral VEGF receptor inhibitor, showed hematologic responses in only 5% of patients, and many patients had to withdraw from the study due to side effects.[471]

Other therapies directed at the microenvironment have similarly shown responses in only a minority of patients. For instance, the combination of pentoxifylline, a phosphodiesterase inhibitor, with dexamethasone and ciprofloxacin (PCD) has been shown to induce hematologic responses in some patients, but most of these were transient and probably represented neutrophil demargination from the corticosteroid.[231] A study combining PCD with amifostine, a chemoprotectant agent, showed a hematologic response rate of 66%, but many of these responses were dexamethasone-induced increments in neutrophil count and long-term results were not reported.[472] Lenalidomide and thalidomide were both previously thought to act via effects on the microenvironment,[473] but with the discovery of lenalidomide's role as a catalyst for cereblon-mediated ubiquitination, as described above, the extent to which it also affects the microenvironment is unclear.

Signal Transduction Inhibitors

Activating mutations in receptor tyrosine kinases like *NRAS* and *FLT3* are relatively uncommon in MDS because they usually act as catalysts for progression to secondary AML.[238] The considerations for use of FLT3 inhibitors in MDS is similar to those in AML, and data are limited in MDS. A more thorough discussion of these agents may be found in the chapter on AML (see Chapter 60).

Isocitrate dehydrogenase (IDH) is occasionally observed in MDS patients, albeit at a lower frequency than in AML. Ivosidenib, an IDH1 inhibitor, and enasidenib, an IDH2 inhibitor, are approved for AML, and have some activity in MDS with IDH mutations.[474] Other IDH inhibitors are in development.

Other Agents

A number of other agents have been used in MDS and reported either in anecdotes or small, nonrandomized series of patients. Historically, many patients with MDS with ring sideroblasts were started on vitamin B_6 because of its efficacy in familial sideroblastic anemia, but it has shown little efficacy in adults.[475] Other dietary supplements, including retinoids (vitamin A analogues), vitamin D,[476] and vitamin K_2,[477] have all been tried due to favorable effects on differentiation in vitro, but have not been effective in humans.

A number of other drugs have also been trialed in humans based on similar observations of pro-differentiation effects in preclinical experiments, all without comparable efficacy in human patients. These include amifostine as a single agent,[478] the solvent hexamethyl bisacetamide,[479] and alpha and gamma interferon.[480]

Both all-trans retinoic acid (ATRA) and ATO have been trialed in small numbers of MDS patients in an attempt to induce differentiation similar to that seen in acute promyelocytic leukemia. ATO has shown responses in up to 20% of MDS patients in several small series,[481–484] but the molecular basis for this action and how to predict who will respond are unclear and adverse effects including cytopenias and cardiac conduction defects are common. ATRA by itself has largely been ineffective.[485,486]

Higher-Risk Disease

Hypomethylating Agents

MDS genomes frequently display aberrant methylation patterns relative to normal hematopoietic cells. This observation was initially made in the 1990s, when investigators noted hypermethylation in the promoters of numerous tumor suppressor genes, including *CDKN2A, CDKN2B*,[487] *FHIT*,[488] *SOCS1*,[489] *CTNNA*1,[490] and others. Later, with the advent of genome-wide methylation profiling, it was further observed that this aberrant methylation is often a global phenomenon in MDS and that global hypermethylation, in particular, appears to confer a poor prognosis.[491]

This characterization of aberrant methylation in MDS soon led to the identification of hypomethylating agents as a candidate class of MDS drugs. The prototypical hypomethylator, 5-azacytidine (azacitidine), was synthesized in the 1960s and its hypomethylating activity first clearly characterized in 1980.[492] It is a 5-azo-substituted pyrimidine analog that incorporates into RNA and is from there converted to a deoxynucleotide and incorporated into DNA, where it binds and irreversibly inhibits DNA methyltransferase 1. The in vitro result is a global decrease in cytosine methylation, which leads to differentiation in some leukemia cell lines. Azacitidine also appears to have non-epigenetic mechanisms of action, including some degree of direct cytotoxicity and immune stimulation.[493] Both azacitidine and the related compound decitabine (5-aza-2′-deoxycytidine) are approved for and frequently administered in both MDS and AML.

Standard dosing of azacitidine is 75 mg/m^2 administered subcutaneously once per day for seven consecutive days each month.[494] This was the dosing schedule used in the first major study of hypomethylating agents in MDS, CALGB 9221, in which azacitidine was found to be superior to best supportive care both in terms of quality of life and risk of progression to AML.[495] In the CALGB study, about 60% of patients had some degree of response to azacitidine, although consensus response criteria were not used. Most of these responses were minor hematologic improvement, but about 15% of patients had a pathologic complete response. Most of those who responded did so within 6 months. There was a nonsignificant trend toward an improvement in overall survival with azacitidine, and side effects tended to be mild, including nausea and vomiting and transient myelosuppression.

Based on these data and a large increase in requests for compassionate use of the drug after CALGB 9221 was first presented in 2002, the FDA granted approval to azacitidine for MDS in 2004. A subsequent study, AZA-001, compared azacitidine 1:1 to the patient and doctor choice of either standard induction, low-dose cytarabine, and best supportive care in 358 patients with higher-risk MDS or CMML, and showed a median nine-month improvement in overall survival for those treated with azacitidine (24 vs. 15 months).[496] This represents the only major study to date in which a survival benefit has been shown for a drug in MDS, and has not been replicated. Other studies have shown that a more convenient 5-day azacitidine dosing schedule appears to be effective, but the 7-day schedule remains the standard. An oral formulation of azacitidine, CC-486, showed a survival advantage in a maintenance trial in AML and has been tested in MDS with clinical activity but wide variation in bioavailability and cytopenias that resulted in early cessation of a randomized placebo-controlled trial.[497]

Although structurally similar to azacitidine, decitabine has a deoxyribose backbone that permits it to be directly incorporated into DNA. At higher doses it introduces DNA cross-linking and cell-cycle arrest, a mechanism more akin to a cytotoxic agent, but at lower doses it appears to primarily act as a hypomethylating agent.[498] Similar to azacitidine, decitabine has been shown to improve outcomes for patients with MDS, including a reduced transfusion requirement and slower transformation to AML. It may induce responses more quickly than azacitidine; for instance, in the multicenter ADOPT study, 90% of patients responded after four cycles of decitabine therapy, rather than the six cycles seen in the largest azacitidine.[499] In contrast to azacitidine, however, decitabine has never been shown to confer an overall survival benefit. Azacitidine and decitabine have never been compared head to head in a large prospective trial, which is a major failure of the MDS clinical trials community.

Some of the difference in outcomes between decitabine and azacitidine may be explained by difficulties establishing the optimal dose and schedule for decitabine; in the earliest trials it was administered at a dose of 15 mg/m^2 given intravenously every eight hours for three days,[500] but subsequent studies showed better hypomethylation and an improved overall response rate when it was given at a dose of 20 mg/m^2 once daily for five consecutive days,[501] the dosing strategy used in ADOPT. Some recent small studies have suggested a different dosing strategy, using frequent administration of low doses of decitabine (0.1 to 0.2 mg/kg/day) in an attempt to minimize the cytotoxic effects of the drug while catching more cells in S phase, when the demethylating activity of the drug would be most effective.[502] On the other hand, a 10-day schedule has also been explored, and while active (including in TP53 mutant disease) is more myelosuppressive.[503,504] An oral formulation of decitabine in combination with cedazuridine, which inhibits breakdown of oral decitabine by cytidine deaminase in the gut, was approved for MDS by the US FDA in July 2020.[505]

Despite the widespread use of hypomethylating agents in MDS, a number of key questions persist. Although studies have shown that each can demethylate the promoters of specific tumor suppressors (e.g., *P15INK4B*[506] and *PLCB1*[507]), it is not clear that this is the dominant in vivo mechanism. Some studies have shown increased demethylation in patients who respond to HMAs,[508] but this has not been a universal observation, and neither pretreatment methylation levels (either global or at specific promoters) nor the net change in methylation with treatment have been consistently predictive of treatment responsiveness.[509]

Several studies have interrogated the influence of somatic mutations on hypomethylating agent sensitivity. *TET2* mutations may increase likelihood of response and *ASXL1* mutations decrease response,[510] but the effect is modest such that results of mutation studies are not clinically actionable. Patients with *TP53* mutations have a high early response rate to hypomethylating agents,[504] but unfortunately the efficacy is not durable.[511]

Once the patient has been failed by HMA therapy, their prognosis is grim. The median survival for higher-risk patients is less than 6 months, and for those in whom the drug was used for lower-risk disease the median survival is only about 15 months.[512] No second-line therapy for higher-risk MDS is FDA approved.

Venetoclax

The oral BCL-2 inhibitor venetoclax in combination with low-dose cytarabine, azacitidine, or decitabine was approved by the FDA for treatment of AML in 2018 on the basis of phase 1/2 for use in AML; subsequent phase 3 studies in AML showed a survival advantage with venetoclax combinations compared to monotherapy with hypomethylating agents.[513] In early studies, venetoclax plus azacitidine appears to have a higher response rate than would be expected with azacitidine alone, especially when used as initial therapy rather than in patients who are already refractory to azacitidine or decitabine.[514,515] Tumor lysis syndrome is rare in myeloid neoplasms but control of leukocytosis before venetoclax initiation is important. Cytopenias are problematic and antimicrobial therapy is essential, and a shorter schedule (e.g., 14 days per 28 days rather than continuous dosing) may reduce the risk of septic death. Randomized data are awaited but not yet available.

APR-246

The TP53 refolding agent APR-246 (eprenetapopt), an analogue of PRIMA1, showed a promising complete response rate when used in combination with hypomethylating agents in patients with MDS associated with TP53 point mutations.[516,517] The TP53 mutant clone is cytoreduced in responding patients. A unique pattern of neurotoxicity that can be partially ameliorated with prochlorperazine is observed, but the drug is otherwise well tolerated. A randomized trial completed accrual in 2020 and unfortunately did not meet the primary endpoint of improved complete response rate with combination therapy compared to HMA monotherapy.

“Histone” Deacetylase Inhibitors

The observation that MDS frequently involves epigenomic abnormalities has provoked interest in other modalities beyond the hypomethylating agents. To date, the next most-studied class of agent is the histone deacetylase inhibitors, which as their name implies block the deacetylation of histone residues as well as deacetylation of other cellular protein. In vitro, application of these drugs leads to large-scale epigenetic modifications, but in vivo, the drugs proved ineffective, with multiple negative randomized trials. These include the ECOG E1905 study of azacitidine with or without entinostat[518]; the US/Canadian Intergroup S1117, a large three-arm trial comparing azacitidine alone to azacitidine plus vorinostat to azacitidine plus lenalidomide[519]; as well as a study of azacitidine with or without pracinostat.[520]

Induction Chemotherapy

AML-like induction regimens (e.g., cytarabine plus an anthracycline) are not effective for most patients with MDS, with available studies suggesting a remission rate of less than 20%. Hematologic recovery is often incomplete, and in many cases the chemotherapy mainly serves to select for the malignant clone. In fact, a randomized trial in higher-risk MDS compared azacitidine to physician and patient choice of alternative therapy that included the possibility of daunorubicin plus cytarabine, and patients treated with azacitidine had better outcomes, although only small numbers of patients were treated with induction.[496]

Induction chemotherapy, however, may be reasonable in selected younger patients, especially as a bridge to HCT.[521] Adding other agents, such as liposomal doxorubicin,[522] topotecan,[522] and thalidomide, does not seem to improve the rates of remission. Approval of CPX-351, a stoichiometrically defined liposomal encapsulation of daunorubicin and cytarabine, in secondary AML and AML with MDS-related changes has prompted interest in studying reduced doses of this agent in higher-risk MDS.[523]

Allogeneic Hematopoietic Cell Transplantation

HCT is the only known curative therapy for MDS.[524] It leverages both the cytoreductive effect of the conditioning regimen and the anti-tumor effect of the newly transplanted stem cells to eliminate abnormal cells. The reality for most MDS patients is significantly more complicated, although outcomes have steadily improved in recent years as centers have gained more experience in transplanting older patients using unrelated and even unmatched donors.[525]

An exhaustive review of stem cell transplantation is beyond the scope of this chapter, but a few points specific to MDS bear mention. Identification of patients for whom transplant might be a reasonable option is an important first step. This group typically includes patients younger than 75 years who are in otherwise good health and have adequate performance.[526] The stage of disease is also important: transplant is usually reserved for those with excess blasts or other forms of higher-risk disease, based on mathematical models,[527,528] but it is important to proceed to transplant before the disease has evolved into acute leukemia. Some centers occasionally offer transplantation to younger patients with lower-risk categories of disease who have higher-risk molecular markers.

Once a decision has been made to proceed to transplant, other decisions must follow. The first involves the source of the stem cells. If a healthy, HLA-matched sibling is available, this is often preferable[529]; however, reflective of the average age of MDS patients, most siblings are older and often have comorbidities, such as cancer or other illnesses, that preclude them from consideration as donors. Clonal hematopoiesis is common in elderly donors, and even when younger donors are used, donor clonal populations can durably engraft in the recipient, but thus far universal screening of prospective donors for clonal mutations cannot be recommended.[530] If a related donor is unavailable, the next best option is a search of the donor registries for an HLA-matched unrelated donor.[531] Compared to related donors, transplant from unrelated donors carries a higher rate of graft-versus-host disease as a consequence of minor antigen mismatch. If a matched unrelated donor cannot be found, options then include an unrelated donor transplant mismatched at one (or occasionally more) HLA loci, or an "alternative donor source," which includes umbilical cord blood[532] and haploidentical donors.[533] In the case of MDS patients, this latter type of transplant is often obtained from one of the patient's children.

The specific choice of conditioning regimen is likely less important in MDS than in other hematologic diseases given the disease's intrinsic chemoresistance, as described above. Options include fludarabine plus busulfan, fludarabine plus melphalan, busulfan plus cyclophosphamide, treosulfan, or cyclophosphamide plus irradiation. Many older patients with MDS are unlikely to tolerate myeloablative doses of conditioning agents and are instead given reduced doses of conditioning agents. These "reduced intensity conditioning" transplants rely more heavily on the graft-versus-tumor effect of the transplant to eliminate the malignant clone.[527,534] Given the intrinsic chemoresistance of MDS stem cells, however, this is usually a reasonable tradeoff, although a randomized trial in AML showed better disease control with a myeloablative approach.[535] Following transplant, patients must remain on immunosuppressive medications for a period of time to prevent the emergence of graft-versus-host disease. A full discussion of post-transplant considerations is outside the scope of this chapter, but most aspects of this area are less specific to MDS than those discussed above.

As mentioned, despite being potentially curative therapy, transplant in MDS is associated with significant morbidity and mortality. One study has suggested that 50% to 60% of lower-risk patients and 20% to 40% with higher-risk disease can expect long-term disease-free survival following transplant,[536] but the alternative view of these data is that a substantial proportion of patients either relapse or die of non-relapse complications of transplant.

Numerous studies have attempted to dissect patient and disease attributes that may predict outcomes following transplant. Poor-risk cytogenetics, including monosomy 7 and complex karyotypes,[537] have been shown to predict a high rate of relapse, and data from a large genomic analysis show that *TP53* mutations have a universally poor prognosis and that *JAK2* and RAS pathway mutations have a poor prognosis specifically among patients over 40.[144] In this study, RAS pathway mutations also suggested a benefit to myeloablative over reduced intensity conditioning, likely reflective of incipient transformation to AML. Short telomeres in the recipient predict for higher non-relapse mortality. Donor clonal hematopoiesis, especially when defined by *DNMT3A* mutations, predicts a higher likelihood of chronic graft versus host disease and may be associated with a reduced risk of relapse, though available studies published thus far are inconclusive.[538] So far, specific cytogenetic or genetic profiles have not been clearly associated with a favorable response to HCT. Pre-existing neutropenia has been shown to predict an increased risk of serious infections in the post-transplant setting.[539] On the other hand, a low blast count (fewer than 5%) is associated with better outcomes, and other data show that patients who achieved a remission or significant response to pre-transplant chemotherapy have better outcomes as well.[540]

Other Therapies for Higher-Risk Disease

Though rarely used in current practice, infusion of autologous hematopoietic cells has been attempted in the past, primarily for patients with oligoblastic disease.[541,542] There are a number of reasons why this approach is suboptimal for MDS patients. The most obvious drawback is that MDS is by definition a disorder of stem cells, such that any autologous infusion will ultimately lead to repopulation of the marrow with the original malignant clone, but without the graft-versus-leukemia effect imparted by an HCT. Moreover, autologous stem cell infusion is really meant to serve as a rescue after high-dose chemotherapy and is thus most successful when given for a chemotherapy-sensitive disease, which MDS is not. Finally, given the ineffective hematopoiesis many patients experience prior to treatment, hematopoietic recovery following high-dose chemotherapy is often poor. Since most patients who would be candidates for autologous stem cell rescue would also be eligible for other, more effective modalities of therapy, there are usually few reasons to pursue this avenue.

Other Drugs

Most drugs known to have activity in AML have been tried for MDS as well, usually with suboptimal results. These include etoposide,[543] irinotecan, gemcitabine,[544] low-dose melphalan,[545] idarubicin,[521] and clofarabine.[546] Both hydroxyurea and low-dose oral etoposide can be used to control proliferation in patients with excess blasts, but they do not target the underlying disease. Clofarabine is sometimes effective as a bridge to transplant therapy in patients with excess blasts despite HMA therapy, but renal and hepatic toxicity and severe skin rash are limiting.[547]

Immune checkpoint inhibitors targeting PD-1 or PD-L1 have had limited efficacy and some immunotoxicity when used as single agents in MDS and AML, even though PD-1, PD-L1, and CTLA-4 are expressed in MDS and expression of immune checkpoints is augmented by hypomethylating agents.[548] Studies using these approaches in combination are ongoing. Randomized trials of anti-CD47 macrophage immune checkpoint inhibition with magrolimab[549] and anti-TIM3 inhibition with sabatolimab are ongoing. Agents that modulate other immune checkpoints such as LAG3, NKG2D/MICA, and CD70 are also being investigated.[550]

FUTURE DIRECTIONS

While the last ten years have witnessed substantial improvements in our understanding of the molecular pathophysiology underlying MDS, similar strides have not been made in its treatment: only 4 drugs—azacitidine in 2004, lenalidomide in 2005, decitabine in 2006 (supplemented by an oral formulation of decitabine and cedazuridine combination in 2020), and luspatercept in 2020—have achieved FDA approval for MDS-specific indications as of this writing. There are few therapies in clinical trials that offer hope of broad or deep efficacy, and much clinical effort has been directed at incremental changes to current practice, such as adjusting dosing schedules of currently approved therapies or using modestly effective drugs in combination. The lack of progress is to a great extent due to unfortunate facts of MDS biology, including its origin in quiescent stem cells, a paucity of targetable activating mutations, and enrichment for poorly targetable mutations with much more subtle effects on growth and differentiation. Efforts are further complicated by the heterogeneity of biology both between and within individual patients, as well as the advanced age and poor overall health of many MDS patients, which are barriers to clinical trial enrollment.[551]

Despite these significant challenges, there is nevertheless great opportunity for improvements in care. Advances in stem cell transplant techniques, including the availability of alternative donor sources, refinements of post-transplant immunosuppression, and augmentation of the graft-versus-tumor effect, should continue to improve the outcomes for MDS patients able to undergo transplant. An equally difficult challenge lies in treatment of those patients ineligible for transplant, and it is in these patients that effective unification of our improving biological understanding of MDS with clinical care is most essential.

CHAPTER 62

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR ACUTE MYELOID LEUKEMIA AND MYELODYSPLASTIC SYNDROME IN ADULTS

John Koreth, Joseph H. Antin, and Corey Cutler

Recent advances in molecular diagnostics continue to shed light on genetic underpinnings of myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). However, with notable exceptions, both diseases remain therapeutic challenges. Fortunately, our ability to provide more precise prognostic information has corresponded with advances in transplantation technology. We are increasingly able to apply transplantation to older people and those with comorbidities and to use alternative donors in patients without matched family members. By applying molecular prognostic criteria, we can provide transplantation to patients with poor outcomes on conventional therapy, and we can avoid transplant-related toxicity in those patients who are likely to do well with supportive care or nontransplant therapy.

Allogeneic hematopoietic stem cell transplantation (HSCT) is curative in MDS and AML due to a combination of the cytotoxicity of the preparative conditioning regimen and the donor-mediated immunologic graft-versus-leukemia (GVL) effect. Regimen intensity ranges from high-dose myeloablative conditioning (MAC) that induces profound and prolonged pancytopenia to reduced-intensity conditioning (RIC) that induces milder cytopenias and is more appropriate for older patients and those with comorbidities in whom MAC may be intolerable. The risk-benefit ratio of conditioning regimen intensity varies with factors like patient age, comorbidities, and relapse risk. In general, more intense regimens cause more treatment-related morbidity and mortality but are associated with a lower relapse rate. Conversely, there are more relapses in RIC HSCT, but the procedure is more tolerable.[1–3]

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR ACUTE MYELOID LEUKEMIA

AML remains the leading indication for allogeneic HSCT in the USA per the Center for International Blood and Marrow Transplant Research (CIBMTR), accounting for almost 40% of the 9028 allogeneic transplants performed in 2018.[4] AML displays considerable heterogeneity with markedly variable survival, traditionally defined by prognostic factors of patient age, comorbidities, white blood cell count, prior MDS or cytotoxic therapy, morphologic remission status, and karyotype, but further refined by its molecular taxonomy and assessment of minimal residual disease. In addition to new prognostic indicators, the availability of novel AML therapeutic agents constitutes an alternative or addition to cytotoxic chemotherapy, and they are also potentially intercalatable with HSCT.

Moreover, on the transplant side, the use of molecular tissue typing in conjunction with novel transplant modalities and better control of treatment-related complications has increased the pool of available donors. As shown in a recent analysis from the European Society for Blood and Marrow Transplantation (EBMT), the ability to use donors that are not fully histocompatible increases the pool of patients in whom HSCT can be an effective therapy.[5,6] Transplants performed using alternative donors are increasing.[4]

In the subsequent sections, we review allogeneic HSCT indications for patients with AML in first complete remissions (CR1) and the challenges for the treatment of relapsed/refractory and secondary AML, highlighting recent changes, including the inclusion of molecular disease markers and assessment of measurable (or minimal) residual disease (MRD). Additionally, we delineate approaches to transplantation for older patients and the role of alternative donor transplantation in AML. Finally, we note the poor prognosis of patients with morphologic AML relapse after HSCT and highlight trials of novel leukemia prophylaxis and therapeutic strategies for such patients.

Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia in First Complete Remission

Adult AML patients can be stratified into good-risk, intermediate-risk, and poor-risk groups based on the disease characteristics including numeric and/or structural chromosomal abnormalities and the presence of specific mutations that can also direct choice of curative post-remission therapy, especially for patients less than 60 years of age (see Chapter 60). For instance, current European LeukemiaNet (ELN) consensus incorporates molecular mutations to derive AML prognostic risk groups (Table 62.1).[7] In current thinking, allogeneic HSCT is generally recommended when the relapse incidence with non-transplant approaches is expected to be above 35% to 40%.

Numerous groups have evaluated prospectively the relative benefits of allogeneic HSCT versus non-allogeneic therapies (consolidation chemotherapy or autologous HSCT) in adult AML patients 18 to 60 years of age in CR1. Treatment allocation was by biologic assignment as a surrogate for true randomization, with allogeneic HSCT for patients with available human leukocyte antigen (HLA)–matched sibling donors (donor group) and non-allogeneic consolidation for those lacking matched sibling donors (no-donor group). Some studies further stratified post-remission outcomes by cytogenetic risk. Individual studies, when analyzed on an intent-to-treat (ITT) donor versus no-donor basis, typically demonstrated that allogeneic HSCT was effective at improving disease-free survival, but overall survival benefit was hard to document because of graft-versus-host disease (GVHD) and other treatment-related mortality. Moreover, transplantation in CR2 salvages some of the patients who relapsed, thus making overall survival similar with the two approaches.

A meta-analysis of over 6000 patients in 24 biologic treatment assignment trials, however, confirmed that overall survival was in fact better in allogeneic matched related donor transplantation in AML-CR1, with a hazard ratio (HR) of death at 0.90 (95% confidence interval [CI], 0.82 to 0.97).[7] Importantly, when stratified by cytogenetic risk, there was an overall survival benefit of allogeneic transplantation (Table 62.2) for both intermediate-risk (HR, 0.83; 95% CI, 0.74 to 0.93) and poor-risk (HR, 0.73; 95% CI, 0.59 to 0.90) cytogenetic groups, but not for good-risk AML-CR1 (HR, 1.07; 95% CI, 0.83 to 1.38) (Fig. 62.1). These findings were particularly relevant for patients with normal cytogenetic AML, who

TABLE 62.1 **European LeukemiaNet Acute Myeloid Leukemia Risk Classification 2017**

Risk Category	Genetic Abnormality
Favorable	t(8;21)(q22;q22.1); *RUNX1-RUNX1T1*
	inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
	Mutated *NPM1* without *FLT3*-ITD or with *FLT3*-ITD$^{\text{low}}$[a]
	Biallelic mutated *CEBPA*
Intermediate	Mutated *NPM1* and *FLT3*-ITD$^{\text{high}}$[a]
	Wild-type *NPM1* without *FLT3*-ITD or with *FLT3*-ITD$^{\text{low}}$[a] (without adverse-risk genetic lesions)
	t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*[b]
	Cytogenetic abnormalities not classified as favorable or adverse
Adverse	t(6;9)(p23;q34.1); *DEK-NUP214*
	t(v;11q23.3); *KMT2A* rearranged
	t(9;22)(q34.1;q11.2); *BCR-ABL1*
	inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2,MECOM(EVI1)*
	−5 or del(5q); −7; −17/abn(17p)
	Complex karyotype,[c] monosomal karyotype[d]
	Wild-type *NPM1* and *FLT3*-ITD$^{\text{high}}$[a]
	Mutated *RUNX1*[e]
	Mutated *ASXL1*[e]
	Mutated *TP53*[f]

[a] Low, low allelic ratio (<0.5); high, high allelic ratio ($\geq$0.5); semiquantitative assessment of *FLT3*- internal tandem duplication (ITD) allelic ratio (using DNA fragment analysis) is determined as the ratio of the area under the curve "*FLT3*-ITD" divided by area under the curve "*FLT3*-wild type"; recent studies indicate that acute myeloid leukemia (AML) with *NPM1* mutation and *FLT3*-ITD low allelic ratio may also have a more favorable prognosis and patients should not routinely be assigned to allogeneic hematopoietic cell transplantation (HCT).

[b] The presence of t(9;11)(p21.3;q23.3) takes precedence over rare, concurrent adverse-risk gene mutations.

[c] Three or more unrelated chromosome abnormalities in the absence of 1 of the WHO-designated recurring translocations or inversions, that is, t(8;21), inv(16) or t(16;16), t(9;11), t(v;11)(v;q23.3), t(6;9), inv(3), or t(3;3); AML with *BCR-ABL1*.

[d] Defined by the presence of one single monosomy (excluding loss of X or Y) in association with at least one additional monosomy or structural chromosome abnormality (excluding core-binding factor AML).

[e] These markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes.

[f] *TP53* mutations are significantly associated with AML with complex and monosomal karyotype.

From Dohner H, Estey E, Grimwade D, et al. Diagnosis and management of AML in adults: 2017 ELN recommendations from an international expert panel. *Blood*. 2017;129:424–447.

constitute the largest subgroup and for whom no consensus regarding optimal post-remission treatment was previously available. These studies however did not have the benefit of prognostic assignment based on FLT3, NPM1, or other molecular markers.

Prognostic Factors for Acute Myeloid Leukemia in First Complete Remission

Good-Risk Acute Myeloid Leukemia

In general, the 15% to 20% of AML patients with core binding factor (CBF) leukemia—t(8;21) (q22;q22) and inv(16)(p13.q22)—are considered to have good-risk disease, with a long-term disease-free survival of approximately 50% to 60% after consolidation chemotherapy, and allogeneic HSCT is not routinely recommended for patients achieving CR1. However, retrospective studies have identified activating mutations in C-KIT (mKIT)—a member of the type III receptor tyrosine kinase family—at exon 17 (mKIT 17) or exon 8 (mKIT 8) in approximately 30% of CBF AMLs, in particular AML with t(8;21), that are associated with increased relapse incidence and likely poorer survival, especially if higher mutant *KIT* levels are present.[8–11] Consensus opinions differ on the implications: ELN guidelines suggest that occurrence of a *KIT* mutation should not assign a patient to a different risk category; rather, patients should be monitored for MRD, whose absence can abrogate the effect of *KIT*.[9] 2019 guidelines of the US National Comprehensive Cancer Network (NCCN) in contrast highlight considering them for clinical trials targeting the molecular abnormality, or for referral to allogeneic transplantation.[12]

Intermediate-Risk Acute Myeloid Leukemia

The intermediate-risk cytogenetic group is heterogeneous and includes cytogenetically normal disease as well as those with karyotypic abnormalities not meeting criteria for good- or poor-risk AML. It previously constituted the largest risk category, accounting for approximately 40% to 50% of adult AML patients less than 60 years of age, but more recently with the refinement of molecular risk predictors, this category has shrunk. Long-term disease-free survival of approximately 40% to 45% is anticipated after consolidation chemotherapy in intermediate-risk AML. However, identification of mutations with prognostic importance such as mutant FLT3 internal tandem duplication (FLT3-ITD), NPM1, and CEBPA (CCAAT/enhancer-binding protein-α) have further individualized treatment decision-making, including allogeneic transplantation.

Over the past decade, "normal" karyotype AML (NK-AML, the largest category within intermediate-risk AML) has been documented to encompass molecular abnormalities with divergent risk. The presence of an isolated NPM1 or biallelic CEBPA mutation improves disease prognosis to slightly below that of AML with CBF translocations, placing them in the favorable-risk category, and most investigators do not offer HSCT in first remission.[13] The favorable impact of NPM1 mutations appears to persist albeit to a lesser extent in older patients, and allogeneic HSCT may be a consideration in older AML.[14–16] In contrast, patients with an isolated FLT3-ITD mutation and NK-AML have outcomes similar to those with poor-risk karyotype.[17] In a report evaluating the 2010 ELN risk classification in a large cohort of patients, for those in the "intermediate I" risk group (includes all patients with NK-AML with FLT3 abnormalities and those lacking both FLT3 and NPM1 mutations), relapse-free survival (RFS) was improved with allogeneic HSCT (94 vs. 7.9 months without allogeneic HSCT).[18]

Although the better-prognosis subgroup within NK-AML may not benefit from early allogeneic transplantation, HSCT appears to be the preferred post-remission therapy for other intermediate-risk AML patients at higher risk for relapse, including those lacking favorable gene mutations like NPM1 without FLT3-ITD, or double mutant CEBPA. However, the dissection of disease complexity requires detailed analysis to identify optimal therapy. For instance, Dohner et al. validated the 2017 NPM1/FLT3-ITD ELN AML risk classification, documenting that allogeneic HSCT benefit is restricted to patients in the "adverse-risk" group (NPM1$^{\text{wt}}$/FLT3-ITD$^{\text{high}}$; NPM1$^{\text{mut}}$/FLT3-ITD$^{\text{high}}$ with high-risk molecular mutations *(RUNX1*, *ASXL1*, *TP53)*; and NPM1$^{\text{wt}}$/FLT3-ITD$^{\text{low}}$ AML with high-risk molecular markers and/or adverse-karyotype). For the "intermediate-risk" group (NPM1$^{\text{mut}}$/FLT3-ITD$^{\text{high}}$; and NPM1$^{\text{wt}}$/FLT3-ITD$^{\text{low}}$, both without adverse-risk karyotype), allogeneic HSCT benefit was restricted to patients who did not receive midostaurin-based treatment on the CALGB 10603/RATIFY trial.[13] Of note, this finding is relevant to AML patients aged 18 to 60 years and requires validation in independent datasets prior to its routine incorporation in clinical decision making. Further, extrapolation to patients aged above 60 years is not warranted, given their overall worse disease outcomes.

TABLE 62.2 **Allogeneic Transplantation Guidelines for Adult Acute Myeloid Leukemia Based on Commonly Assessed Cytogenetic and Molecular Markers**

AML Category	Prognostic Impact	Allogeneic Transplantation	Notes
AML-CR1: Younger Adults			
Good-risk disease			
APL	Favorable	No	APL is treatable by chemotherapy.
CBF-AML *without mKIT*	Favorable	No	t(8;21) AML with high WBC count at diagnosis may have worse prognosis.
CBF-AML *with mKIT*	Intermediate	Possible: MRD, MUD Uncertain: MMUD, UCB, haplo	
Intermediate-Risk Disease			
CN-AML *with CEBPA*	Favorable	No	Benefit likely restricted to *DM-CEBPA*.
CN-AML *with mutant NPM1 but not FLT-3-ITD*	Favorable	Possible: MRD	Emerging data suggests allogeneic hematopoietic stem cell transplantation benefit for this category, with reduced relapse and improved DFS in patients >40 years.
CN-AML *with FLT-3-ITD*	Unfavorable[a]	Yes: MRD, MUD Possible[b]: MMUD, UCB, haplo	Unfavorable risk may be restricted to AML *with FLT-3-ITD allelic ratio >0.51*.
Other intermediate-risk disease	Intermediate or Unfavorable	Yes: MRD Likely acceptable[a]: MUD Possible[b]: MMUD, UCB, haplo	Likely considerable underlying clinical heterogeneity. Molecular risk profiling may further delineate risk in this category.
Poor-Risk Disease			
Monosomal karyotype *absent*	Unfavorable	Yes: MRD, MUD Likely acceptable[b]: MMUD, UCB, haplo	
Monosomal karyotype *present*	Very unfavorable	Yes: MRD, MUD Acceptable[b]: MMUD, UCB, haplo	
Abnormal 17(p)	Very unfavorable	Yes: MRD, MUD Acceptable[b]: MMUD, UCB, haplo	
AML-CR1: older adults	Unfavorable	Yes: MRD, MUD Likely acceptable[b]: MMUD, UCB, haplo	
AML-CR1: t-AML, AML/MDS	Unfavorable	Yes: MRD, MUD Acceptable[b]: MMUD, UCB, haplo	Molecular risk profiling may supersede clinical classification of secondary AML, especially in older patients.
AML-CR2	Very unfavorable	Yes: MRD, MUD Acceptable[b]: MMUD, UCB, haplo	
AML not in remission	Very unfavorable	Yes: MRD, MUD Uncertain: MMUD, UCB, haplo	For selected patients: good performance status, little comorbidity, lower leukemic burden; CIBMTR risk score may be useful.

[a] If no sibling donor available.
[b] If no timely matched donor available.
AML, Acute myeloid leukemia; *APL*, acute promyelocytic leukemia; *CBF*, core binding factor; *CIBMTR*, Center for International Blood and Marrow Transplant Research; *CN*, cytogenetically normal; *CR1*, first complete remission; *CR2*, second complete remission; *DFS*, disease-free survival; *haplo*, haploidentical; *MDS*, myelodysplastic syndrome; *MMUD*, mismatched unrelated donor; *MRD*, matched related donor; *MUD*, matched unrelated donor; *t-AML*, therapy-related AML; *UCB*, umbilical cord blood; *WBC*, white blood cell.

Poor-Risk Acute Myeloid Leukemia

In poor-risk AML, relapse rates are high and survival rates are anticipated to be 15% or lower with conventional therapy. Allogeneic HSCT with a matched sibling or unrelated donor results in long-term survival of 30% to 40% and is considered the treatment of choice for adults less than 60 years of age with poor-risk AML. There remains, however, a subgroup of poor-risk AML that may have particularly adverse prognosis, for whom additional novel therapeutic strategies may be necessary.

The monosomal karyotype (MK) is defined by the presence of a single autosomal monosomy, in association with at least one additional monosomy or non-good-risk structural chromosomal abnormality (i.e., excluding CBF mutation AML).[16] In the original report, MK-positive AML patients had a long-term survival of only 3% to 4%, and these generally dismal chemotherapeutic outcomes have been confirmed by other investigators.[19] Allogeneic transplantation appears to only partly ameliorate the impact of MK-positive karyotype, which remained an adverse prognostic factor after HSCT, and was associated with a relapse risk of 62% and poor survival of 15% at 4 years.[20]

Importantly, some if not all of the negative impact of MK and complex karyotype (CK) AML is its association with deletions of chromosome 5 (−5/5q−) and especially with abnormal (abnl)17p (site of TP53 gene). In a retrospective analysis of 236 high-risk AML-CR1 patients of whom nearly half (49%) received reduced-intensity allogeneic HSCT, patients with abnl(17p) had a 2-year EFS of 11%, those with −5/5q− but no abnl(17p) had a 2-year EFS of 29%, and those with high-risk AML (including MK or CK) without either abnl(17p) or −5/5q− had a 2-year EFS of 49%.[21] Further, in

updated analyses, the negative impact of abnl(17p) appears minimally improved after allogeneic HSCT.[22,23] Improving HSCT outcomes in TP53 mutant and other extremely poor-risk AML remains a high priority for the future, and clinical trials of novel conditioning (e.g., Venetoclax-based) and post-transplant maintenance (e.g., APR-246) approaches are strongly encouraged for such patients.

Measurable Residual Disease Assessment in Acute Myeloid Leukemia

Sequential monitoring of MRD via sensitive phenotyping (e.g., multicolor flow cytometry [MFC]) or molecular methods (e.g., quantitative PCR [qPCR], digital droplet PCR [ddPCR], deep error-corrected next-generation sequencing [NGS]) to detect AML-associated immunophenotypes or mutations respectively, at a sensitivity of at least 1×10^{-3}, is applicable to the vast majority of AML and provides a useful guide to post-remission AML management. Indeed, MRD negativity is emerging as an alternative therapeutic endpoint that supplements (and may replace) morphologic AML remission criteria.

As reviewed by Dohner et al., mutational assessment at early post-remission time points can distinguish patients at a differing probability of relapse.[24] As they highlight, MRD status has been found to be a better predictor of relapse risk than the presence of cooperating mutations involving *KIT* and *FLT3*-ITD in CBF-AML, or *FLT3-ITD*, *DNMT3A*, and *WT1* in *NPM1*-mutated AML. Sequential MRD-monitoring studies have shown that persistent high-level PCR positivity, or a rising level of leukemic transcripts after an initial molecular response, invariably predict relapse. Validated AML-associated mutations for MRD monitoring include *RUNX1-RUNX1T1*, *CBFB-MYH11*, and *PML-RARA* translocations (*KMT2A* and *DEK-NUP214* translocations are also AML-associated).[25] Other likely prognostic MRD mutations include *NPM1*, RAS pathway mutations (*FLT3-ITD* and *-TKD*), *N*- and *K-RAS*, *PTPN11* or *KIT*, whose persistence in CR indicates a likely higher risk of relapse. However, in the non-transplant context, the persistence of AML-associated mutations needs to be distinguished from the persistence of underlying clonal-hematopoiesis (CH) or MDS-associated mutations (e.g., DTA: DNMT3A, TET2, ASXL1). Future studies will help further distinguish mutations that are reliable indicators of leukemic clones associated with AML relapse versus mutations associated with preleukemic clones that are poorly predictive of relapse, despite persistence at high levels after chemotherapy and during remission. Whether MRD-based early interventions can prevent overt relapse remains under investigation. Preemptive therapy may be particularly relevant with allogeneic HSCT where MRD status may inform conditioning strategy, or post-hematopoietic cell transplantation (HCT) measures aiming to avoid frank relapse. These data support routine inclusion of MRD assessment to help inform transplant decision making in AML-CR1.

Patients with persistent MRD or with early MRD reoccurrence can receive salvage therapy as a bridge to allogeneic HSCT before hematologic relapse or proceed directly to transplant depending on donor availability and the likelihood of success with salvage therapy. The GIMEMA AML1310 study undertook risk-adapted treatment assignment of young adults with newly diagnosed intermediate-risk AML to allogeneic HSCT based on MFC-based MRD assessments, reporting promising 2-year disease-free survival and overall survival of 67% and 70% respectively for MRD$^+$ intermediate-risk AML patients assigned allogeneic HSCT.[26] Importantly, their finding of similar survival of MRD$^+$ intermediate-risk AML patients (assigned allogeneic HSCT) versus those who were MRD$^-$ (assigned autologous HSCT) suggests that allotransplantation may ameliorate the negative impact of persistent MRD, although other studies suggest it does not fully abrogate the negative effect of unfavorable pre-transplant MRD. For instance, in *NPM1*-mutant AML, high-level MRD for *NPM1*, or low-level MRD for *NPM1* plus presence of *FLT3-ITD*, had impaired post-transplant survival.[27] More intensive conditioning may offer therapeutic benefit for patients with persistent MRD pre-transplant. Deep error-corrected 13-gene NGS-based reanalysis of the BMTCTN 0901 study randomizing older AML patients to MAC versus RIC documented relapse protection and survival benefit for pre-transplant MRD$^+$ patients assigned MAC HSCT.[28] Importantly, the benefit was restricted to those with persistent AML-associated mutations, but not for those with CH-associated (*DNMT3A*, *TET2*, *ASXL1*) mutations pre-transplant. These findings need to be validated prior to incorporation in routine clinical practice.

In the post-transplant context, persistent or recurrent recipient MRD positivity is also associated with an increased risk of AML relapse.[29] However, many uncertainties remain, for instance with regards to MRD assessment modalities, thresholds, assessment frequency and timepoints, and the prognostic implications of recurrence or persistence of specific mutations and their recrudescence patterns. Importantly, for post-transplantation testing, detection of *either* AML- or CH-associated mutations would be concerning for recrudescent donor hematopoiesis and disease. However, therapeutic interventions based on the post-transplant assessment of MRD, ranging from immune suppression (IS) taper, donor lymphocyte infusion (DLI) and modified DLI (mDLI), hypomethylating agents (HMAs), and AML mutation-specific targeted therapies (e.g., *FLT3* inhibitors) may offer utility and are currently undergoing prospective evaluation.[29]

Transplantation Regimen Intensity in Acute Myeloid Leukemia

Myeloablative HSCT remains the standard of care for younger adults with AML. However, treatment-related mortality after MAC remains appreciable. Lower-intensity regimens offering less treatment-related toxicity are gaining in popularity. One report retrospectively compared RIC transplantation with chemotherapy in high-risk AML on a donor versus no-donor basis. They identified a leukemia-free survival benefit in the donor group (54% vs. 30%, $P = .01$).[30] This indicates that both MAC and RIC HSCT offer antileukemic benefit compared to non-transplant therapies.

Several groups compared MAC versus RIC transplantation, documenting similar overall and leukemia-free survival, with some reporting lower treatment-related mortality offset by increased relapse risk, especially for patients not in complete remission at the time of HSCT. A CIBMTR study compared 3731 MAC, 1041 RIC, and 407 nonmyeloablative (NMA) transplantations, reporting adjusted 5-year overall survival (OS) of 34%, 33%, and 26%, respectively.[31] The authors concluded that, although NMA transplantation increased relapse and impaired survival, RIC and MAC regimens had similar overall and leukemia-free survival. While a small randomized trial documented similar outcomes of MAC versus RIC transplantation in AML-CR1,[1] a larger prospective randomized trial of MAC versus RIC transplantation in AML or MDS patients closed after the accrual of 272 of planned 356 patients due to an increased relapse and impaired long-term survival in the RIC arm.[2] Additionally, as discussed previously, post-hoc analysis of this study documented that ablative conditioning can offer therapeutic benefit for patients with detectable pre-transplant MRD, offering relapse protection and survival benefit compared to RIC HSCT.[28]

RIC transplantation does, however, offer the option of curative allogeneic HSCT in older or sicker AML-CR patients for whom the toxicity of MAC transplantation might be prejudicial, especially if combined with novel approaches to augment the GVL effect in the peri- and post-transplant setting. Conversely, patients with good performance status but high AML relapse risk could be preferentially selected for MAC.

Alternative Donor Transplantation in Acute Myeloid Leukemia

HSCT from an HLA-matched sibling donor has been the standard of care for prospective biologic treatment assignment studies evaluating post-remission therapies. Patients lacking sibling donors could be considered for alternative donors: unrelated adult donors, umbilical cord blood (UCB), or haploidentical donor transplantation.

Unrelated Adult Donors

Given the very poor outcomes after non-allogeneic therapy in poor-risk AML, and the documented benefit of HLA-matched sibling donor HSCT, clinical practice has been to undertake HLA-matched unrelated donor transplantation for younger adults with poor-risk AML in CR1 who lack sibling donors. A retrospective analysis of HLA-matched siblings compared with unrelated donor HSCT in poor-risk AML-CR1 documented comparable outcomes with HLA-matched siblings and HLA well-matched unrelated donors with 3-year OS of 45% compared with 53% ($P = .63$).[32] Outcomes were not as good for partially HLA-mismatched unrelated donors (one-locus HLA mismatch), with 3-year OS of 31% ($P = .026$). Smaller prospective studies have also shown equivalent results, confirming the suitability of well-matched unrelated donor HSCT in poor-risk AML.[33,34]

There is limited data comparing HLA-matched sibling with unrelated donors in intermediate-risk AML, although at least one study documented similar outcomes with either donor type.[35] Current practice is to offer HLA-matched unrelated donor HSCT to intermediate-risk AML patients in first remission, especially if there are adverse molecular lesions.

Umbilical Cord Blood Donors

Another important issue is the use of UCB transplantation for AML in CR1. These data are harder to interpret because most studies reported outcomes for “acute leukemia,” rather than AML-CR1. A European registry study documented similar outcomes of UCB versus unrelated donor bone marrow (BM) transplantation in adults with acute leukemia, whereas a CIBMTR study showed better outcomes with HLA-matched unrelated donor BM transplantation but similar outcomes of UCB and HLA-mismatched unrelated donor BM transplantation.[36,37] A large analysis of adult acute leukemia (including 880 AML patients) compared the outcomes of single-unit 4–6/6 HLA-matched (HLA-A, -B, -DRB1) UCB with 8/8 or 7/8 HLA-matched (HLA-A, -B, -C, DRB1) BM or peripheral blood stem cell (PBSC) transplantation and documented similar leukemia-free survival regardless of stem cell source or degree of HLA match. There was higher treatment-related mortality after UCB transplantation.[38] Transplantation in CR1 resulted in similar 2-year leukemia-free survivals of 44%, 50%, 52%, 39%, and 41% with UCB, 8/8 PBSC, 8/8 BM, 7/8 PBSC, and 7/8 BM transplantation, respectively. In contrast, a Japanese study evaluated outcomes of 484 AML patients receiving 4 to 6/6 UCB compared with 8/8 unrelated donor BM transplantation and documented a similar relapse risk with UCB transplantation, but higher treatment-related mortality and worse overall and leukemia-free survival.[39]

Double unit UCB (DUCB) transplantation is commonly used for larger patients. Indeed, since 2005, the number of adults receiving DUCB has exceeded those receiving single-unit UCB products. Limited data suggest similar outcomes of myeloablative DUCB, HLA-matched unrelated, and sibling donor HSCT in hematologic malignancies.[40] However, only a subset of patients had AML. The role of DUCB in AML remains to be better delineated. Overall, from 2003 to 2011, there was a steady increase in the numbers of transplants using UCB, after which, however, UCB transplant activity declined, in part owing to issues around UCB treatment-related mortality, including delayed engraftment, infections, and NRM. In general, current clinical practice envisages the use of UCB transplantation in younger adults with high-risk AML in CR1 who lack suitable HLA-matched donors. However, the increasing utilization of haploidentical transplant (discussed below) is associated with and may be the cause of a concurrent decline in UCB transplantation, in part due to cost and convenience advantages, with comparable outcomes to HLA-matched transplantation.

Reducing treatment toxicity will be important to advance UCB transplantation. A trial of 79 adult AML cord recipients (60% DUCB), identified a low 2-year NRM incidence of 20%, suggestive of progress in this metric.[41] Importantly, a retrospective report highlighting potential curative benefit in acute leukemia and MDS patients with detectable pre-transplant MRD with UCB compared to URD HSCT, if validated, would be a reason to reconsider the trend against UCB HSCT.[42] Additionally, recent results of the international, multicenter, randomized Phase III study treating 125 patients aged 12 to 65 years with high-risk hematologic malignancies (including AML) undergoing transplant, documenting significant shortening of the median time to neutrophil engraftment for patients who received omidubicel UCB compared to the comparator group receiving usual UCB (12 days; 95% CI: 10 to 15 days vs. 22 days; 95% CI: 19 to 25 days),[43] offer a means to alleviate some of the clinical concerns regarding UCB HSCT to better harness its antileukemic potential.

Haploidentical Donors

Per CIBMTR data, transplants performed using alternative donors are increasing. From 2012 onward, there has been an increase in the numbers of transplants from "Other Relatives," likely due to the use of haploidentical (haplo) donors. This trend has continued to rise with these transplants representing 21% of transplants and nearing numbers of HLA-identical sibling transplants that represent 25% of allogeneic transplants in the United States in 2018. Haplo-transplantation (haplo-HSCT) is particularly interesting given the potential enhancement of GVL activity by natural killer cells and allogeneic T cells responding to the HLA disparity.[44] An advantage of this approach is the rapidity and near-universal availability of donors.

Of current haplo-HSCT regimens, those incorporating post-transplantation cyclophosphamide (PTCy) for the prevention of GVHD have gained increasing prominence, with low rates of treatment-related mortality and GVHD.[45,46] For AML/MDS, a retrospective analysis found no significant differences between outcomes of matched unrelated ($n = 108$) or haploidentical ($n = 32$) donor HSCT with PTCy.[47] A large CIBMTR analysis documented similar 3-year OS for AML after MUD versus haplo-HSCT,[48] while another documented equivalent post-HSCT outcomes, with less chronic GVHD in PTCy-based haplo-HSCT.[49] In a systemic review and meta-analysis comparing MRD versus PTCy-based haplo-HSCT, haplo-HSCT was associated with ~50% lower risk of chronic GVHD (HR, 0.55; 95% CI, 0.41–0.74), but higher risk of NRM (HR, 1.36; 95% CI, 1.12–1.66).[50] Relapse, survival, acute GVHD, and GVHD-free relapse-free survival (GRFS) were not significantly different between the groups. Indeed, in a recent large CIBMTR registry analysis, haplo-HSCT had the best GRFS and OS outcomes compared to UCB and MMUD donors.[51]

The reduction in chronic GVHD risk is likely PTCy-related and independent of donor source, as documented by Phase II randomized comparison in HLA-matched and mismatched unrelated donor transplantation, wherein a PTCy-based GVHD regimen offered significant improvement in GVHD and GRFS endpoints.[52] The recent Phase III randomized HOVON-96 study confirms the benefit of PTCy-based versus cyclosporine/mycophenolate mofetil GVHD prophylaxis for HLA-matched HSCT.[53] Overall, however, these results highlight the increasing utilization and acceptability of PTCy-based haplo-HSCT, though issues with regards haplo-donor selection (parent vs. haplo-sibling vs. child), donor-specific antibodies, cytokine release syndrome (especially after infusion of haplo PBSC grafts, as is increasingly popular), post-PTCy immunologic dysfunction and reconstitution, and unique aspects of AML relapse in the haplo-HSCT context are areas of ongoing study.

Hematopoietic Stem Cell Transplantation for Relapsed, Refractory, and Induction-Failure Acute Myeloid Leukemia

Outcomes are typically poor for AML patients not in morphologic remission at the time of allogeneic HSCT, although the literature in this regard is limited, heterogeneous, and likely subject to patient selection and publication bias. A large analysis of MAC HSCT for acute leukemia in relapse or in primary induction failure (including 1673 AML patients) documented a 3-year OS of 19% in AML.[54] On multivariable analysis, risk factors at time of HSCT of poor-risk cytogenetic AML, CR1 duration of less than 6 months, circulating AML blasts, performance score of less than 90%, and lack of an HLA-matched sibling donor predicted for 3-year survivals ranging between 42% (zero risk factors) and 6% (three or more risk factors). The major cause of death remains AML relapse, and innovative strategies to reduce leukemic burden before transplantation and enhance GVL effect after transplantation are likely required to improve survival of this extremely high-risk patient population.

In one instance for this patient population, the use of novel apoptosis-inducing agents (e.g., venetoclax) or agents targeting specific AML molecular pathways (e.g., FLT3, IDH 1/2, mTOR) with limited off-target toxicity as a bridge to allogeneic HSCT could offer important clinical benefit. In another instance, the use of novel adoptive cell therapies (e.g., cytokine-induced memory-like NK cells[55]) or graft-engineering approaches (e.g., αβ T cell-[56] or regulatory T cell- [Treg] engineered grafts[57]) to enhance GVL while controlling GVHD are important innovations under evaluation for high-risk leukemia. Finally, the ability to rapidly proceed to allogeneic transplantation may also be important given the dismal outcome of chemotherapy alone, suggesting a role for expeditious transplantation in this setting, especially for patients temporarily achieving a remission.

Hematopoietic Stem Cell Transplantation for Therapy-Related and Secondary Acute Myeloid Leukemia

Therapy-related AML (t-AML) currently accounts for ~10% to 20% of newly diagnosed AML, and its incidence is likely to rise in the future, given rising cancer survivorship. Post-remission therapy using conventional chemotherapy is usually not curative in secondary AML (s-AML: t-AML and AML arising from antecedent MDS or MPD) with the rare exception of CBF-AML, specifically inv(16) and t(15;17). Allogeneic HSCT is less effective in s-AML. The poorer survival appears multifactorial due to poor-risk cytogenetics and tumor-associated mutations (e.g., TP53, PPM1D), lower likelihood of entering remission, older patient age, and impaired organ function from prior cancer therapy; although some reports documented similar post-transplantation survival compared to de novo AML when adjusted for risk factors like disease status and cytogenetics.[32,58] An observational analysis of 545 patients with t-AML identified risk factors influencing HSCT outcomes: age greater than 35 years, poor-risk cytogenetics, AML not in remission, and lack of well-matched donors. A prognostic score could stratify outcomes from 5-year OS of 50% (zero risk factors) to 4% (four risk factors).[59]

Molecular genotyping offers insights into the clinical heterogeneity of s-AML. In a seminal analysis, Lindsley et al identified eight genes specifically mutated in s-AML (SRSF2, SF3B1, U2AF1, ZRSR2, SXL1, EZH2, BCOR, STAG2) that also identify worse prognosis "de novo" elderly AML, likely indicating undiagnosed antecedent MDS. They also identified a molecular signature of "de novo" type AML. Finally, they confirmed that TP53, PPM1D mutations comprised a distinct set of AML with the worst outcomes. Molecular risk stratification offers the potential to redefine the clinical diagnosis of s-AML, refine AML risk prognostication, and potentially better select remission-inducing and post-remission therapy.[60]

Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia in Older Adults

AML incidence rises with age, with a median age at diagnosis of 67 years.[61] For AML patients older than 60 years, consolidation chemotherapy is unlikely to be curative (Fig. 62.2). Even after adjusting for increased incidence of poor prognosis features like adverse cytogenetic and molecular markers, secondary AML, comorbidities, and poorer performance status, older age remains an independent predictor of poor survival with conventional chemotherapy. A priori, age-related CH may be a relevant variable for impaired survival, though this remains to be confirmed.[62,63] Although allogeneic HSCT is a curative therapy in the older age-group, there is considerable reluctance to refer these patients for transplantation, in contrast to younger adults with AML, in part due to outdated assumptions regarding the tolerability of allogeneic transplantation but also due to lack of comparative data regarding outcomes.

Several reports have documented the feasibility of RIC transplantation with acceptable toxicity and reasonable survival in patients 60 years of age and above, including those with AML. Indeed, chronologic age alone does not appear to be a prognostic factor in RIC allogeneic transplantation for AML.[64,65] In a case-control study comparing RIC transplantation with chemotherapy for AML patients 60 to 70 years of age, allogeneic HSCT was associated with lower relapse risk (32% vs. 81%, $P < .001$), greater treatment-related mortality (36% vs. 4%; $P < .001$), and longer 3-year leukemia-free survival (32% vs. 15%, $P = .001$), with a borderline 3-year OS benefit (37% vs. 25%, $P = .08$).[66]

Overall, for physically fit older AML patients, especially those between 60 and 70 years of age, a donor search should be undertaken promptly at diagnosis, disease control with intensive induction chemotherapy is beneficial, and they should be considered for potentially curative allogeneic transplantation upon entering complete remission. Broadly speaking, molecular and karytotypic AML risk prognostication also applies to older patients being considered for RIC HSCT, with several caveats:

First, favorable-risk (e.g., CBF-AML) disease retains a relatively favorable impact in older patients, though data indicating equivalent outcomes of non-transplantation and allogeneic HSCT treatment cannot be extrapolated to older patients. Allogeneic HSCT likely offers additional benefit. For instance, in the UK National Cancer Research Institute (NCRI) AML16 trial of patients with median age of above 65 years, NPM1 mutant FLT3-ITD negative AML treated with intensive chemotherapy had a 3-year OS of only 26%, with a relapse incidence of 73%.[67] Additionally, in a combined SWOG/NCRI cohort, patients with NPM1mutant FLT3-ITD negative AML who were aged 55 to 65 years had a significantly improved 2-year OS of 70% versus 27% for those aged above 65 years ($P < .001$). The survival benefit of NPM1 mutant FLT3-ITD negative AML was absent in patients aged above 65 years.[68] Importantly, in a separate donor versus no-donor analysis, NPM1 mutant AML patients with an allogeneic donor had significantly lower 3-year relapse rates (14% vs. 46%) and improved RFS (71% vs. 47%), indicating a beneficial antileukemic effect of allogeneic HSCT in this AML subgroup.[69]

Second, certain AML cohorts (e.g., MK and TP53 mutant AML) have an extremely poor prognosis with high risk of disease relapse,[22,23,70] and the adequacy of "usual" RIC HSCT is questionable in this AML subgroup. Such patients should be appropriately counseled prior to proceeding with allogeneic HSCT, with consideration to conditioning intensity escalation if possible. Novel clinical trials focused on enhancing GVL are a priority for this ultra-high-risk AML subgroup.

Acute Myeloid Leukemia Relapse After Transplantation

AML relapse after transplant is common, associated with dismal outcomes, and remains a major obstacle to HSCT success.[71] Up to 40% of patients with AML/MDS relapse after undergoing HLA-matched HSCT.[72] Powerful donor-derived immune responses underlie the GVL effect, and immune escape (i.e., tumor evasion of the donor immune system) contributes to relapse after HSCT.

In HLA-matched HSCT, presentation of host hematopoietic and/or tumor epitopes within the concordant HLA context can invoke T cell receptor (TCR)-mediated recognition and elimination by donor T effector (Teff) cells to induce curative GVT responses that may be antagonized by loss of Class I HLA or suppression of Class II HLA on tumor cells, by suppression of co-stimulatory immune pathways, by immune suppressive T regulatory (Treg) cells, or by activation of inhibitory immune checkpoint pathways.[73–78] While the loss of tumor Class I HLA (typically mismatched allele) can occur during relapse after HLA-mismatched and haploidentical HSCT, it is uncommon in HLA-matched and absent in UCB HSCT,[77–79] highlighting the importance of individualized tumor versus donor immune interactions in each clinical context.

Inhibitory immune checkpoint pathways play an important role in relapse after HSCT.[75] The engagement of cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) and programmed death 1 (PD-1)

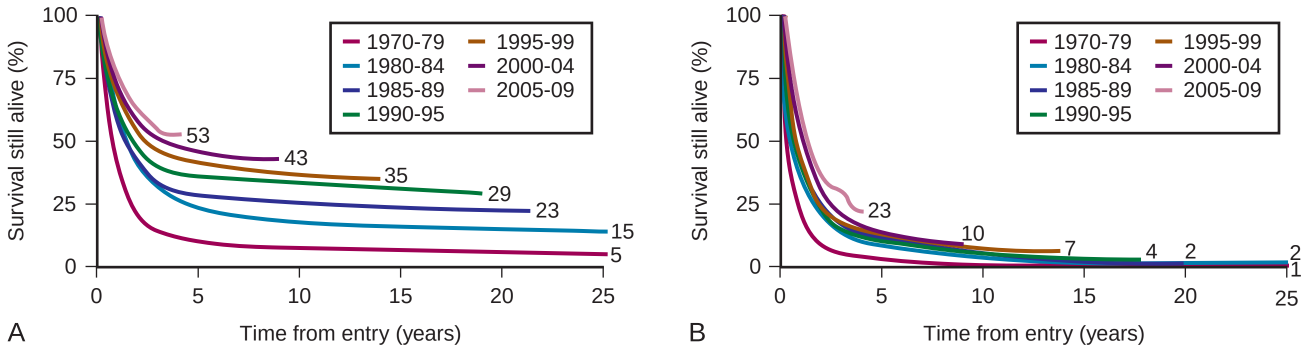

Figure 62.2 CHANGE IN ACUTE MYELOID LEUKEMIA OVERALL SURVIVAL WITH TIME. (A) Age 15 to 59 years. (B) Age 60 years or greater. *(Data from Burnett A, Wetzler M, Löwenberg B. Therapeutic advances in acute myeloid leukemia. J Clin Oncol. 2011;29:487.)*

receptors by their ligands B7-1/2 and PD-L1/2, respectively, inhibits effector T cell function. Tumor cells often express these inhibitory ligands, thereby selectively blocking antitumor immunity. In murine models, PD-1 blockade led to an increase in GVHD, whereas selective CTLA-4 blockade with Ipilimumab (Ipi) to treat late HSCT relapses augmented GVT without accelerating GVHD.[80,81] Outside of HSCT, Ipi monotherapy has limited efficacy in relapsed AML/MDS.[82]

For patients with targetable mutations, or for therapies broadly augmenting GVL and controlling disease relapse, maintenance strategies to prevent AML relapse in the post-transplant context are worth evaluating. For instance, early-phase trials of maintenance therapy with HMAs for MDS/AML (e.g., azacytidine), and targeting of FLT3-ITD AML (e.g., sorafenib) reported preliminary safety and efficacy.[83–85] In the randomized phase II SORMAIN study, 83 FLT3-ITD AML patients who had undergone HSCT and were stably engrafted without grade II or higher acute GVHD were randomly assigned to sorafenib maintenance for up to 24 months versus placebo. At 30 months, OS favored the sorafenib arm, with a HR of 0.447 ($P = .03$).[86] Preliminary results of the randomized phase II RADIUS trial of post-transplant midostaurin likely support this conclusion, with a 43% reduction in the risk of FLT3-ITD AML relapse.[87] Interestingly, recent data show that sorafenib also promotes GVL activity in mice and humans through IL-15 production in FLT3-ITD-mutant leukemia cells.[88]

While falling donor chimerism after HSCT can identify cohorts at higher relapse risk,[89,90] more specific and sensitive MRD assessments in the post-HSCT context can better predict relapse. Importantly, early identification of patients at high risk of relapse after allogeneic HSCT offers the opportunity for targeted early intervention prior to morphologic relapse. Prospective prevention trials focused on the high-risk setting offer an informative population for evaluation of intervention efficacy and are a high priority. The ongoing randomized phase III trial of gilteritinib (BMTCTN 1506, NCT02997202) will help definitively address the issue of FLT3-ITD maintenance post-transplant, especially in those at high risk, as a highly sensitive and specific MRD assay will be used throughout the trial to provide information about which patients may or may not benefit from maintenance therapy. Similar trials for the prevention of AML relapse after transplant in patients with other targetable mutations (e.g., IDH1/2) are eagerly anticipated.

The treatment options for patients with morphologic disease relapse after HSCT include withdrawal of IS, DLI, chemotherapy (including novel agents), second allogeneic transplantation, or supportive care.[91] Taper of IS and DLI are used especially in patients without GVHD to enhance antileukemic GVL effect. DLI has limited efficacy, in the range of 15% to 30% for patients with relapsed AML, and many responses are incomplete or temporary. Of note, recommended DLI dose is ~1-log lower in haplo-HSCT; and it is not expected to have efficacy in relapse associated with mismatched HLA loss on tumor cells but still carries a risk of GVHD and should be avoided in that context. DLI outcomes are better in patients who relapsed beyond 6 months after HSCT, those with lower leukemic burden (less than 35% BM blasts), patients with good-risk cytogenetics, and those who achieved remission before DLI.[92]

Novel options to enhance curative GVL effect include infusion of selected donor lymphocyte subpopulations via mDLI (e.g., CD25 Treg-depleted DLI[93]), other immune effectors (e.g., cytokine-induced memory-like [CIML] NK cells[55]), and use of immune checkpoint inhibitors (e.g., CTLA-4 blockade[94]) A second allogeneic HSCT has demonstrable but limited efficacy, and the duration of remission of more than a year after initial HSCT is the major predictor of survival.[95]

TRANSPLANTATION FOR MYELODYSPLASTIC SYNDROME

MDS comprises a heterogeneous group of clonal hematologic stem cell disorders characterized by varying degrees of cytopenias and risk for transformation into acute leukemia (see Chapter 61).[96] The incidence and prevalence of MDS has increased significantly over the last 20 years as a result of increasing longevity of the population and increasing physician awareness.[97–99] New therapeutic options such as HMAs, immunomodulatory drugs, and differentiation induction agents may improve hematologic parameters and reduce transfusion requirements,[100–102] and even prolong survival,[102] but allogeneic HSCT is the only known curative therapeutic option.

MDS is currently the third most common indication for allogeneic HSCT as reported to the CIBMTR.[103] Outcomes following transplantation for MDS have steadily improved over time, and now 40% to 65% of patients undergoing transplants are long-term survivors. MDS is a disease predominantly of older individuals, and with the increased use and acceptance of RIC into the eighth decade of life, it is anticipated that transplantation volume for MDS will continue to increase in the coming years.

Transplantation Trials in Myelodysplastic Syndrome—Comparison With Non-Transplantation Therapies

It is now clear that allogeneic transplantation offers a survival advantage over conventional therapies in MDS, and prospective trials have confirmed this assertion. In the first prospective trial that assigned subjects in a donor versus no donor fashion, a survival advantage in the donor arm ($n = 112$) over those without a donor ($n = 50$) was noted. At 4 years from the time of registration, OS was 37% in the donor arm in comparison with 15% in the no donor arm ($P < .02$) and importantly, there did not appear to be an initial decrement in early survival in the donor arm, suggesting that early TRM after transplantation is comparable to mortality associated with non-transplant therapies in a high-risk subject cohort. In this trial, however, subjects with CMML, secondary MDS, and AML were included, as were subjects with lower-risk MDS.[104] In a prospective randomized biologic assignment study, the German MDS group treated all enrolled subjects with 4 cycles of azacytidine, followed by a biologic assignment to further azacytidine or transplantation. The authors reported superior outcomes in the group that proceeded to transplantation ($n = 83$) in comparison to the continued azacytidine group ($n = 26$), with 49% survival in the transplant arm in comparison with 22% in the continued azacytidine arm at 3 years ($P = .027$).[105]

At the Dana-Farber Cancer Institute, we followed the outcomes of two distinct groups of patients who were referred for transplantation. The first group comprised patients with higher-risk MDS, defined as either IPSS Intermediate-2 or High-Risk disease, the presence of high-risk cytogenetics, or those with secondary MDS ($n = 175$). The second group comprised patients whose transplant indication was refractory cytopenias alone ($n = 115$). In the high-risk group, subjects who chose transplantation had improved outcomes in comparison with those who did not (multivariable HR for death 0.57, $P = .01$) while no advantage was noted in the group with cytopenias alone (multivariable HR 1.33, $P = .36$). Moreover, the benefits of transplantation were associated with "early" transplantation, defined by the median time to transplant in the study.[106]

The most definitive prospective trial comparing transplantation and non-transplantation approaches was recently published by the Blood and Marrow Transplantation Clinical Trials Network. In this biologic assignment trial, 384 subjects (260 donor, 124 no donor) between the ages of 50 to 75 with higher-risk MDS were followed prospectively after assignment. At 3 years, there was a 21.3% improvement in OS (47.9% vs. 26.6%, $P = .0001$) and a 15.2% improvement in leukemia-free survival (35.9% vs. 21.8%, $P = .003$) in an ITT analysis.[107] Based on this trial results, we concluded that all patients who are potential candidates for HSCT should be referred to a transplantation center early in their disease course so that a discussion regarding the appropriateness of transplantation can occur and a donor search can be initiated, where appropriate.

Contemporary Results in Ablative and Reduced-Intensity Transplantation for Myelodysplastic Syndrome

The role of conditioning intensity in transplantation has been debated since the introduction of reduced-intensity regimens (RIC), and several comparative studies have now been published. The premise behind all of these comparisons is that RIC should be associated with a reduction in early treatment-related mortality, whereas myeloablative (MAC) approaches should be associated with a reduction in disease relapse. The net effect of these two opposing risks is anticipated to be no difference in outcomes. In an analysis by the EBMT of over 800 patients with MDS, the 3-year relapse rate was significantly higher after RIC (HR, 1.64; $P = .001$), but with less treatment-related mortality (HR, 0.61; $P = .015$), leading to similar 3-year OS (45% vs. 41%, $P = 0.8$). When limited to individuals above 50 years of age, no difference in outcome stratified by conditioning intensity (32% vs. 30%, $P = .73$) was noted (Fig. 62.3).[108] Two recent CIBMTR analyses additionally address this controversy. In the first study, 951 subjects with MDS were stratified by conditioning regimen. In this study, myeloablative regimens (including BuCy, FluBu4, and FluMel) were associated with the best overall outcomes, using RFS as the main study endpoint.[109] In the other CIBMTR second study, where only subjects aged 40 to 65 were included, myeloablation resulted in superior outcomes only in subjects with low or intermediate disease risk index (DRI) scores, with no advantage for dose intensity when high DRI was noted.[110] It is to be noted that the latter two studies included subjects with AML as well as MDS.

As retrospective studies are generally not considered definitive, prospective trials to answer this important question have now been performed. In a multicenter prospective study by the Blood and Marrow Transplant Clinical Trials Network, patients aged 18 to 65 were randomized to allogeneic transplant using reduced intensity or MAC. This trial was halted early due to an observed survival advantage in the AML cohort with MAC but too few MDS patients were enrolled to make definitive conclusions in these patients.[2] A second prospective study by the EBMT randomized patients up to the age of 65 to reduced intensity or MAC similarly showed no statistical difference in nonrelapse mortality, relapse, or disease-free survival.[111] Based on these studies, consensus favors MAC for those under 65 years old with an acceptable HCT comorbidity index score and RIC for all patients 65 years and older or those with higher comorbidity scores.

Using Prognostic Models to Define the Timing of Transplantation

While the prospective comparative trials have defined the superiority of transplantation over non-transplant therapies for select groups of patients,

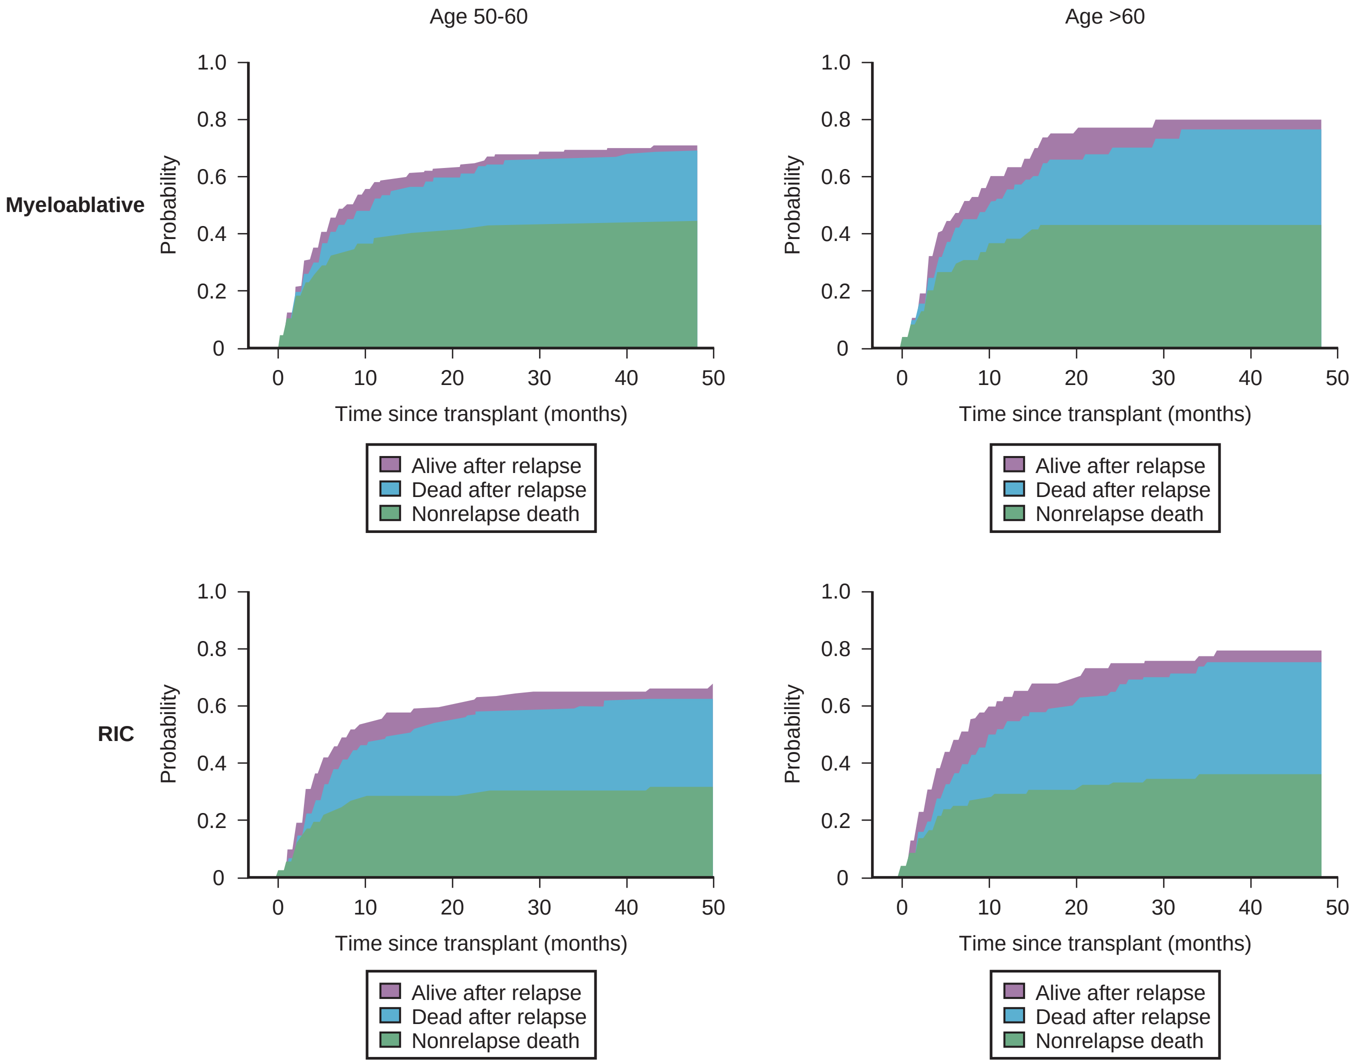

Figure 62.3 COMPETING RISK CUMULATIVE INCIDENCES FOR RELAPSE AND NONRELAPSE MORTALITY AMONG INDIVIDUALS ABOVE AGE 50 YEARS. *RIC*, Reduced-intensity conditioning. *(Data from Lim Z, Brand R, Martino R, et al. Allogeneic hematopoietic stem-cell transplantation for patients 50 years or older with myelodysplastic syndromes or secondary acute myeloid leukemia. J Clin Oncol. 2010;28:405.)*

the optimal timing for transplant informing the prospective trials was approached using Markov modeling and scoring systems that use clinical, pathological, and cytogenetic risk assignment. The most widely used clinical prognostic system is the IPSS, which can predict both non-transplantation outcomes as well as myeloablative transplantation outcomes.[112–114] The IPSS-R has recently supplanted the IPSS as the dominant prognostic scoring system.[115] Several groups have attempted to validate this newer prognostic construct with transplant outcomes. A cohort of 519 MDS patients was reported by the GITMO, and their outcomes were stratified by IPSS-R. In addition to the IPSS-R, MK and the HCT comorbidity index independently predicted outcomes. The 5-year survival outcomes were 71%, 58%, 39%, and 23% in the low, intermediate, high, and very high-risk patients when classified by the IPSS-R.[116]

Markov decision models have suggested that the optimal timing of transplantation is at the time of diagnosis of Intermediate-2 or high-risk disease,[114,117] although one analysis suggested that even patients with Intermediate-1 risk disease should be offered transplantation.[118] The first model utilizing the IPSS-R has been presented, suggesting optimal outcomes were obtained with immediate transplantation for patients with Intermediate risk or higher disease and delayed transplantation for low and very low risk disease.[119] A shortcoming of all of these analyses is the inability to provide treatment decision guidance at clinically relevant times for patients not undergoing immediate HSCT because other important clinical events, such as a new transfusion requirement, recurrent infection, or recurrent bleeding episodes certainly could be considered triggers to move on to transplantation. Thus, it is useful to subdivide patients with lower-risk MDS into more-refined prognostic groups that may benefit from HSCT.[120]

Transfusion frequency and resultant iron overload have both been demonstrated to be important prognostic factors in HSCT outcomes. Platzbecker et al. compared the effects of transfusion dependency at the time of HSCT showing that transfusion-dependent patients have more low-risk features but still have inferior overall survival, with a 3-year OS of 49% compared with 60% in a transfusion-independent group ($P = .1$).[121] The Pavia group examined a cohort of patients stratified by IPSS to determine the relevance of the newer World Health Organization (WHO) histologic classification scheme and to determine if transfusion requirement influenced outcomes among different IPSS groups. For patients with low- and intermediate-1 risk IPSS scores, the WHO histologic classification scheme significantly differentiated survival among the different histologic subtypes within each IPSS range.[122] More importantly, the authors demonstrated a significant effect on survival based on the requirement for transfusion support. As would be expected, outcomes in patients with higher-grade myelodysplasia were affected less by transfusion requirement than were patients with less-advanced WHO histologic classifications. As a result, the impact of the transfusion requirement was then incorporated into the WHO Prognostic Scoring System (WPSS).[123] In this system, the effect of regular transfusion requirement (defined as requiring at least one transfusion every 8 weeks in a 4-month period) was given the same regression weight as progressing between cytogenetic risk groups. In contrast to the initial IPSS publication, which carries prognostic information only at the time of initial MDS diagnosis, this model was time-dependent, such that patients could be continually reevaluated by the scoring model and updated prognostic information could be generated at any time in the patient's treatment course. As such, the development of new cytogenetic changes or the development of a transfusion need adds useful information that helps guide treatment decisions, including the decision to proceed to HSCT as well as estimating transplantation outcomes. A decision analysis incorporating WPSS stage to determine the optimal timing of transplantation demonstrated a survival advantage for transplantation performed with intermediate WPSS stage,[118] although this prognostic scoring system is infrequently used.

Molecular Prognostic Factors

Perhaps even more than in AML, mutation analysis undoubtedly led to a shift from rudimentary clinical prognostic models to molecularly defined models for prognosis and to guide therapy in MDS. As many as 75% of patients can be found to have one or more mutations.[124] Numerous individual genes and whole-genome expression profiling have demonstrated significant associations with MDS outcome, and now, some of these mutational profiles have been associated with the transplantation outcome.

Examining a cohort of 87 patients who underwent allogeneic transplantation at Dana-Farber Cancer Institute, Bejar et al. were able to demonstrate the adverse prognostic impact of three specific mutations on outcome after transplantation.[125] In this cohort, while 92% of subjects had at least one identifiable mutation, those with TET2 and DNMT3A had worse prognoses than those without these mutations, while those with mutations in TP53 had the worst outcomes, with no subjects surviving beyond 2 years from transplantation. Mutations in TP53 were extremely powerful predictors of relapse and were better prognosticators than cytogenetic status; subjects with CKs in the absence of TP53 mutations had similar outcomes to subjects without CKs, possibly heralding the decline of the cytogenetic signature as the most important prognostic marker in transplantation. More recent studies have confirmed the adverse impact of TP53 mutations along with mutations in RAS pathway genes and CK.[126] The impact of molecular mutations was further confirmed in an analysis of the prospective randomized trial of reduced intensity or myeloablative transplantation, where MDS subjects with mutations in one or more genes of a 10-gene panel were associated with poorer outcomes among subjects randomized to reduced-intensity transplantation when compared with MAC.[127]

The most comprehensive analysis of genomic alterations and transplantation outcome was performed in a cohort of 1514 patients in the CIBMTR registry.[128] Importantly, nearly 1200 patients undergoing transplantation had one or more mutations noted (79%). The most important prognostic factor that emerged from this analysis was the importance of TP53 mutations, which were associated with far inferior outcomes related to excess relapse. RAS pathway mutations (including mutations in *NRAS, KRAS, PTPN11, CBL, NF1, RIT1, FLT3,* and *KIT*) were similarly associated with excess risk of relapse, which could be overcome partially by increasing conditioning intensity. Mutations in JAK2, however, were associated with excess treatment-related mortality.

When examining characteristics of TP53 mutations in the transplant cohort, subjects with missense TP53 mutations were noted to have better outcomes when compared with those with truncated TP53 mutations.[128] In the non-transplant setting, patients with monoallelic TP53 mutations had presentations similar to patients with bi-allelic mutations and fare better.[129] At least one group has demonstrated reasonable outcomes for patients transplanted with known TP53 mutations.[130] Patients with TP53 and other adverse-risk prognostic mutations should be encouraged to participate in novel clinical trials to reduce the rate of relapse after transplantation.

The Role of Pretransplantation Therapy in Myelodysplastic Syndrome

The role of cytoreductive chemotherapy before HSCT for MDS remains controversial. Consensus guidelines[131] recommend debulking therapy in patients with greater than 10% blasts in the marrow, although this recommendation is not based on prospective evidence. Many analyses have demonstrated that outcomes are improved with lower disease burden at the time of HSCT,[132] but previously, only conventional chemotherapy was offered. The analyses that compare chemotherapy to no chemotherapy before HSCT are inherently biased because patients who do poorly or expire with chemotherapy are not included in HSCT outcome data and might have had favorable outcomes if not exposed to cytotoxic agents. On the other hand, responsiveness to chemotherapy may indicate more favorable disease biology, and this has been correlated with improved outcomes after HSCT.[133] With the advent of DNA hypomethylating therapy, the use of conventional chemotherapy has markedly diminished prior to transplantation in MDS. The effect of DNA hypomethylating therapy on

HSCT outcomes has recently been studied by several groups.[134–136] Compared retrospectively, it does not appear that pretransplantation hypomethylating therapy offers a survival advantage, but these agents continue to be used widely to prevent disease progression and to reduce transfusion needs, while donor selection is performed in patients destined to undergo transplantation. Older analyses have compared the use of traditional chemotherapy with hypomethylating therapy prior to transplantation. In the smaller of the older analyses, there was no advantage to hypomethylating therapy over conventional chemotherapy,[136] while in the larger of the two, the use of both chemotherapy and hypomethylating therapy prior to transplantation was associated with adverse outcomes, presumably on the basis of identifying subjects with more aggressive disease biology.[134] More recent analyses continue to demonstrate similar outcomes when transplant without debulking is compared to pretransplant therapy,[137] and an EBMT analysis failed to demonstrate differences in survival measured from the time of transplantation when pre-transplant hypomethylating therapy was compared with traditional chemotherapy[138]; however, only a prospective randomized trial with survival measured from the time of randomization to pre-transplant therapy can rationally answer the question as to the most appropriate pre-transplant therapy.

Theoretical advantages associated with the use of HMAs prior to transplant include upregulation of the expression of cancer-testis antigens,[139,140] killer immunoglobulin-like receptor (KIR) ligands,[141] HLA molecules,[142] and other minor antigens on tumor cells,[143] all of which may enhance graft-versus-MDS effects. HMAs have been used after transplantation to reduce the risk for relapse,[85] but randomized trials in myeloid malignancies have not yet demonstrated efficacy.[144]

Transplantation in Older Patients and in Patients With Comorbidity

Older adults represent the fastest-growing fraction of transplantation activity, and there has been a dramatic increase in transplantation for MDS for individuals in the eighth decade of life.[145] As such, specific accommodations need to be considered for these patients. However, it is critical to realize that with proper patient selection, transplantation outcomes in older individuals are very similar to those of younger patients. In a landmark study conducted by the CIBMTR, the outcomes of 688 patients aged 65 or older were compared with 592 subjects aged 55 to 64 at the time of transplantation. 3-year OS was 37% versus 42% in the older and younger groups respectively, with no differences noted in multivariable analyses (HR for mortality 1.09, $P = .23$).[146] This analysis, as well as an older study,[64] therefore demonstrates that age alone cannot be used as a discriminator for transplantation appropriateness. However, with increasing age comes increasing comorbidity, and the CIBMTR analysis clearly demonstrated that a comorbidity index score of 4 or greater was associated with inferior transplantation outcomes.[146] The Hematopoietic Cell Transplantation Comorbidity Index, developed by Sorror and colleagues,[147,148] has been shown to carry the greatest prognostic value, even in patients with MDS not undergoing transplantation.[149] More recently, an enhanced index that incorporates both age and clinical comorbidity was developed and demonstrated to have even more prognostic power than either of the components alone. In this scoring system, those with the highest age-adjusted comorbidity scores have nonrelapse mortality that might exceed 50% at 5 years, with concomitant survival that is less than 20%.[150] The consideration of comorbidity before HSCT is even more relevant now that RIC has been shown to be equally effective in the treatment of MDS.[2]

An elevated pre-HSCT serum ferritin level was strongly associated with lower overall and disease-free survival in patients with AML and MDS after transplantation, and this was largely attributable to increased treatment-related mortality.[151] Similarly, a prospective single-institution study of 190 adult patients undergoing MAC HSCT demonstrated that elevated pretransplantation serum ferritin level was associated with increased risk for 100-day mortality, acute GVHD, and bloodstream infections or death as a composite endpoint.[152] It has now been recognized that the elevated ferritin level can predict inferior outcomes even after RIC transplantation.[153] As a laboratory prognostic factor, ferritin should be considered a marker of comorbidity, as ferritin is a marker of inflammation as well as iron overload. As such, ferritin levels could influence the decision to pursue high-intensity or reduced-intensity HSCT, and iron chelation therapy should be considered prior to transplantation when feasible.

There are several approaches to the transplantation of older patients with MDS that can improve outcomes. In older subjects, careful attention to frailty with geriatric assessment should be performed prior to transplantation. A comprehensive intervention strategy to preserve function has been demonstrated to improve nonrelapse mortality in a group of older subjects, not limited to MDS patients.[154] Selection of the most appropriate conditioning regimen has been demonstrated to have an impact in transplantation for MDS, and one CIBMTR study suggested that a more intensive Fludarabine-Melphalan regimen, while associated with slightly higher rates of treatment-related mortality, was associated with improved outcomes in comparison with a lower intensity Fludarabine-Busulfan regimen.[155] However, excess treatment-related mortality is noted in subjects undergoing transplantation with more intensive regimens who have unrecognized shorter telomere lengths, and in these analyses, routine assessment of telomeropathy should be considered in all older subjects planning to undergo melphalan-based conditioning and transplantation.[156]

Alternative Donor Transplantation in Myelodysplastic Syndrome

Early results using alternative donors in MDS were not encouraging, with treatment-related mortality approaching 30% and long-term survival of only 30% using mismatched unrelated, haploidentical, and UCB.[157] More contemporary registry and comparative analyses suggest that outcomes have improved marginally, now demonstrating survival in approximately 40% of patients, with only minor differences between haploidentical or mismatched unrelated donors, but with UCB faring the worst.[158]

The largest series reporting on outcomes in UCB transplantation reported on 176 subjects with a median age of 56 years at the time of transplantation (2004 to 2013). Despite this relatively young age, OS was only 30%, with high rates of treatment-related mortality.[159] An older comparative analysis demonstrated no advantage of mismatched unrelated donors over UCB,[160] but the more recent analysis suggesting a disadvantage in UCB.[158]

There has been more interest recently in the use of haploidentical donors given the ease of identifying donors and lower costs associated with graft procurement. In one comparative analysis that included both patients with AML and MDS, no major differences in outcomes were noted when matched related, unrelated or haploidentical donors were used.[161] However, a larger CIBMTR analysis restricted to RIC in subjects with MDS demonstrated higher relapse and lower disease-free survival in recipients of haploidentical transplantation when compared with matched unrelated donors.[162]

Treatment and Prevention of Relapse Following Transplantation

The treatment of relapse following allogeneic HSCT for MDS is similar to the treatment of AML; manipulation of immunosuppression with or without DLI is of modest utility[163] and generally requires re-institution of pre-transplant chemotherapy for success. As there are no targeted therapy agents available for MDS at this time, DNA hypomethylating therapy is most commonly used. DNA hypomethylating therapy has been attempted as post-transplant maintenance therapy in an attempt to reduce the risk of relapse. In the initial phase 1 trial, escalating doses of azacytidine were given to 45 subjects with AML or MDS. The maximum-tolerated dose was 32 mg/m^2 given for 5 days of a 30-day cycle.[85] When tested in a prospective, randomized trial of 187 subjects, however, there was no benefit noted in either relapse-free or overall survival.[144] As maintenance therapy has become the standard in AML with a molecular target (i.e., Flt3), the search for a maintenance strategy that improves outcomes is actively being pursued. The addition of the bcl-2 inhibitor, venetoclax, might hold promise in this regard.[164]

FUTURE DIRECTIONS

Despite the progress that has been made in conventional therapy for both AML and MDS, allogeneic HSCT has the best track record for curing the disease. Although HSCT has limitations, reductions in toxicity, improvements in donor availability, and new strategies to enhance GVL while limiting GVHD promise to further improve survival. Advances in mutation analysis provide insights into the pathophysiology of MDS and AML and suggest routes for targeted therapy. However, in many circumstances targeted therapy may not be feasible; thus the utility of molecular prognostic indicators is to identify patients who will benefit from early transplantation.

CHAPTER 63

ACUTE MYELOID LEUKEMIA IN CHILDREN

C. Michel Zwaan, Olaf Heidenreich, and E. Anders Kolb

Acute myeloid leukemia (AML) is a complex and heterogeneous group of malignancies in which genetic and epigenetic alterations lead to differentiation arrest and/or uncontrolled expansion of myeloid cell precursors. Pediatric AML is characterized by a wide array of genetic aberrations that are often not seen or differ in frequency when compared to AML diagnosed in adults and mainly comprise different fusion genes.[1,2] Though the mutational landscape of childhood AML is now well-described,[2] and despite the recent approvals of various targeted compounds for use in adults with AML, there are no new targeted therapies approved for use in children.[3] This is due to several factors, such as delays to implement clinical studies in children, relevance of some targets in children, and/or class-related toxicity concerns (e.g., Hedgehog pathway inhibitors that may induce skeletal toxicity).

Improvements in survival have been largely achieved through the successful intensification of broadly active chemotherapy (cytarabine and anthracyclines), the effective use of hematopoietic stem cell transplantation (HSCT), improved methods for risk stratification including early response assessments, advanced diagnostics to detect genetic aberrations, improvements in supportive care, and increasing retrieval rates at relapse.[4,5]

Overall survival (OS) rates for children with AML who are treated on contemporary clinical trials are now greater than 70% overall, and for some genotypes, OS rates are above 80%.[5] However event-free survival (EFS) rates still fall behind, ranging from 50% to 65% (summarized in Table 63.1),[1] and the OS for other genotypes are unacceptably low despite maximal intensification of standard chemotherapy. Genomic and biologic insights into the mechanisms of leukemogenesis have both helped to identify patients a priori who will have a poor prognosis, and may potentially benefit from an HSCT as well, and identified potential targets for new therapies. Survivors of childhood AML are at significant risk for serious long-term side effects including cardiomyopathy, infertility, and second malignancies.

Future advances in childhood AML must include a better understanding of whether targeted therapies approved in older adults can be effective in children with AML by determining the dependency of childhood leukemia cells on targetable oncogene products and understanding the compensatory mechanism of resistance to conventional and targeted therapies. This should lead to higher cure rates with less long-term toxicity.

EPIDEMIOLOGY

AML accounts for approximately 20% of cases of acute leukemia in children and adolescents younger than 20 years of age. The incidence rates have remained constant over the past 40 years, are similar between boys and girls, and are highest during the first 2 years of life before the incidence rises again in adolescents/young adults. However, the age distribution may vary between subtypes. For example, acute promyelocytic leukemia (APL) and core-binding factor (CBF) leukemia are rare in children younger than 3 years of age, whereas the incidence of acute megakaryoblastic leukemia (AMKL) and "myeloid leukemia of Down syndrome" (ML DS) is highest in infants and young children, yet rare among teenagers. The distribution of AML subtypes may also vary among ethnic groups, with some studies suggesting a higher incidence of APL among Hispanic/Mediterranean populations.

Constitutional syndromes that are associated with an increased predisposition to AML include Down syndrome (DS), Fanconi anemia, Bloom syndrome, neurofibromatosis, Noonan syndrome, congenital neutropenia, and germline haploinsufficiency of the specific oncogenes (e.g., the *Runt-related transcription factor-1* or *RUNX1* gene),[6] though these constitute only a small subset of AML diagnosed in children. The World Health Organization (WHO) 2016 classification also provides a listing of myeloid malignancies that can develop in patients with germline predispositions (Table 63.2).[7] Exposure to ionizing radiation, alkylating agents, topoisomerase II inhibitors, and benzene are among the few environmental factors proven to increase the risk of AML. In the majority of cases of childhood AML, neither a genetic nor environmental cause can be identified.

PATHOBIOLOGY

The French–American–British (FAB) classification system uses morphologic and histochemical features of the leukemic cells to sub-classify AML, though with limited prognostic and therapeutic significance.[8] The WHO 2016 classification system (see Table 63.2) uses specific cytogenetic alterations and molecular genetic lesions to classify AML.[7] Recent genomic approaches have validated the distinct genomic heterogeneity within AML.[2] In addition, these approaches have identified new genetic subtypes as well as lesions that are enriched within leukemias that have normal karyotypes, that is, genetic changes not identifiably by standard karyotype analysis or miscellaneous chromosomal alterations (Fig. 63.1). This chapter discusses many of the known molecular subtypes and their associated prognosis.

Recent DNA and RNA sequencing efforts have significantly expanded the list of molecular lesions that underlie AML.[2,9–11] Pediatric AML is characterized by very few somatic mutations per cell, though there are many distinct mutations described. Data support models for childhood AML where single and catastrophic translocation events, that result in the generation of an entirely novel gene product such as *RUNX1/RUNX1T1*, initiate leukemogenesis in early hematopoietic stem and progenitor cells. Additional acquired leukemogenic mutational "hits" ultimately lead to a malignant transformation. Common initiating mutations described for adults with AML include *isocitrate dehydrogenase1/2* (*IDH1/2*) and *DNA methyltransferase 3 alpha* (*DNMT3A*) that alter gene function. In contrast to chromosomal rearrangements, mutations in these genes are exceedingly rare in children. There may also be a developmental context that mediates the potency of these chromosomal alterations and their requirement for secondary mutations.[12] Hematopoietic progenitor cells in children are fundamentally different than those of older adults. Because of their much higher proliferative and self-renewal capacity, the fetal, infant and pediatric hematopoietic stem and progenitor cell compartment provides a much more supportive environment for initiating genetic lesions than the adult one. It should be no surprise that stem cells within different developmental phases will require different oncogenic events needed for a malignant transformation.

It is useful to conceptualize mutations in AML as falling into two broad classes: class I mutations confer a proliferative or survival advantage; and class II mutations block differentiation and promote self-renewal.[13] In general, class I and class II mutations frequently cooperate in leukemogenesis. Interestingly, many of the class II mutations arise from translocation events that lead to chimeric transcription factors with oncogenic properties. Moreover, the relationship

WHO 2016 Classification	Classification of Myeloid Neoplasms With Germline Predisposition
Acute myeloid leukemia with recurrent genetic abnormalities AML with t(8;21)(q22;q22); RUNX1-RUNX1T1 AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); CBFB-MYH11 APL with t(15;17)(q22;q12); PML-RARA AML with t(9;11)(p22;q23); KMT2A-KMT2AT3 AML with t(6;9)(p23;q34); DEK-NUP214 AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); RPN1-EVI1 AML (megakaryoblastic) with t(1;22)(p13;q13); RBM15-MKL1 AML with mutated NPM1 AML with mutated CEBPA *Provisional entity*: AML with BCR-ABL1 *Provisional entity*: AML with mutated RUNX1 Acute myeloid leukemia with myelodysplasia-related changes Therapy-related myeloid neoplasms Acute myeloid leukemia, not otherwise specified AML with minimal differentiation AML without maturation AML with maturation Acute myelomonocytic leukemia Acute monoblastic/monocytic leukemia Pure erythroid leukemia Acute megakaryoblastic leukemia Acute basophilic leukemia Acute panmyelosis with myelofibrosis Myeloid sarcoma Myeloid proliferations related to Down syndrome Transient abnormal myelopoiesis Myeloid leukemia associated with Down syndrome	Myeloid neoplasms with germline predisposition without a pre-existing disorder or organ dysfunction AML with germline *CEBPA* mutation Myeloid neoplasms with germline *DDX41* mutation Myeloid neoplasms with germline predisposition and pre-existing platelet disorders Myeloid neoplasms with germline RUNX1 mutation Myeloid neoplasms with germline ANKRD26 mutation Myeloid neoplasms with germline ETV6 mutation Myeloid neoplasms with germline predisposition and other organ dysfunction Myeloid neoplasms with germline GATA2 mutation Myeloid neoplasms associated with bone marrow failure syndromes Myeloid neoplasms associated with telomere biology disorders Myeloid neoplasms associated with Down syndrome

Modified from Arber DA. The 2016 WHO classification of acute myeloid leukemia: what the practicing clinician needs to know. *Semin Hematol.* 2019;56:90–95.
AML, Acute myeloid leukemia; *APL*, acute promyelocytic leukemia; *NMP1*, nucleophosmin 1; *WHO*, World Health Organization.

between these class I and class II mutations is non-random, for example, *KIT* (class I) mutations are mostly found in CBF AML (class II), and *fms-like tyrosine kinase 3* (*FLT3*) mutations (class I) are mostly found in AML with *nucleoporin 98* (*NUP98*) fusions (class II) or *nucleophosmin* (*NPM1*) mutations (class II). However, although more amenable to conventional drug design than class II mutations, class I mutations are generally secondary events and, thus, frequently subclonal.

In this chapter, we discuss the major subtypes of pediatric AML, our current understanding of the biologic processes that mediate disease, and how these major subtypes may impact survival following conventional therapy. The following section highlights some of the major genetic driver events in leukemogenesis in children. Chapter 59 provides a more detailed overview of the pathobiology of AML with a focus on genetics in adult AML.

Fusion Genes Resulting From Chromosomal Rearrangements

About 60% of all pediatric AML cases are associated with six genetic loci targeting five different protein complexes: the transcription factor CBF with 21q22 (*RUNX1*) and 16q22 (*CBFB*) rearrangements, the epigenetic modifier KMT2A with 11q23 (*KMT2A*, previously known as *MLL*) translocations, the transcription factor retinoic acid receptor alpha with 17q21 (*RARA*) translocations, and the nuclear pore component nucleoporin 98 and 96 precursor with 11p15 (*NUP98*).

Chromosomal Rearrangements Affecting Core-Binding Factor

The CBF transcription complex is a heterodimeric complex composed of a DNA-binding RUNX member (either RUNX1, 2, or 3) and CBFβ. The RUNX1:CBFβ complex functions as a master regulator of the definitive hematopoiesis. Mutations in the genes encoding the RUNX1/CBFβ transcription factor complex are one of the most common lesions seen in de novo AML, occurring in approximately 25% of cases.[2]

The translocation t(8;21)(q22;q22) is the most common translocation found in pediatric AML and fuses the DNA-binding domain of RUNX1 to almost the entire coding region of RUNX1T1. The closely related translocation t(16;21) (q24;q22) fuses *RUNX1* to *CBF2A3*, a paralog of *RUNX1T1*. Following the discovery of RUNX1, the inv(16)(p13;q22) and the less common t(16;16)(p13;q22) result in a fusion between CBFβ and MYH11, frequently seen in acute monoblastic leukemias with eosinophilia (FAB-M4Eo). The CBFβ/MYH11 fusion protein retains the RUNX1 binding domain and therefore its ability to interact with wild-type RUNX1. Both fusion proteins interfere with normal RUNX1 functions but exert also RUNX1-independent functions. In particular, RUNX1/RUNX1T1 can initiate leukemogenesis but requires secondary mutations for establishing AML. Consistent with this, *RUNX1/RUNX1T1* expressing progenitors can persist in the bone marrow for years without expanding into overt leukemia.[14] Nevertheless, AMLs are addicted to these fusion proteins and their transcriptional programs.[15] Cooperating mutations include both classic class I mutations including *FLT3*, *KIT*, and *RAS* members and epigenetic regulators such as *ASXL1* and 2 or *EZH2*.

Patients with CBF mutations tend to have an improved survival with conventional therapy and even improved survival following relapse, although this is more apparent for inv(16) than for t(8;21) rearranged cases.[16] As a result, in some collaborative group protocols, patients with CBF AML receive fewer courses of intensive chemotherapy.

KMT2A Gene Rearrangements

The *KMT2A* gene, located on chromosome 11 band q23, encodes the MLL histone methylase. Upon proteolytic cleavage, it is part of a multiprotein complex involved in chromatin remodeling. Knockout of *KMT2A* inhibits myeloid and lymphoid differentiation and rapidly leads to bone marrow failure in mice. These results suggest that the MLL protein is not only required for definitive hematopoiesis but is also required for maintenance of HSCs in postnatal hematopoiesis.

Chromosomal translocations involving the *KMT2A* gene are associated with both AML and ALL leukemias. There are more

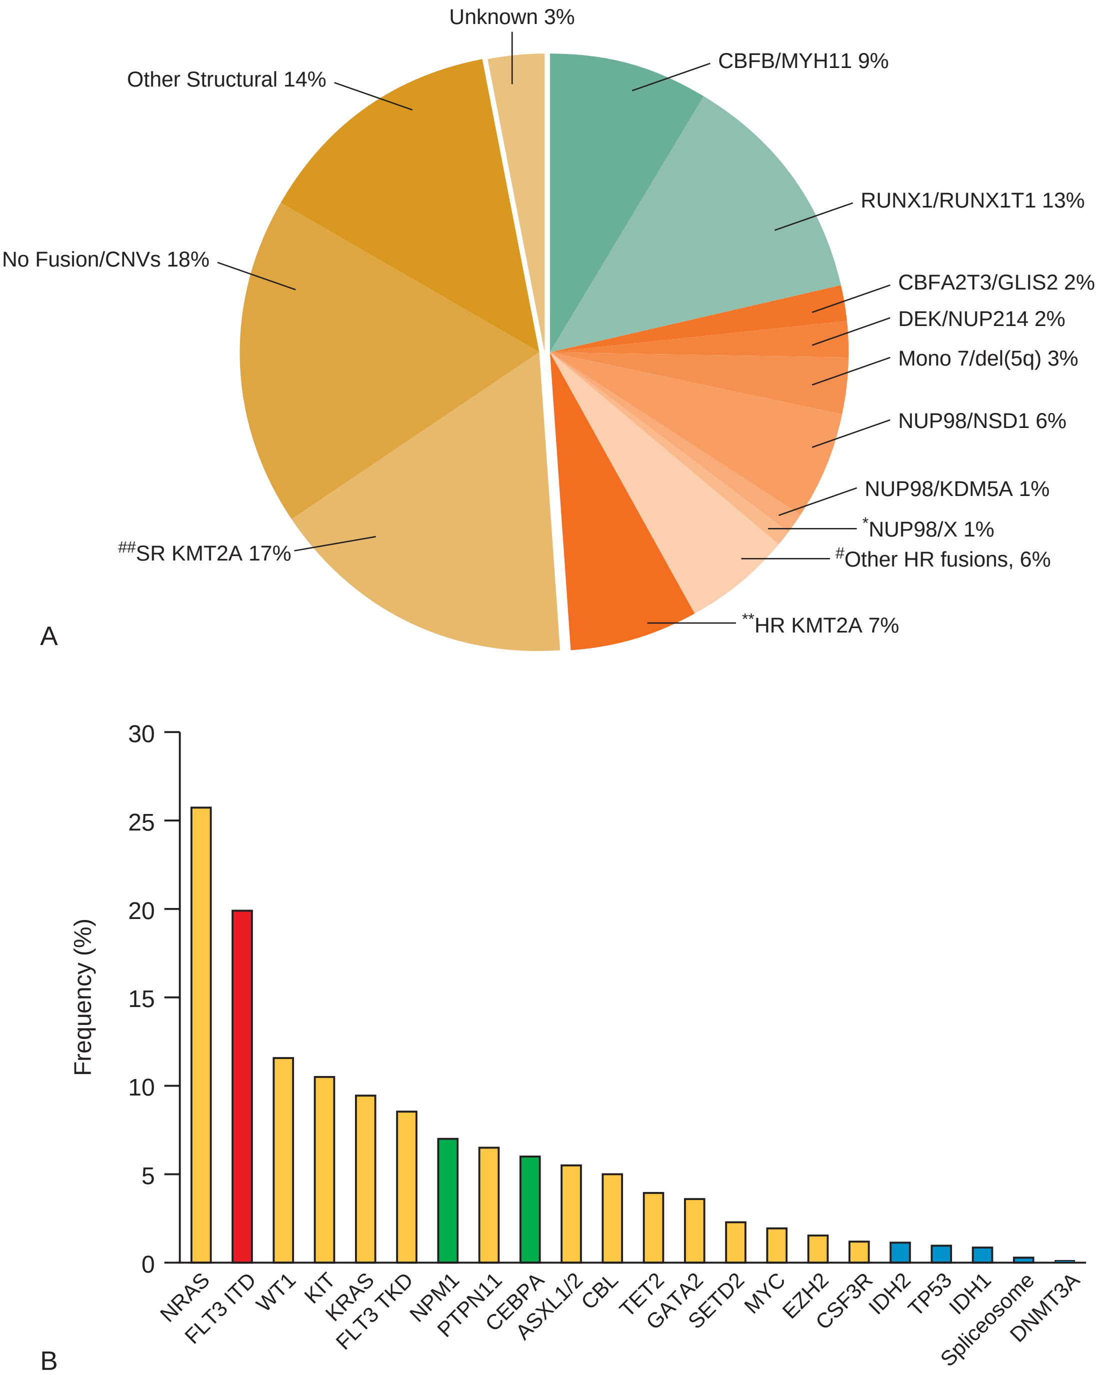

Figure 63.1 FREQUENCIES OF RECURRENT GENETIC LESIONS IN CHILDHOOD ACUTE MYELOID LEUKEMIA (AML). DNA and RNA sequencing results on 2273 children with AML treated on Children's Oncology Group Phase 3 trials from 2006 to 2018 reveal the distribution of gene fusion events (A) and small insertions and deletions (B). *Continued.*

than 100 different fusion partners identified, although nine specific genes account for more than 90% of the fusion events.[17] *KMT2A* rearrangements are found in 60% to 70% of infants with leukemia (predominantly *KMT2A/AFF1*), regardless of immunophenotype, but are less common in older children and adults. The distribution of translocation partners varies depending on the age of the patient and the immunophenotype of leukemia, with *KMT2A/MLLT10* being more frequent in infant and pediatric AML. The majority of active KMT2A fusion proteins contain the N-terminus of KMT2A and the C-terminus of the fusion partner gene, while the function of reciprocal fusion proteins harboring the KMT2A C-terminus are not well understood. The prognostic significance of *KMT2A* mutations is often dictated by the fusion partner and can range from favorable to highly unfavorable.[18] Next-generation sequencing of *KMT2A*-rearranged leukemias demonstrated a paucity of cooperating mutations, although approximately 50% carry an activating tyrosine kinase mutation.[19] However, those mutations are often absent at relapse, confirming they may represent secondary events in irrelevant subclones. *KMT2A* fusion genes alone are sufficient for leukemogenesis, and the targeting of cooperating mutations may not result in a therapeutic benefit.

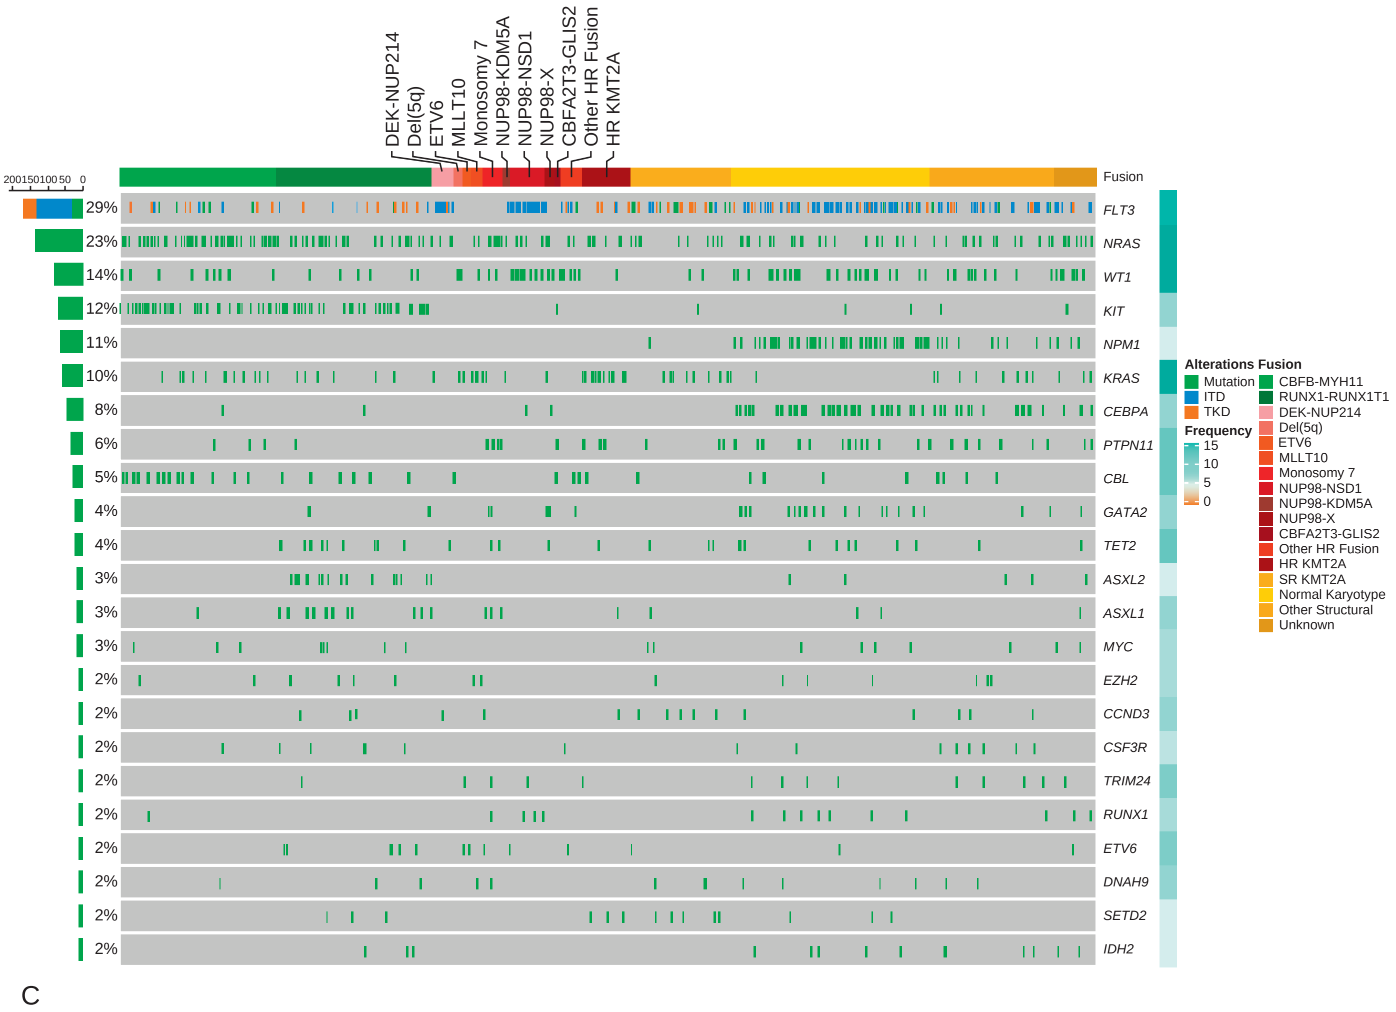

Figure 63.1 cont'd Fusions and small insertions and deletions are often co-occurring (C), though the pattern of co-occurring mutations varies by fusion type. In (C) each hash mark represents an individual patient.

RARA Gene Rearrangements

The hallmark of APL is chromosomal translocations involving the *RARA* gene at 17q22 coding for the retinoic acid receptor alpha. The binding of retinoid acid to a heterodimer of RARA and retinoid X receptor (RXR) leads to a conformational change and converts a transcriptional repressor to an activator that drives granulopoiesis. About 98% of all APL cases harbor the translocation t(15;17)(q24;q21) fusing the *PML* gene to *RARA*. The remaining 2% consist of eight additional translocations with the fusion proteins ZBTB16/RARA (also known as PLZF/RARA) and STAT5B/RARA, being resistant to retinoid acids including all-trans-retinoic acid (ATRA). The most frequently observed secondary mutations with 25% to 60% of all cases are internal tandem duplications of *FLT3*.

PML/RARA represses RARA-RXR-driven gene expression and also alters the localization of wild-type PML away from nuclear bodies, thereby interfering with processes such as DNA damage response and telomere maintenance ultimately inhibiting senescence. Importantly, PML/RARA-expressing APL is highly sensitive to ATRA, inducing a conformational change that relieves the transcriptional repression and drives terminal granulocytic differentiation associated with apoptosis. At higher doses, ATRA also induces degradation of the fusion protein. ATRA alone achieves remission very efficiently but has a high relapse rate, whereas combinations of ATRA with combination chemotherapy yield cure rates of more than 90%. Arsenic trioxide (ATO) has also been shown to induce remissions in patients who had failed ATRA and conventional chemotherapy. Similar to ATRA, ATO triggers degradation of PML/RARA and induces apoptosis of APL, while low doses promote maturation and differentiation. The combination of ATRA with ATO achieves similar cure rates as ATRA with standard chemotherapy but avoids the side effects associated with anthracycline-based combination chemotherapy.[20,21] This regimen may convert APL into the first leukemia that can be cured by targeted therapy alone.

NUP98 Rearrangements

The *NUP98* gene at chromosome 11p15 encodes a 186 kDa precursor protein that by autoproteolytic cleavage matures in two nucleoporins of 98 kDa 96 kDa. Both proteins are components of the nuclear pore complex. In addition, NUP98 binds to promoter regions and activates gene expression by recruiting histone methylases that methylate lysine 4 of histone 3 (H3K4). Initially shown to be a fusion partner with *HOXA9* in the t(7;11)(p15;p15) translocation, it is similar to *KMT2A* in that multiply other fusion partners have been subsequently identified. Most *NUP98* fusions are the result of inversions or balanced translocations. Due to their cryptic nature—NUP98 rearrangements are not visible by standard karyotype analysis—their frequency has initially been underestimated. Recent next-generation sequencing analyses established that 5% to 9% of infant and pediatric AMLs harbor *NUP98* rearrangements, an incidence significantly higher than in adult AML.[2,9,22] Some standard fluorescent in situ hybridization (FISH) panels now include probes capable of identifying *NUP98* fusions.

The most common *NUP98* translocation in childhood AML is t(5;11)(q35;p15) fusing *NUP98* to *NSD1*, encoding a histone methylase with a preference for methylating lysine residues 36 and 20 in histones 3 and 4 (H3K36 and H4K20), respectively, thereby modulating gene expression. The NUP98/NSD1 contains the NSD1 SET domain, harboring the methylase activity. Thus, NUP98/NSD1 activates and maintains gene expression by methylating H3K36 of its target genes. Another prominent *NUP98* fusion is t(11;12)(p15;p13), *NUP98/KDM5A*, that occurs mainly in AMKL, where it constitutes approximately 8% of pediatric non–DS-AMKL cases.[9]

AMLs with *NUP98* rearrangements are characterized by high expression of both the *HOXA* and the *HOXB* cluster, thereby driving leukemic self-renewal. H3K4 methylation by MLL has been shown to direct NUP98/JARID1 binding to and activation of *HOXA* expression. Similarly, NSD1 binds to methylated H3K4 and H3K9 by its PHD domain, which is also kept in the NUP98/NSD1 fusion protein. Furthermore, NUP98/KDM5A has also been demonstrated to bind to H3K4me3 nucleosomes via a PHD finger. This dependency of NUP98 fusion proteins on a functional MLL complex suggests that this group of AMLs may also benefit from drugs developed for *KMT2A* mutated AML.

Interestingly, the majority of NUP98/NSD1-positive AMLs also harbor the *FLT3-ITD* mutation and, to a lesser extent, *Wilms tumor 1 (WT1)* mutations. Such patients have a dismal outcome with current chemotherapy regimens.[22] In this context, FLT3 inhibitors may offer another targeted option for this hard-to-treat AML cohort.

Chromosomal Rearrangements Involving E26 Transformation Specific Family Members

Several members of the E26 transformation specific (ETS) transcription factor family including ERG, FLI1, and SPI1 (also known as PU.1) are crucial regulators of hematopoiesis. They support both normal and malignant hematopoiesis by cooperating with CBF and its fusion proteins RUNX1/RUNX1T1 and CBFB/MYH11. Moreover, the expression of *ERG* is directly regulated by these leukemic fusion proteins.

In particular, *ERG* (21q22) and *FLI1* (11q24) are targets of chromosomal rearrangements leading to a fusion with *FUS* (16p11) or its paralog *EWSR1* (22q12). These translocations are prominent in Ewing sarcoma but are also observed mainly in older children and young adults with AML.

The FUS protein orchestrates both transcription and splicing by binding to RNA polymerase II with its N-terminus while interacting with RNA and the U1 snRNP via C-terminal domains. The translocations fuse the N-terminal regions of FUS and EWSR1 to the C-terminal ETS DNA-binding domains of ERG or FLI1. The resultant fusion protein dysregulates gene expression both by aberrantly activating gene expression and by interfering with RNA splicing. Interestingly, FUS/ERG co-occupies genomic binding sites with the RXR:RARA nuclear receptor complex. In line with this observation, treatment of a FUS/ERG-positive AML cell line with ATRA has been shown to block proliferation and induce differentiation. However, in particular, *FUS/ERG*-positive AML has a very poor prognosis with current treatment regimens.

Another member of the ETS genes is ETV6, whose fusion to RUNX1 is found in 25% of all pediatric ALL cases. The translocation t(7;12)(q36;p13) fuses *ETV6* to the homeobox gene *MNX1*. This translocation generates a very heterogeneous fusion; the corresponding fusion transcript is only detected in 50% of all cases and it has remained unclear if the ETV6 moiety is expressed at all, suggesting that high expression of MNX alone may be the leukemic driver. The translocation is with 30% incidence one of the most frequent rearrangements in infant AML.[23] AMLs with this translocation have an unfavorable prognosis.

DEK/NUP214

The translocation t(6;9)(p23;q34), identified in less than 2% of all pediatric AML, is a rare location that is associated with a poor clinical outcome. Similar to NUP98, NUP214 is part of the nuclear pore complex; by interaction with transporter proteins such as CRM1, XPO1, and NXF1, it is involved in protein and mRNA transport across the nuclear membrane. DEK recruits histone deacetylases to DNA and is an epigenetic regulator of transcription and splicing. Its transcriptional signature includes the activation of HOXA and HOXB expression. Another similarity with *NUP98* fusions is the more than 50% incidence of the FLT3-ITD mutation. *DEK/NUP214* predicts a poor clinical outcome with lower rates of complete remission (CR) and OS.[24]

KAT6A Fusions

The *KAT6A* gene at chromosome 8p11 encodes the histone acetyl transferase (HAT) MOZ (also known as MYST) that is a coactivator for transcription factors including RUNX1 and is required for maintaining the hematopoietic stem cell pool. The two main translocations involve with *CREBBP* and *EP300* at 16p13 and 22q13, respectively, another two closely related HATs. Interestingly, each fusion protein contains both HAT domains from the fusion partners and leads to increased HOXA expression. Both fusions are with less than 1% of all AML cases rare and are mainly associated with monocytic AML of FAB subtype 4 and 5 in infants and young children. Although occasional spontaneous regressions have been reported for *KAT6A/CREBBP*, especially in young children, both translocations predict an unfavorable clinical outcome.[25]

RBM15/MRTFA

The *RBM15* gene at chromosome 1p13 encodes an RNA-binding protein that controls the methylation of RNA at the N6 of adenosines and the splicing of genes relevant of megakaryopoiesis including *MPL*. *MPL* is the receptor for thrombopoietin and an inducer of HOX-gene expression. About 10% of all pediatric AMKL cases harbor the translocation t(1;22)(p13;q13), which fuses RBM15 to MRTFA (also known as MKL). MRTFA is a regulator of myogenesis and cell migration. By interacting with serum response factor, it integrates RAC, RHO, and CDC42 GTPase signaling by binding to G-acting and activates the expression of cytoskeletal genes. Notably, RBM15/MRTFA retains all functional domains of each partner protein. This translocation is associated with an intermediate clinical outcome.[9]

CBF2A3/GLIS2

Until recently, with the exception of the *RBM15/MRTFA* fusion, the genetic etiology of non-DS-AMKL had remained elusive. Transcriptome sequencing of a small cohort identified a cryptic inversion on chromosome 16 [inv(16)(p13.3q24.3)] in half of the patients that resulted in the joining of *CBFA2T3*, a member of the ETO family of nuclear corepressors also involved in *RUNX1* translocations, to *GLIS2*, a member of the GLI family of transcription factors. This translocation is almost exclusively found in children younger than 4 years. *CBFA2T3/GLIS2* AMKL has a distinct gene expression signature: the transcription factor GATA1 required for megakaryopoiesis, and which is mutated in DS-associated AMKL, is downregulated, while ERG as a promoter of self-renewal is upregulated. Patients harboring this mutation have an extremely poor prognosis.[11,26]

Cytogenetically Normal Acute Myeloid Leukemia

Approximately 10% of all infant AML and 25% of pediatric AML cases lack chromosomal aberrations detectable by traditional karyotyping. Different from adult AML single-gene mutations are still uncommon in this group, RNA sequencing has identified cryptic gene fusions are most common in this normal karyotype population.

Small Insertion and Deletions

While fusion genes found in pediatric AML affect transcription factor or epigenetic modulator complexes, smaller insertions and deletions (Indels) may impact the function of key members of signal-transduction pathways such as the RAS-MAPK, JAK-STAT, and PI3K-AKT pathways. Some of them such as *CEBPA* and *nucleophosmin 1 (NPM1)* mutations are leukemia-initiating events and clonal, while others and in particular mutations of signal transducers are secondary events and tend to be subclonal. It is currently unclear if and to what extent subclonal populations may affect the pathobiology of the whole AML by cell-cell contact or secretion of growth-promoting factors.

CCAAT/Enhancer-Binding Protein Alpha (C/EBPα)

C/EBPα is a transcription factor that contains two N-terminal transcriptional activation domains and a C-terminal DNA-binding basic region followed by a leucine zipper domain that mediates homo- and hetero-dimerization with other CEBP family members. In the hematopoietic system, the *CEBPA* gene is expressed in adult HSCs, myeloid progenitors, and granulocytes but not macrophages. C/EBPα is a key regulator of granulopoiesis by regulating the expression of many myeloid genes. Conditional knockout of *CEBPA* in adult mice induces proliferation of HSCs and blocks the transition from common myeloid progenitors to the more differentiated granulocyte monocyte progenitor, leading to an accumulation of myeloid blasts. Mutations that reduce the transcriptional activity of C/EBPα occur in between 5% and 14% of AML patients, primarily in FAB-M1/2 AMLs with a normal karyotype.[27] Two classes of *CEBPA* mutations have been defined, and often occur together: mutations that occur within the first 300 bp of the CEBPA gene that eliminate expression of the p42 isoform but have no effect on the translation of p30; and mutations in the 3′ end of the gene that affect dimerization and DNA-binding. The most frequent pattern seen in patients is a combination of the two types of mutations, one on each allele. Patients with "double mutations" usually have good clinical outcome.[28] Interestingly, CEBPA is repressed by RUNX1/RUNX1T1 and *CEBPA* mutations, and *RUNX1/RUNX1T1* are mutually exclusive.

Wilms' Tumor 1

The *WT1* gene is located on chromosome 11p13 and is a zinc-finger protein binding to nucleic acids. WT1 is significantly expressed only in a few adult tissues including HSCs. Therefore, it is currently being studied as a target for T-cell receptor (TCR) gene therapy of AML.[29]

Similar to CEBPA, it regulates quiescence in early progenitors and promotes myeloid differentiation. Subject to alternative splicing itself, isoforms act as transcription factors or modulators of alternative splicing. *WT1* mutations are found in 10% of pediatric AMLs, are mostly in-frame, and seem to affect its DNA-binding. Among children with *WT1* mutations, 35% are cytogenetically normal, 27% have otherwise favorable cytogenetics, and 36% have the *FLT3/ITD* mutation.[30] However, *WT1* mutations also frequently co-occur with *NUP98/NSD1* fusions, a group with very poor outcome. Event-free and OS in children with *WT1* mutations tends to be lower than those with wild-type WT1, especially in combination with *FLT3-ITD*.[31]

Nucleophosmin 1

NPM1 is often mutated in cytogenetically normal AML and is unique in that it has both oncogenic and tumor suppressor functions. The protein shuttles between the nucleus and cytoplasm, taking part in many cellular processes including regulating ribosomal RNA transcription/processing, transport of pre-ribosomal particles to the cytoplasm, DNA-histone and nucleosome assembly, DNA repair as well as regulating the activity and stability of tumor suppressors such as p53 and its regulator ARF. Alterations of *NPM1* in AML include rare chromosomal translocations such as t(3;5)(q25;q34)[*NPM1-MLF1*] in AML and t(5;17)(q35;q21)[*NPM1-RARA*] in variant APL; the vast majority of changes comprise point mutations that alter its C-terminus, resulting in the creation of a new nuclear export signal. Each of these genetic alterations alters the normal shuttling of NPM between the cytoplasm and nucleus, resulting in constitutive cytoplasmic localization. AMLs with *NPM1* mutations drive *HOX*-gene expression and respond to treatment with a menin inhibitor, suggesting a crucial involvement of the MLL-menin complex in the transcriptional program of mutated NPM. Mutations in *NPM1* are found in 35% of cytogenetically normal adult AMLs, but only in 12% of pediatric AMLs, mostly with normal cytogenetics. *NPM1* mutations are associated with a favorable prognosis even in the context of FLT3-ITD co-occurrence.[32]

GATA1 Mutations

ML DS is associated with a hematologic disorder in infancy, termed transient myeloproliferative disease (TMD; also referred to as "transient abnormal myelopoiesis" or TAM). Approximately 20% of TMD cases patients will later develop AMKL, typically between 1 and 4 years of age. AMKL is the most frequent type of AML in children with DS, and the incidence in these patients is 500-fold higher than in the general population.

The family of GATA transcription factors comprises three members that are expressed in hematopoietic cells (*GATA1*, *GATA2*, and *GATA3*). GATA1 is required for the development of erythrocytes, megakaryocytes, eosinophils, and mast cells. Mutations detected in DS patients with TMD or AMKL consist of short deletions, insertions, and point mutations, typically in exon 2, that eliminate the exon 2 transcription start site. Transcription may still occur, utilizing an exon 3 start site and resulting in a shorter mutant protein (GATA1s) that retains the ability to bind DNA and interact with its cofactor but lacks the transcriptional activation domain and hence has reduced transactivation potential.

GATA1 mutations can be already found at birth in TMD patients and are maintained in patients progressing to DS-AMKL. However, AMKL blasts carry a higher burden of mutations, with additional lesions in epigenetic and kinase-signaling genes leading to the progression of the disease. Collectively, these findings support a model whereby TMD blasts arise secondary to *GATA1* mutations, acquiring this so-called *first hit*, and migrate to and persist in the bone marrow. The occurrence of additional mutations provides the cooperating events that are necessary for full-blown leukemia to develop.[33]

FMS-Like Tyrosine Kinase 3

FLT3 is a class III receptor tyrosine kinase that is normally expressed in early hematopoietic progenitors that are CD34+/c-KIT+. When bound by its ligand (FL), the receptor dimerizes, leading to activation of the receptor's intrinsic tyrosine kinase activity. The activated kinase signals through a variety of pathways including the phosphatidylinositol 3-kinase (PI3K) and RAS signal-transduction cascades through phosphorylation of cytoplasmic substrates.

FLT3 mutations with an incidence of more than 20% of all cases frequent cooperating lesions in pediatric AML.[2] It results from a fragment of the juxtamembrane-domain coding sequence that is duplicated and inserted, the length of which varies from 3 to 400 bp. The juxtamembrane domain is a negative regulator of the kinase activity and the ITD leads to a disruption of this autoinhibitory activity. As a result of the disruption of this domain, the mutant *FLT3*-ITD undergoes ligand-independent dimerization and tyrosine autophosphorylation, and this constitutively active tyrosine kinase activates the downstream targets that are normally regulated by the native receptor. Transplantation of bone marrow cells transduced with *FLT3*-ITD into mice leads to a myeloproliferative disorder but not leukemia, underscoring the importance of cooperative mutations in *FLT3*-ITD–positive malignancy.

FLT3-TKD mutations occur in the activation loop of the kinase domain, leading to constitutive activation. In a wild-type setting, ligand-induced activation of FLT3 causes an active configuration to form, allowing kinase activity. The TKD mutations interfere with the inhibitory loop and thus are similar to ITD in disrupting the regulation of signaling but differ in that they do not require dimerization for constitutive activation. While both mutations lead to constitutive activation of AKT and extracellular signal-related kinase (ERK)1/2 from the PI3K and RAS signaling cascades, respectively, data suggest that strong signal transducer and activator of transcription (STAT5) activation is only observed in *FLT3*-ITD cells.[34] The negative prognostic implications of *FLT3*-ITD are more pronounced than of TKD mutations. Outcome is also affected by co-occurring mutations: *NPM1* mutations yielded better outcomes, while *WT1* mutations and the *NUP98/NSD1* fusion gene further diminished survival when co-occurring with *FLT3-ITD*. Several small-molecule inhibitors targeting FLT3 are currently under clinical evaluation and are discussed elsewhere in this chapter.

RAS Mutations

RAS proteins couple receptor activation with downstream effector pathways, altering proliferation, differentiation, and apoptosis. In AML, *NRAS* mutations predominate, followed in frequency by *KRAS*, while *HRAS* mutations have not been reported. RAS proteins cycle between an inactive GDP-bound state and an active GTP-bound state. Somatic mutations occur at amino acid residues, which impair their intrinsic GTPase activity and also confer resistance to GTPase-activating proteins leading to persistence of a GTP-bound (and therefore active) state. Less common mutations affecting RAS proteins, occurring in the *NF1, CBL*, and *PTPN11* genes, can also promote the active GTP-bound state. Activation of the RAS pathway mediates effects through cell cycle progression, promotes survival, and stimulates actin reorganization and vesicle trafficking, all of which have been shown in various model systems to contribute to RAS-induced tumorigenesis. *RAS* mutations are frequently co-occurring with chromosomal rearrangements affecting *KMT2A* or CBF. Though among the most common mutations observed in children with AML, paired diagnostic and relapse specimens show that RAS pathway mutations may appear, disappear, or change allele frequency from diagnosis to relapse, suggesting that the mutations are mainly subclonal and may not influence outcome.[2,31]

Specific Acute Myeloid Leukemia Subtypes

Acute Promyelocytic Leukemia

APL is morphologically identified as AML-M3. In the late 1970s, it was discovered that leukemia cells could be forced to differentiate in vitro when exposed to retinoic acid. Based on this observation, a 5-year-old girl with refractory APL was treated with ATRA and remained disease-free. Subsequently, in 24 patients the CR rate improved to 96% with ATRA alone. In addition to high CR rates, ATRA has improved long-term outcomes. Of relevance, ATRA diminishes the initial bleeding tendency the disease is associated with and reduces early mortality.[20]

ATRA is not the only targeted agent for APL. Ai-ling 1, a Chinese remedy historically used to treat a variety of illnesses, was tested in the 1970s in more than 1000 patients with different cancers and was found to induce remissions in approximately two-thirds of patients with APL. The effective component of this remedy was arsenic (III) trioxide (ATO). Importantly, ATO was able to induce remissions in patients who had failed ATRA and conventional chemotherapy. At high concentrations, ATO induces apoptosis of APL, while low doses promote maturation and differentiation.

Approaches to the diagnosis, supportive care measures, and treatment of childhood APL are similar to those in adults with APL, including the immediate initiation of ATRA when APL is suspected, followed by the continued use of ATRA and ATO, with or without the addition of conventional chemotherapy.[20,21] Follow-up of patients after the end of treatment using Q-polymerase chain reaction (PCR) is essential, as treating molecular relapse yields better results than salvaging overt relapse. An overview of recent pediatric APL studies is given in Table 63.1.

Transient Myeloproliferative Disease and Myeloid Leukemia of Down Syndrome

ML DS is associated with a hematologic disorder in infancy, termed TMD. In this disorder, a clonal population of megakaryoblasts accumulates in the peripheral blood, originating from the fetal liver where hematopoiesis takes place prenatally. In the majority of cases, remission is spontaneous within 3 months in the absence of treatment. In certain cases, treatment with cytarabine may be indicated, for example, to avoid liver failure in case of severe hyperbilirubinemia or in case of massive organomegaly. Both Children's Oncology Group (COG) and BFM have described the natural history of children with TMD. The BFM group tried unsuccessfully to treat children with persistent TMD with low-dose cytarabine to prevent later ML DS. Results of the two studies are detailed in Table 63.1.

In approximately 20% of TMD cases, patients will later develop AMKL, typically between 1 and 4 years of age. AMKL is the most frequent type of AML in children with DS, and the incidence in these patients is 500-fold higher than in the general population.

Children with ML DS have a favorable prognosis, with OS rates greater than 90%, and should be treated in cooperative group trials that are designed to minimize toxicity while maintaining high cure rates by reducing cumulative chemotherapy exposure, as first demonstrated by Ravindranath and colleagues in the AML8498 study.[35,36] An overview of more recent trials in ML DS is given in Table 63.1. The excellent outcome has been at least partly attributed to increased drug sensitivity of the leukemic blasts to chemotherapeutic agents, allowing for dose-reducing chemotherapy. This nicely makes up for the greater risk of toxicity (especially mucositis and infections) with chemotherapy in these children, especially for anthracyclines. Unfortunately, children with ML DS suffering from relapse are almost incurable, which is a poorly understood phenomenon.

Clinical and Laboratory Manifestations and Diagnosis of Acute Myeloid Leukemia in Children

Most children with AML present with symptoms of bone marrow failure, including pallor, fatigue, bleeding (spontaneous nose or gum bleeding), bruising (petechiae), fever, and/or infection. Hepatosplenomegaly, lymphadenopathy, and bone pain are common but usually less prominent than in children with ALL. Because of the acute nature of the process, weight loss and other signs of chronic disease are rare. In some cases, the predominant clinical signs result not from bone marrow disease, but from extramedullary myeloid tumors, referred to as *chloromas* or *granulocytic sarcomas*, which most often arise in the orbital or spinal regions. Other clinical manifestations include gingival hypertrophy, commonly seen in AML cases with a monocytic component, and skin or subcutaneous nodules. Cutaneous lesions may be single or multiple violaceous papules or nodules, are most common in infants, and may be mistaken for the blueberry muffin lesions that are associated with congenital infection. Skin nodules sometimes develop before bone marrow involvement and may regress spontaneously. Patients with highly elevated leukocyte counts (hyperleukocytosis) may also present with central nervous system (CNS) symptoms (bleeding, seizure, or stroke) or pulmonary symptoms related to hyperviscosity. Testicular infiltration may occur in a minority of patients.

Among children with AML, the median leukocyte count at diagnosis is approximately 20 × 10^9/L, with a median hemoglobin concentration of approximately 9 g/dL and a median platelet count of 60 × 10^9/L. Although a minority of children with AML have no morphologically detectable circulating blasts, careful examination of the peripheral blood smear and/or flow cytometry will reveal leukemic cells in most cases. Sometimes a diagnosis will only become evident with a bone marrow aspirate/trephine or biopsy of a chloroma. Prolonged prothrombin, thrombin, and partial thromboplastin times, as well as decreased fibrinogen levels, are seen in the majority of patients with APL and about 5% of other AML cases. Clinically, these patients present with significant bleeding tendency typical for clotting disorders such as large bruises rather than just petechiae.

Abnormalities of serum chemistries may include hyperuricemia, although this is less common and less severe than hyperuricemia associated with ALL. The presence of hypokalemia, a rare finding in patients with ALL, suggests a diagnosis of monoblastic leukemia. Tumor lysis may also be evident from low calcium and high phosphate levels as well as increased creatinine levels. High LDH levels may be indicative of tumor burden and rates of cellular turn-over.

Among patients who present with circulating blasts, the differential diagnosis is generally limited to various types of leukemia, including AML, ALL, and juvenile myelomonocytic leukemia (JMML). For patients who do not have blasts in their blood at the time of presentation, the differential diagnosis is determined by signs and symptoms and may include aplastic anemia, autoimmune or inflammatory disease, infection, and solid malignancies.

In most cases, the final diagnosis of AML is made by bone marrow examination. A bone marrow aspiration should be performed for morphologic examination, immunophenotyping, genetic, and molecular studies, whereas a bone marrow biopsy is used to assess cellularity and dysplastic features, or when an aspirate fails.[5] A diagnosis of AML is confirmed when 20% or more of nucleated bone marrow cells are blasts of myeloid origin, or when the blasts contain AML-specific genetic lesions, regardless of blast percentage. In children, the blast percentage may not be the most reliable marker to differentiate pediatric AML from myelodysplastic syndrome (MDS), and other clinical factors may need to be taken into account.[37] Nowadays, a morphological diagnosis of AML is confirmed using multiparameter flow cytometry, including markers that diagnose precursor stage such as CD34, CD117, CD133, and HLA-DR, as well as lineage-specific markers, for example, CD41, CD42, and CD61 for megakaryocytic differentiation.[5] The mandatory minimal panel required to fulfill WHO and EGIL criteria for AML includes CD34, CD117, CD11b, CD11c, CD13, CD14, CD15, CD33, CD64, CD65, iMPO, i-lysozyme, CD41, and CD61; and for MPAL: CD19, iCD79a, iCD22, CD10, and iCD3. Aberrant markers may be present and may help to define patient-specific leukemia-associated immune-phenotype (LAIP) that can be used for flow cytometric minimal residual disease (MRD) detection during treatment, including for example, CD2, CD7, CD19, or CD56.[38,39] In case a LAIP cannot be established, MRD can still be followed using the "different from normal" approach, which uses aberrant differentiation/maturation profiles compared to normal, as described in the European Leukemia Net (ELN) MRD Working party guidelines.[40] Moreover, flow cytometry may help to assess response after the first and second course of chemotherapy, as a reliable blast percentage after chemotherapy in the context of regenerating bone marrow may be difficult to assess. In difficult cases, FISH or Q-PCR may also be helpful in response determination (see box on Diagnosis of Acute Myeloid Leukemia).

When 20% to 30% of blasts are present and advanced MDS is considered in the differential diagnosis, repeated bone-marrow punctures may be needed to assess disease progression over time, as well as clinical signs such as organomegaly or CNS involvement that favor a diagnosis of AML over advanced MDS.[37] Identifying underlying MDS is relevant as children with MDS need to be transplanted as definitive therapy.

When a diagnosis of AML is confirmed, most investigators classify each case according to the WHO 2016 criteria (see Table 63.2). This requires at least some genetic studies, and groups make use of various techniques including G-banding (conventional karyotyping), which can detect structural and numerical cytogenetic abnormalities in 70% to 80% of children with AML[41]; FISH to confirm karyotype findings and identify cryptic rearrangements undetectable by G-banding; and molecular genetic approaches such as PCR, target-panel sequencing, genome-wide RNA sequencing, exome sequencing, or whole-genome sequencing.[2] Diagnostic testing may be dependent on resources and the requirements to use these markers for risk-group differentiation. Quantitative PCR of certain markers such as fusion genes may also be used for tracking residual disease during therapy.

Since AML may involve the CNS, examination of the cerebrospinal fluid (CSF) should also be performed as part of the initial workup of all patients. Although CNS leukemia is traditionally defined as the presence of at ≥5 leukocytes/μL of CSF with leukemic blast cells present, the significance of lower levels of CNS involvement differs between studies. The diagnosis of CNS involvement may also be based on the presence of cranial nerve palsies or radiologic evidence of leukemic infiltration. Some groups defer examination of the CSF until day 8 of therapy, especially in cases with hyperleukocytosis.

DIAGNOSIS OF ACUTE MYELOID LEUKEMIA

With a suspected acute leukemia or a suspected acute myeloid leukemia, immunophenotyping of the bone marrow is required to confirm the diagnosis. Histologic and immunohistochemical evaluation of a bone marrow biopsy is helpful, but immunophenotyping by flow cytometry is necessary for both diagnostic and monitoring purposes. When a bone marrow aspiration is not feasible, a diagnosis can be made on peripheral blood. Omission of a bone marrow aspiration should be reserved for exceptional circumstances.

Karyotyping by G-banding and FISH is necessary for classification according to WHO guidelines. It is important to ensure that the FISH probes used account for the unique molecular subtypes of pediatric AML. Confirmation of e.g., KMT2A fusion partners, NUP98 fusions, loss of ETV6, all have a profound impact on risk stratification, treatment decisions (e.g., HSCT), and prognosis.

Molecular diagnostics to identify FLT3-ITD, NPM1, and CEBPA mutations are a minimum requirement for correct WHO classification of AML. Additional DNA/RNA sequencing panels for confirmation of fusion partners, detection of cryptic fusions, and identifying of other disease-modifying mutations should be strongly considered if available.

Prognostic Factors

In the past, FAB-type and WBC were considered prognostic factors, but they have been replaced by more robust predictors of outcome, such as genetic features, which are strongly associated with outcome (see risk-group stratification in Table 63.3).

Response to therapy reflects features specific to leukemia (genetic alterations and inherent sensitivity to chemotherapy), characteristics of the host (pharmacokinetics and genomics and drug metabolism), as well as the intensity and components of therapy, and is therefore a key predictor of outcome. However, morphologic examination of the bone marrow, especially during periods of brisk hematopoietic recovery after intensive chemotherapy, is subjective and lacks the sensitivity and specificity required to accurately assess response. Methods that rely on leukemia-specific features that distinguish residual leukemia cells from normal hematopoietic precursors can provide more precise estimates of MRD. Techniques applicable to AML include RNA-based PCR analysis of leukemia-specific gene fusions, quantitative analysis of *WT1*-expression, deep sequencing to detect leukemia-specific mutations, and flow cytometric detection of aberrant immunophenotypes. Although PCR detection of fusion transcripts is sensitive to a level of 0.01% to 0.001%, it can be applied to only about 50% of cases. In addition, the significance of persistence of fusion transcript expression is not consistent across subtypes of AML. For example, persistent expression of *PML-RARA* is associated with a high risk of relapse among patients with APL, whereas the *RUNX1-RUNX1T1* and *CBFβ-MYH11* transcripts can be detected in patients with CBF leukemia who are in long-term remission, unless there are rising MRD-levels using Q-PCR. In contrast, the sensitivity of flow-based MRD assays is only 0.1% to 0.01%, but this technique can be applied to more than 90% of cases.[40,42] However, even a deep initial

COG, Children's Oncology Group; *CR*, Complete remission; *FAB*, French-American-British; *MRD*, minimal residual disease; *NMP1, nucleophosmin 1*.

[a] MyeChild—United Kingdom and France.

[b] Only *CEBPA* bZIP mutation positive patients without a FLT3-ITD are low risk in MyeChild.

[c] Only if 90 days or older at diagnosis.

[d] FLT3-ITD with a WT1 mutation (BFM) and/or *NUP98* fusion (SJCRH).

[e] FLT3-ITD without NPM1 or *CEBPA* bZIP mutations.

[f] NOPHO-DB-SHIP defines a poor response as: EOi2 and ≥15% leukemic cells in the bone marrow at day 22 or any other time-point prior to course 2, or Flow MRD ≥0.1%–4.9% in the bone marrow before start of consolidation, or FLT3-ITD/NPM1 wild type.

response, which suggests that the bulk of cells is killed by chemotherapy, is no guarantee that the leukemia will not relapse from remaining clonal cells. Currently, not yet enough information is available on the prognostic value of MRD response per genetic subcategory. It is clear, however, regardless of the method used, that we need a better understanding of why some MRD negative patients relapse and some MRD positive patients do not.

Risk-Group Stratification

Most collaborative groups apply a combination of genetic aberrations and early response to therapy as criteria for risk stratification, as shown in Table 63.3.

Investigators from almost all study groups consider children with CBF leukemias to have low or standard-risk AML. Approximately a third of children with CBF mutations will have co-occurring *KIT* mutations.[16] Although *KIT* mutations confer an inferior prognosis in adults with CBF leukemia, their prognostic significance in children is variable and may be treatment-dependent.

Mutations of the *NPM1* gene are seen primarily in AML cases with normal karyotypes, with or without internal tandem duplications of the *FLT3* gene (*FLT3*-ITD). Children whose blasts contain *NPM1* mutations, normal karyotypes, and wild-type *FLT3* appear to have a more favorable prognosis, although the data to support their classification as low-risk patients are not as strong as that for children with CBF leukemia. Similarly, biallelic mutations of *CEBPA* are associated with normal karyotypes and a favorable outcome in adults with AML but occur in less than 5% of childhood AML cases. Nevertheless, they are likely to be associated with a favorable outcome and are included as a low-risk feature in many treatment protocols. Although *IDH* mutations are rare in children, they have been reported as having relatively good clinical outcome, perhaps because of their association with *NPM1* mutations.

Genetic abnormalities for which there is strong evidence of an association with a high risk of relapse include *WT1* mutations and *FLT3*-ITD, especially when occurring together in the leukemic clone. The outcome of patients with *FLT3*-ITD is especially poor in cases with high allelic ratios of *FLT3*-ITD to wild-type *FLT3* but may also be dependent on the associated fusion gene when present. For example, the prognosis of *FLT3*-ITD in the context of APL differs vastly from a combination with *NUP98-NSD1*. Translocations that create chimeric fusion genes and likely confer a poor prognosis are summarized in Table 63.3. The prognostic impact of other lesions, such as mutations of *RUNX1*, *TET2*, or *DNMT3A*, is not well documented.

Therapy

CR and OS rates are now greater than 90% and 70% on collaborative group study protocols for children with AML, respectively (see Table 63.1, Fig. 63.2).

In general, treatment consists of four to five blocks of intensive chemotherapy followed by HSCT in CR1 in selected high-risk patients. There is not a lot of evidence to support maintenance therapy after intensive chemotherapy.

Most induction regimens are based on the combination of cytarabine and daunorubicin, first developed in the 1970s. Attempts to improve remission induction rates have included the addition of etoposide or other nucleoside analogs (cladribine or fludarabine), dose-intensification of cytarabine, the replacement of daunorubicin with idarubicin, mitoxantrone, or liposomal daunorubicin, and the addition of gemtuzumab ozogamicin (GO). Although all these interventions were generally found to be safe, randomized clinical trials mostly demonstrated similar remission rates regardless of the intervention. Most protocols assess CR rates after 1 to 2 blocks of treatment using both morphologies (using Cheson or ELN criteria)[43,44] combined with flow cytometry.

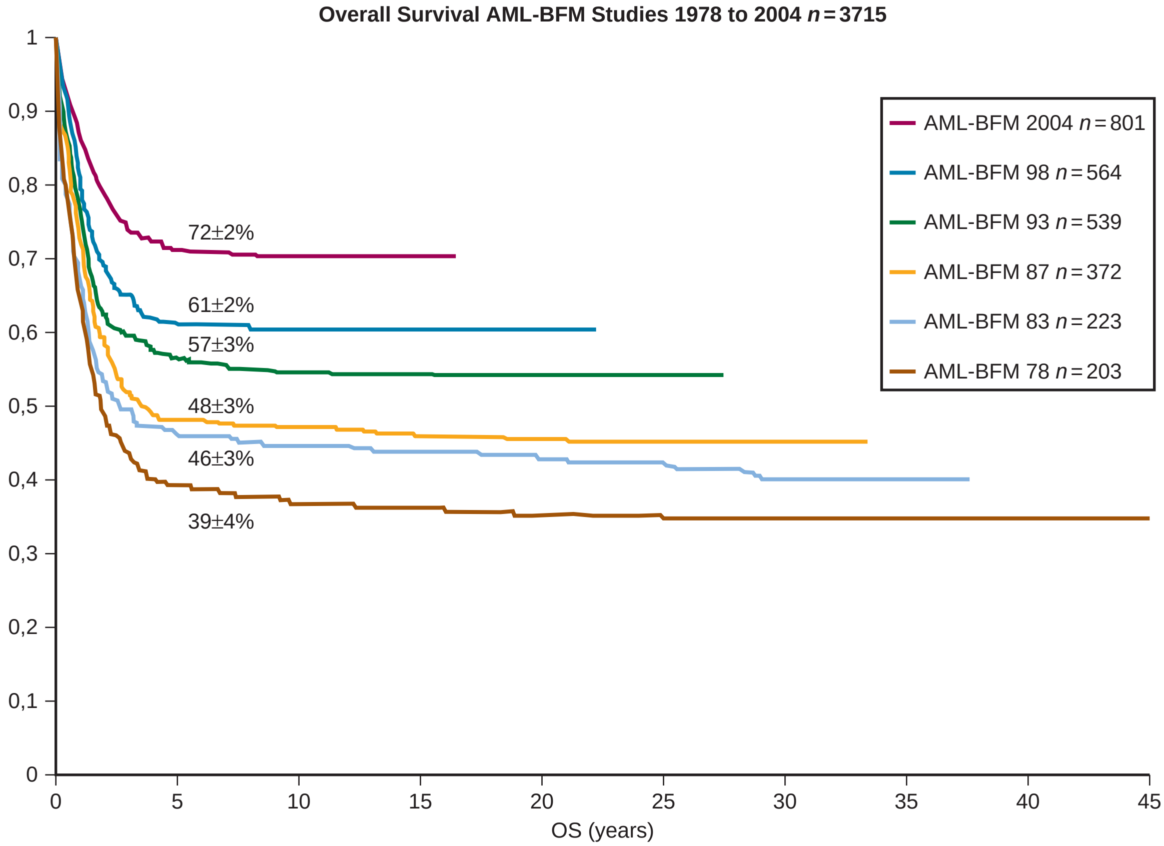

Figure 63.2 Improvement in overall survival for children with acute myeloid leukemia (AML) treated on successive AML-BFM Study Group protocols. *(Data kindly provided by Prof Dr. D Reinhardt, AML-BFM Study Group, Essen, Germany, June 2020.)*

Infants are in general treated on AML protocols that are also used for older children with specific—however, often empiric—dose modification guidelines. There is no indication—different from infants in ALL—that they have a significantly worse outcome than older children with AML.[45]

Clinical trials conducted during the 1980s and 1990s demonstrated that intensive post-remission therapy, administered as intensive chemotherapy and/or HSCT, significantly improved outcome and hence is an essential component of therapy for all children with AML. By contrast, low-dose maintenance therapy may actually lower the survival rates due to poor salvage rates at relapse. The role of autologous HSCT has been studied but without clear benefit.

Trials performed during the past 20 years (see Table 63.1) have sought to determine the optimal duration of post-remission therapy, the benefit of new agents, the value of MRD monitoring, and the role of HSCT. However, like the interventions used to improve remission induction rates, many of the post-remission interventions have had only modest effects on survival. For example, in the COG AAML0531 trial,[46] 1022 patients were randomly assigned to receive standard chemotherapy with or without the addition of three doses of GO. Although the incorporation of GO was associated with a better EFS (53% vs. 47%), there was no difference in OS between arms (69% vs. 65%). In this trial, GO had the greatest impact among patients with favorable karyotypes, *KMT2A* fusions, and *FLT3*/ITD, suggesting that the efficacy of even broadly targeted therapies may be defined by the molecularly defined subtypes of AML.

In the non-randomized 2012 AML-BFM registry ($n = 324$), the impact of a revised risk-group stratification without changes in the chemotherapy regimen but resulting in a higher frequency of HSCT in CR1 was studied using a historical comparator (AML-BFM 04). During the registry time-period, a slightly higher number of patients were allocated to the very high-risk group based on the identification of newly identified high-risk molecular lesions. Moreover, the indication for HSCT was broadened (using molecular subtype and induction response) which led to a higher percentage of patients with HSCT in CR1 (34% compared to 15% in study AML-BFM 04). As a result of these changes and general improvements in supportive care, EFS improved from 52% in AML-BFM 04 to 62%, and OS improved from the historical 71% to 80%.[47]

Improvements in HSCT, such as more comprehensive HLA typing, improved donor availability, have led to fewer short- and long-term side effects. In recent trials, there is no significant difference in survival regardless of whether the donor was related or unrelated. There is clear evidence of anti-leukemic efficacy of HSCT for some children with AML. A well-balanced approach considering procedural morbidity and mortality is important.[48,49]

All children with AML receive intrathecal chemotherapy for prevention of CNS-relapse although the exact number of required intrathecals is not known. Prophylactic cranial irradiation is abandoned by all collaborative groups. Some collaborative groups mainly use cytarabine, others use triple therapy for intrathecal administration. Children with initial CNS involvement are considered candidates for more intensive intrathecal therapy and/or cranial irradiation. High-dose cytarabine may also have a protective effect on CNS-relapse given expected CNS-penetration.

Despite all efforts in finding better ways of cure, intensive cytarabine/anthracycline-based chemotherapy is still the standard of care in pediatric AML treatment. An increase in OS over time is clear despite modest improvements in EFS. OS improvements are most likely due to improvements in risk-group stratification, post-relapse therapy, supportive care (transfusions, infectious complications, nutritional support), and HSCT.[4]

Relapses occur in 25% to 30% of AML patients, and time to relapse is associated with genetic features and with outcome.[50] Especially early relapse after HSCT in CR1 has a dismal prognosis. Late relapse, however, is curable in many patients with the use of 1 to 2 blocks of intensive chemotherapy plus HSCT in all patients. In North America, first relapse patients are often recruited in studies of novel agents (summarized in Table 63.4). Given the concern for long-term cardiac toxicity with high cumulative dosages of anthracyclines, in Europe, liposomal daunorubicin was used off-label as the anthracycline of choice in these patients. However, this compound is no longer available. Recent results with CPX-351 (Vyxeos), a liposomal cytarabine/daunorubicin combination in a fixed ratio, generated in the COG, may set the new standard for relapsed AML if results hold-up in larger studies (see box on Treatment of Relapsed Acute Myeloid Leukemia).[51]

TREATMENT OF RELAPSED ACUTE MYELOID LEUKEMIA

The survival for pediatric patients with AML who have suffered relapse of their disease is at best 40%–50%. At the same time outcome in AML overall has improved in part by better retrieval of patients at relapse compared to decades ago. The largest study to date is the AML 2002/01 study in which 394 patients were enrolled showing approximately 40% survival. There was a clear distinction in outcome between early first and late first relapse, with the latter doing much better. For patients in second or later relapse, the outcome is even worse. This indicates that especially early first relapse and second relapse patients are candidates for experimental approaches. Such approaches should include the use of novel tyrosine kinase inhibitors, targeted agents, and antibody-drug conjugates or immunotherapy. Despite the fact that in recent years many drugs were approved for use in adult AML, this has not happened for children. Therefore, recently, a meeting with all stakeholders was organized to speed up drug development for children with AML.[63] It was concluded that patients with newly diagnosed or relapsed *FLT3*-mutated AML should be enrolled in clinical trials that incorporate second- or third-generation *FLT3* inhibitors, and that T-cell engaging antibodies and antibody-drug conjugates should be prioritized for development, focusing on targets such as CD123 or CD33. As a result of this workshop trans-Atlantic collaboration was initiated to test these agents in children presenting with relapse. Such collaboration is needed to have sufficient numbers to generate data in a reasonable time window. Because it is imperative to study new agents in scientifically rational and clinically safe trials, we believe that efforts should be made to enroll all patients with newly diagnosed and relapsed AML on research protocols.

Supportive Care

Supportive care is an essential component of the management of children with AML. For example, infectious complications are a major cause of morbidity and mortality in children with AML, with a cumulative incidence of documented infection greater than 60% in patients who do not receive prophylactic antibiotics. Randomized controlled trials conducted in adults with AML demonstrated that prophylactic antibiotics, such as oral levofloxacin, are effective at reducing the incidence of bacterial infection. A randomized study in North America in children with leukemia receiving intensive therapy showed that receipt of levofloxacin prophylaxis compared with no prophylaxis resulted in a significant reduction in rates of bacteremia.[52]

Apart from gram-negative infections, viridans group streptococcal infections are also a potential risk, especially after using high-dose cytarabine. Studies are needed to show how this can be prevented, given the limited efficacy of pencilline prohylaxis. Moreover, many children receive prophylaxis against *Pneumocystis jirovecci* pneumonia during intensive chemotherapy treatment.

Disseminated fungal infections, most commonly caused by *Candida* and *Aspergillus* species, are also frequently seen in children with AML. Because several randomized, controlled trials demonstrated the benefits of prophylactic antifungal therapy in adults with cancer, many pediatric oncologists recommend antifungal prophylaxis for children with AML.[53] Nowadays, many agents are available for prophylaxis or treatment of invasive fungal infections. The choice of agent should depend on species and the resistance pattern, as well as on, for example, CNS involvement of the infection. Apart from improvements in treatment, there are also major improvements in the early detection of fungal infections, such as serum galactomannan testing and early CT-scans of the lungs to detect nodules that are suggestive of fungal infection. However, better detection methods are needed.

TABLE 63.4 Results of Recent Clinical Trials for Relapsed/Refractory Pediatric Acute Myeloid Leukemia

Study	Years of Enrollment	Study Question	Relapse Status	Number of Patients	CR (%)	EFS (%) and (median follow-up)	OS (%) and (median follow-up)	Reference

Antiviral prophylaxis is often added using chemotherapy that induces severe lymphopenia such as clofarabine or fludarabine or post-HSCT to avoid viral reactivations, for example, using prophylactic dosing of valaciclovir.

Initial leukocyte counts greater than 100,000/μL are associated with risks of intracranial hemorrhage and respiratory insufficiency secondary to leukostasis. The potential benefit of leucapheresis and exchange transfusions over direct initiation of chemotherapy remains a matter of debate, but aggressive management to reduce tumor burden is critical to the prevention of morbidity and mortality.

Other relevant supportive care measurements include transfusion support for anemia and thrombocytopenia, and nutritional support using either tube feeding or total parenteral nutrition. Measures for cardio-protection are discussed in the following section.

Late Effects

AML treatment may be associated with serious long-term toxicity, largely dependent on the cumulative dose of chemotherapy agents, side effects of treatment, and the need for irradiation and/or HSCT.

A well-known risk is that of long-term cardiac toxicity, especially using mitoxantrone, although most collaborative groups have tried to reduce anthracycline exposure and/or use cardioprotective agents or liposomal anthracycline formulations.[54] In a recent study, 12% of children suffered from cardiac toxicity during 5-year follow-up, with 70% occurring during protocol treatment, also compromising EFS and OS rates.[55] In the Dutch Cancer Survivor study, 6165 childhood cancer survivors (CCSs) diagnosed between 1963 and 2002 were included, and cardiac follow-up was available in 95% of patients. The cumulative incidence of developing heart failure 40 years after childhood cancer diagnosis was 4.4% (3.4% to 5.5%) among all CCS.[54] CCS treated with mitoxantrone, cyclophosphamide, anthracyclines, or radiotherapy involving the heart were at high risk. To prevent cardiac toxicity, in Europe, liposomal daunorubicin (Daunoxome) has been used off-label as preferred anthracycline at relapse,[4] based on the anticipation that the liposomal encapsulation avoids penetration in the heart muscle. Unfortunately, this drug is no longer available, and in fact, the real evidence for a cardioprotective effect was scant. Whether the new liposomal formulation of daunorubicin and cytarabine (Vyxeos) can prevent such damage is currently unknown. Another drug that may be used to prevent cardiac toxicity is dexrazoxane, which can be given together with anthracylines, but there have been concerns about potentially reducing anticancer efficacy. This was not confirmed in a meta-analysis, nor was there evidence for a higher rate of second malignancies.[56]

High-dose cytarabine may be associated with peripheral or central neurological toxicity such as, for example, cerebellar toxicity. Children who have received cranial irradiation may suffer from neuropsychological long-term sequelae. HSCT may be associated with long-term toxicity depending on the agents used in the preparative regimen, as well as the occurrence of acute and chronic graft versus host disease. Testicular irradiation may lead to infertility and/or hormonal dysfunction. Children receiving long-term mechanical ventilation due to for example serious infectious complications may have reduced pulmonary function. Cerebral bleeding or infarction due to hyperleukocytosis may affect neurological functioning.

Despite all these potential side effects, many children survive without noticeable long-term effects, but this summary clearly demonstrates that children treated for AML should be followed in specialized long-term follow-up clinics. Moreover, new treatment modalities are needed to increase outcome but also ensure a better quality of life for those that survive.

Future Directions

Tyrosine Kinase Inhibitors

AML cells commonly possess aberrant receptor tyrosine kinase activity as a result of genetic alterations, such as *FLT3*-ITD. These alterations are seen in approximately 10% to 15% of pediatric and 30% of adult AML cases, and are associated with a poor outcome, and are druggable targets.

Recent studies have demonstrated that sorafenib, sunitinib, and other FLT3 inhibitors are active in patients with *FLT3* mutations but that prolonged use of these agents is associated with the development of resistance, most commonly caused by the acquisition of secondary point mutations in the kinase domain.[57,58] In adults, two FLT3 inhibitors have been authorized for use by the Food and Drug Administration (FDA), including midostaurin in newly diagnosed patients in combination with chemotherapy and gilteritinib as monotherapy for relapsed AML. In children studies with various FLT3 inhibitors are planned or ongoing, including the two approved drugs, as well as quizartinib and the recently completed COG study of sorafenib. These studies are urgently needed to determine the optimal dose and schedule required to improve the long-term outcome of patients with *FLT3* mutations.

Antibody-Based Therapies

Most antibody-directed therapies for AML have focused on CD33, which is expressed on the surface of leukemia blasts in greater than 90% of cases. GO, a humanized anti-CD33 antibody conjugated to calicheamicin, was approved by the United States FDA in 2000 but was later withdrawn from the market because of concerns of toxicity. However, the results of randomized trials that were completed after the withdrawal of GO suggest that the addition of GO to conventional chemotherapy reduces the risk of relapse and improves event-free survival in newly diagnosed patients.[46] Meta-analyses demonstrate that the benefit of GO was greatest among low-risk patients, with only modest benefits seen in intermediate-risk patients and no benefits in patients with high-risk disease. In pediatrics, GO is only labeled for use in children 15 years of age and older. Despite the availability of early-phase studies and a randomized phase 3 study by COG, none of these studies used the fractionated administration used in the adult studies.[46,59] The MyeChild trial, a collaboration between the French and UK AML groups, currently investigates this in newly diagnosed pediatric AML. New antibody-drug conjugates (ADCs) are currently under development, including CD123 directed agents. It is anticipated that CD123 is better expressed on leukemic stem cells and that therefore its anti-leukemic potential might be more pronounced.

An alternative approach to enhancing the efficacy of CD33/CD123-directed therapy is through the development of CD33/CD123-CD3-directed bispecific T-cell engaging antibodies. By bridging CD33/CD123 with TCRs, these antibodies can direct T-cell effector functions to AML cells. In preclinical models, the CD33/CD3 compound AMG 330 was able to recruit T-cells, resulting in potent CD33-dependent cytotoxicity. Other compounds targeting CD123 are currently in the early stages of clinical development, including a pediatric flotetuzumab study that has just recruited its first subjects (NCT04158739).

Epigenetic Agents

Abnormal regulation of epigenetic modification, such as histone acetylation and DNA methylation, is likely a key factor in the pathogenesis of AML. However, studies using HDAC inhibitors and hypomethylating agents (HMAs) in pediatric AML have not significantly changed the treatment landscape to date. Drug development in elderly patients with AML often uses an HMA backbone to which a new agent is added; however, in children, more aggressive backbone therapy is often needed due to the blastic nature of the disease.

Chimeric Antigen Receptor-Modified T Cells

T cells can be redirected to target cells of interest through the use of chimeric antigen receptors (CARs), which link a target cell ligand-recognition domain to signaling regions from the TCR. First-generation CARs typically incorporated the TCRζ cytoplasmic domain, but it was later demonstrated that tandem signaling domains incorporating the TCR along with costimulatory or co-receptor signals provided more robust stimulation and enhanced the survival, expansion, and activity of CAR-modified T cells. The clinical effectiveness of CAR-modified T cells was first established in B-cell malignancies and led to the market authorization of tisagenlecleucel.

A major challenge to extending the success achieved with CD19-specific CARs (tisagenlecleucel) to AML is identifying the proper recognition domain because effective therapy will require eradication of the leukemic initiating cells as well as their more mature descendants.[60] The widespread expression of CD33 on leukemic cells and the absence of down-modulation after GO treatment indicate that it is a robust target. Preclinical studies performed in NOD-SCID mouse models suggest that CD33 CAR-modified T cells should be investigated. However, the potential depletion of normal hematopoietic precursors or committed myeloid progenitor cells may cause unacceptable long-term neutropenia and require rescue with an allogeneic HSCT. In addition, the absence of CD33 expression on leukemic stem cells in some cases may limit the efficacy of such therapy. Future clinical trials and additional modifications of CD33 and/or CD123 CARs will address these important issues. Other targets for CAR-T-cell therapy may include CD70, CLL-1, or FLT3. All studies are very early in development.

Regulatory Landscape and Initiatives

In Europe, companies are obliged to perform pediatric studies when they develop new agents for a disease that also exists in children. The development plan needs to be laid down in a Pediatric Investigational Plan (PIP) that needs to be approved prior to obtaining market authorization in adults.[61,62] In North America, FDA Regulatory requirements and incentives have led to clinical evaluation of few agents for children with AML. With the Research to Accelerate Cures and Equity (RACE) for Children Act, there is hope that regulatory requirements for target-driven testing in children will improve drug development in pediatric AML. In preparation for the RACE for Children Act, the FDA developed a pediatric molecular target list that may trigger pediatric development or may result in a waiver when a target is on the “automatic waiver” list (https://www.fda.gov/media/120331/download). Some of the targets are high priority for pediatric AML. However, as the number of available relapsed/refractory patients is limited, prioritization needs to take place in selection agents for clinical trials in children with relapsed/refractory AML.

The Accelerate group (https://www.accelerate-platform.org/) organized a meeting in 2019 with all stake holders involved in the treatment of pediatric AML to discuss how to speed up pediatric drug development for childhood AML.[63] This Pediatric Strategy Forum prioritized the development of FLT3 inhibitors and CD123-directed compounds, which are discussed elsewhere in this chapter. This meeting helped to create an international environment to develop drugs for children with AML, which is still a disease with high medical need, and at the same time may fulfill the needs of the companies and regulators.

CONCLUSION

The prognosis of pediatric AML has increased stepwise over the last decades but is still heavily based on intensive chemotherapy and/or HSCT which has remained relatively unchanged over the last decade. Recent studies of the genetics and biology of AML have identified new therapeutics targets and have led to the development of novel therapies, many of which are now in early-phase clinical trials. We hope that these efforts will lead to the development of more effective and less toxic treatments in the near future. However, the evaluation of these treatment strategies will require collaboration between cooperative groups to ensure that adequate numbers of patients to which each therapy is directed can be studied.

CHAPTER 64

BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM

Andrew A. Lane

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a hematopoietic-derived malignancy thought to occur by transformation of plasmacytoid dendritic cells (pDCs) or pDC progenitors. Normal pDCs are immune cells that recognize microbes via Toll-like receptors and are the principal producers of type 1 interferons in the setting of infection. The disease was formally named BPDCN in 2008, based on recognition that the malignant cells shared features with pDCs, such as cell surface markers, gene expression, and ability to stimulate T-cell function. Previous names for the disease included blastic natural killer (NK) cell lymphoma, CD4+CD56+ hematodermic neoplasm, and acute agranular CD4-positive NK cell leukemia. In 2016, BPDCN was added as a distinct malignancy in the World Health Organization (WHO) pathological classification, after previously having been categorized as a subtype of acute myeloid leukemia (AML).[1]

EPIDEMIOLOGY

It remains challenging to accurately quantify the incidence of BPDCN due to the variety of names the disease had previously and because it was only recently given a code in the International Classification of Diseases (ICD). BPDCN incidence has been estimated by various sources as approximately 0.5% of all hematologic malignancies, 0.45/1,000,000 population, or 200 to 500 cases per year in the United States.[2] The true incidence of BPDCN may be underestimated due to unfamiliarity with the disease among clinicians and pathologists, and because at least 20% of patients with BPDCN have a pre-existing myeloid neoplasm, such as chronic myelomonocytic leukemia (CMML), myelodysplastic syndrome (MDS), or AML. Careful clinical and pathological examination is necessary to distinguish between BPDCN and AML, particularly in patients with a known myeloid disorder (discussed in more detail later). In particular, BPDCN should be considered when patients with a myeloid neoplasm develop skin lesions. As recognition of BPDCN as a distinct entity improves and because there is an approved BPDCN-specific targeted therapy available and others in development, biopsy-confirmed incidence of the disease may continue to rise.

The median age of diagnosis in adult patients is approximately 60 to 65 years old. The disease also occurs in children and there is a bimodal incidence pattern, similar to what is observed in B-cell acute lymphoblastic leukemia, with a separate pediatric peak of BPDCN incidence at age 8 to 10 years. There is a striking male predominance in adults with BPDCN, with men affected 3 to 4 times more frequently than women. The disease is not nearly as gender-biased in children, where the male incidence is only 1.2 times higher than in females.[3] There is no exposure history clearly linked to BPDCN, such as prior chemotherapy, radiation, or environmental toxins. Different from conventional dendritic cells (cDCs), which present processed antigens to lymphocytes, pDCs' primary role is to sense pathogens and activate the immune system by producing interferon α and β. Thus, there has been interest in determining if BPDCN has an infectious etiology. However, there has been no infection linked to BPDCN, neither in empirical assessment of specific viruses, such as Epstein-Barr virus, nor in unbiased microbial metagenomics using next-generation sequencing.[4]

PATHOBIOLOGY

pDCs develop from a common myeloid-dendritic progenitor that is found in the bone marrow. After maturation, they circulate as 0.5% to 1% of peripheral blood mononuclear cells and are also found in secondary lymphoid organs such as lymph nodes, tonsil, and spleen. They are not frequently detected in the skin under normal circumstances. It is not clear if a specific stage of hematopoietic stem cells, pDC progenitors, or mature pDCs is the target for transformation to BPDCN. Similarly, we do not know if the initial transformation event takes place in bone marrow, peripheral blood, lymphoid organs, or skin. Investigation of these questions regarding the developmental ontogeny of BPDCN is an active area of ongoing research.[5]

At least 50% of BPDCNs have an abnormal karyotype by cytogenetic analysis.[6] However, there is no consistent translocation, mutation, deletion, or amplification event that defines all cases of BPDCN. Recurrent copy loss of specific chromosomes is a common feature, including minimal deleted regions that include known tumor suppressor genes, many of which are cell cycle regulators: 7p12 (*IKZF1*), 9p21 (*CDKN2A/CDKN2B*), 12p13 (*CDKN1B*), 13q11 (*LATS2*), 13q13 (*RB1*), and 17p (*TP53*). Rearrangements of 8q24 involving the *MYC* gene were reported in 40% of cases in a Japanese BPDCN population, with at least half only detectable using fluorescence in situ hybridization (FISH).[7] In that series, *MYC* rearrangement was associated with poorer overall survival (OS) in univariate analysis. In a subset, the translocation t(6;8)(p21;q24) positions an enhancer region of the dendritic lineage-specific gene *RUNX2* on 6p21 upstream of the *MYC* gene, driving its high expression. Despite these findings, in our center's BPDCN population, we have not seen these high rates of *MYC* rearrangement, possibly related to differences in North American and Japanese populations. Therefore, we do not routinely perform FISH for *MYC* abnormalities. Pediatric BPDCN may also be distinct cytogenetically as it is enriched compared to adults for translocations involving the *MYB* locus and does not have other adult-type BPDCN-associated gene mutations.[8]

Somatic mutations acquired in BPDCN cells overlap with the genes mutated in myeloid malignancies, supporting a similar cell of origin.[9] The affected genes are particularly overlapping with those observed in patients with MDS and CMML, and include *TET2*, *ASXL1*, RNA splicing factors (e.g., *SF3B1*, *SRSF2*, *U2AF1*, *ZRSR2*), *TP53*, and others mutated in AML, including *IDH1*, *IDH2*, *KRAS*, and *NRAS*. Some series identified mutations in transcription factors that may be involved in pDC lineage-related transformation, including *IKZF1*, *IKZF2*, *IKZF3*, and *ZEB2*. Unlike AML, mutations in *DNMT3A*, *FLT3*, and *NPM1* are not common.

Gene expression profiling, including by single cell RNA sequencing, support that the closest normal counterpart of BPDCN is the pDC or its immediate precursors.[10] BPDCNs also express high levels of the antiapoptotic gene *BCL2*[11] and have upregulated expression of nuclear factor kappa B (NF-κB) gene signatures,[12] which may suggest targets for therapy.

CLINICAL MANIFESTATIONS AND RECOMMENDED DIAGNOSTIC EVALUATION

The most striking and unique feature of BPDCN is its involvement of the skin. At least 80% of patients have skin involvement at the time of initial diagnosis. The skin lesions can be single, or widespread and numerous; they can be nodular and indurated or can be patchy erythema that mimics inflammatory or allergic conditions. However, the most common skin presentation is one or more violaceous, bruise-like plaques or tumors that can be found in any region of the body (Fig. 64.1). The disease usually begins with a single lesion, which often then spreads to contiguous areas or more distantly in the skin. Interestingly, up to 50% of patients will not have concurrent bone marrow involvement (so-called "skin-only" disease). In those with bone marrow disease, only a minority will have circulating peripheral blood BPDCN cells. Anemia or thrombocytopenia are signs that the bone marrow may be involved. Lymph node and/or splenic involvement is present in approximately 40%. BPDCN has an increased propensity to involve other visceral sites such as the lung, breast, oral cavity, and other mucosa such as the cervix. In our experience, extramedullary involvement by BPDCN is more frequent than in AML, including compared to AMLs with monocytic differentiation (FAB M4 and M5), which can involve mucosal surfaces, gingiva, and other organs including the central nervous system.

We recommend that the initial evaluation for a patient with suspected BPDCN includes a full body skin exam, preferably by a dermatologist or oncologist with experience in skin malignancies, with skin biopsy of suspicious lesions; a bone marrow aspiration and biopsy; and full body imaging with either contrast-enhanced CT scan or positron emission tomography (PET)-CT scan.

Central nervous system (CNS) involvement by BPDCN is more frequent than in AML or other myeloid neoplasms such as MDS and CMML. Occult CNS involvement at diagnosis may be as high as 30%, and symptomatic CNS disease is often a feature of relapsed or refractory disease. Therefore, we recommend lumbar puncture for cytology and flow cytometry, plus prophylactic intrathecal chemotherapy for all patients at diagnosis, and for all patients with neurologic symptoms or signs at any time in their disease course. For patients with no CNS involvement at diagnosis, we recommend a full course of prophylactic intrathecal chemotherapy, concurrent with systemic therapy, following a regimen similar to that used for high-risk acute lymphoblastic leukemia.

HISTOPATHOLOGY

Skin biopsy reveals a dense monomorphous infiltrate in the dermis and subcutis of blastoid cells (Fig. 64.2). The epidermis is typically spared and there is usually a clear "grenz zone," an uninvolved strip of papillary dermis just below the epidermis. The individual tumor cells are medium to large sized with scant cytoplasm and have similar appearance in skin, marrow, lymph nodes, blood, and other involved sites. Some have a plasmacytoid appearance with eccentric nuclei, cytoplasmic vacuolation, and/or extended cytoplasmic projections similar to "hand-mirror" cells that are seen in acute lymphoblastic leukemia. Mitotic figures are often present.

The classic immunophenotype of BPDCN cells is positivity for CD123 (IL-3 receptor α chain), CD4, and CD56, on CD45-positive cells indicating hematopoietic origin. The cells fall in the CD45 dim, side-scatter low "blast gate" on flow cytometry. Staining for the proto-oncogene T-cell leukemia/lymphoma protein 1A (TCL-1) is often positive, although this marker is not specific for BPDCN and can also be expressed in several lymphoid malignancies. Terminal deoxynucleotidyl transferase (TdT) is positive in approximately one-third of cases. The pDC antigen CD303 (BDCA-2) is lost in some BPDCNs, but when positive, its expression supports the diagnosis. CD4 or CD56 may be negative in a minority (approximately 8%) of cases. One diagnostic schema suggests that BPDCN is likely if the tumor cells express at least 4 of 5 markers among CD123, CD4, CD56, TCL-1, and CD303.[13] CD34 is usually negative. Myeloperoxidase and lysozyme are negative in BPDCN and when either is positive makes AML more likely.

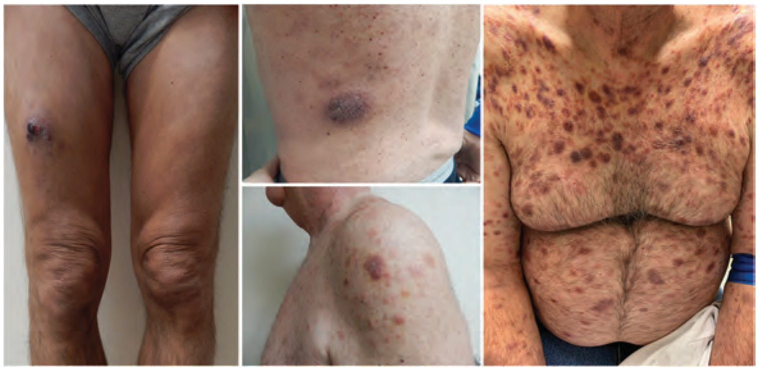

Figure 64.1 BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM (BPDCN) SKIN LESION PHOTOGRAPHS FROM FOUR INDIVIDUALS SHOWING DIFFERENT PRESENTATIONS OF CUTANEOUS DISEASE.

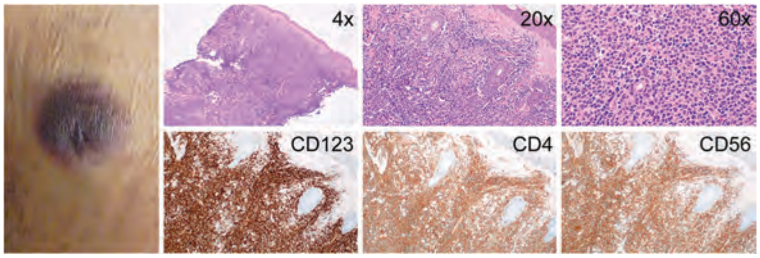

Figure 64.2 BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM (BPDCN) SKIN LESION, SKIN BIOPSY PHOTOMICROGRAPHS, AND IMMUNOHISTOCHEMISTRY (AT 20× MAGNIFICATION) FOR CD123, CD4, AND CD56.

DIFFERENTIAL DIAGNOSIS

Acute Myeloid Leukemia and Other CD56+ Neoplasms With Skin Involvement

Given the association with preexisting hematopoietic neoplasms, all patients with myeloid disorders, including MDS, CMML, AML, myeloproliferative neoplasms, and clonal hematopoiesis who develop skin lesion(s) should undergo a biopsy and evaluation for BPDCN (Box 64.1). Collaboration with a dermatologist and hematopathologist is recommended. The principal differential diagnoses include hematologic malignancies that are CD56 positive and/or present with skin lesions (Table 64.1). AML can be CD123, CD4, and CD56 positive, and some are CD34 negative. In these cases, myeloperoxidase or lysozyme positivity, or presence of other monocytic/myelomonocytic markers such as CD13, CD15, or CD117 favor a diagnosis of AML over BPDCN. Negativity for CD123 or TCL-1 also favors AML over BPDCN. The most challenging situation is when there are no skin lesions; in those cases, immunophenotyping on bone marrow biopsy immunohistochemistry and flow cytometry must be used to distinguish between AML and BPDCN. Extranodal NK/T-cell lymphoma may involve the skin and express CD56 but is associated with Epstein-Barr virus positivity and is CD123 negative. Cutaneous T-cell lymphoma (CTCL) can also be CD56 positive, but expresses mature T-cell markers (CD2, CD3, CD5, CD7, CD8) and is negative for CD123.

Mature Plasmacytoid Dendritic Cell Proliferation

Mature plasmacytoid dendritic cell proliferation (MPDCP) is associated with myeloid neoplasms, particularly CMML, MDS, and AML, but can be seen in any myeloid neoplasm and especially those with monocytic differentiation.[14] MPDCP is usually detected as clonally expanded aggregates of pDCs distinguishable from BPDCN by their clustered localization, mature morphology, and CD56 negativity. MPDCPs are characterized by a low Ki-67 proliferation index (<10%) and they lack TdT. In contrast, in BPDCN, TdT is positive in about one-third of cases, with expression in 10% to 80% of the cells and the Ki-67 proliferation index is 20% to 80%. There is no clear evidence that patients with MPDCP are more likely to develop subsequent BPDCN, but this has not been studied in great depth.

BOX 64.1 Diagnostic Dilemma: Skin Lesions in a Patient With Myelodysplastic Syndrome

A 71-year-old man has a 9-month history of myelodysplastic syndrome (MDS), classified as MDS-EB2 (with 12% bone marrow blasts at the time of diagnosis). The MDS blasts were CD45 positive, CD34 positive, myeloperoxidase positive, CD123 negative, and HLA-DR negative. After 4 cycles of decitabine monotherapy he has stable bone marrow blast percentage and no significant change in his pre-treatment anemia and thrombocytopenia. He presents to clinic with a new purple, painless, 3 cm diameter raised tumor on his forehead. Skin biopsy reveals a dense dermal infiltrate of medium to large-sized cells with blastoid appearance that are CD45 positive and concerning for myeloid sarcoma on histopathology. However, upon further staining, the skin tumor cells are CD34 negative, myeloperoxidase and lysozyme negative, CD123 bright, and HLA-DR positive, raising the possibility of BPDCN. Additional immunohistochemistry revealed that the skin tumor cells were also CD4, CD56, and TCL1 positive, confirming the diagnosis of BPDCN.

PROGNOSIS

The median survival of adults with BPDCN is between 12 and 24 months, irrespective of initial pattern of disease.[15,16] Children have better outcomes, likely owing to higher rates of complete remission after initial chemotherapy and lower likelihood of relapse after entering remission.[3] Positivity for TdT, negativity for CD303, and high Ki-67 proliferation index are associated with improved survival, whereas age over 60 and abnormal karyotype portend worse survival.[16] Biallelic loss of 9p21.3 and haploinsufficiency of 5q31 are associated with poor prognosis, as may be mutation of *TET2*, *IDH1*, *IDH2*, or *DNMT3A*.[17,18] Independent association of specific clinical or molecular features with prognosis remains difficult given the relatively small sample size of most studies.

THERAPY

Hematopoietic cell transplantation (HCT) is the only known curative therapy for BPDCN, with most data suggesting that allogeneic HCT (allo-HCT) is associated with better outcomes than autologous hematopoietic cell transplantation (auto-HCT). Therefore, our overall management strategy is to induce a complete remission and then proceed to allo-HCT (Fig. 64.3). The only drug approved specifically for BPDCN is tagraxofusp-erzs (previously called SL-401), a recombinant protein consisting of interleukin-3 (IL-3) fused to a truncated diphtheria toxin (DT) payload. Tagraxofusp delivers DT to cells that express CD123, which is the α chain of the IL-3 receptor and is highly expressed on all BPDCNs. Our practice is to treat adult patients with tagraxofusp as first-line induction therapy. If ineligible for tagraxofusp, due to specific safety parameters such as low baseline serum albumin (<3.2 mg/dL) or if tagraxofusp is unavailable, we recommend intensive induction with acute leukemia chemotherapy, preferably an acute lymphoid leukemia (ALL) regimen (e.g., hyper-CVAD, parts A and B). There are no data comparing tagraxofusp to intensive induction chemotherapy for initial treatment of BPDCN. We recommend using tagraxofusp first, followed by salvage intensive chemotherapy if a CR is not achieved, rather than the reverse order, because tagraxofusp is less likely to cause lasting toxicities that preclude subsequent intensive induction

TABLE 64.1 Hematologic Malignancies That Involve the Skin and are Often CD56+

	CD123	CD4	CD56	MPO and/or Lysozyme	EBV Markers	Mature T-Cell Markers (CD2, CD3, CD5, CD7, CD8)
BPDCN	++	+	+	–	–	–
AML or myeloid sarcoma	– to ++	– to +	– to +	+	–	–
NK/T-cell lymphoma	–	–	+	–	+	+
CTCL	–	–	+	–	–	+

These are the most common immunophenotypes. Aberrant expression of any one of these markers can occur in some cases, so no single marker should be used to make a diagnosis. *AML*, Acute myeloid leukemia; *BPDCN*, plastic plasmacytoid dendritic cell neoplasm; *CTCL*, cutaneous T-cell lymphoma; *EBV*, Epstein Barr virus; *MPO*, myeloperoxidase; *NK*, natural killer.

chemotherapy. In contrast, patients who have received intensive induction chemotherapy may have infectious complications after myelosuppression or hypoalbuminemia following prolonged hospitalization that could make them ineligible for tagraxofusp. Patients who achieve complete remission with induction therapy, either with tagraxofusp or chemotherapy, are then referred for allo-HCT. However, given the relatively small sample size of studies to date and lack of head-to-head comparative data, clinical trial participation is preferred at all stages of the disease.

Tagraxofusp

Tagraxofusp was approved by the US Food and Drug Administration in 2018 based on the results of a phase 1/2 multicenter, prospective, open-label clinical trial for patients with either treatment-naïve or relapsed/refractory BPDCN.[19] The median age was 70 (range 22 to 84) years old. Among the 29 subjects treated at the FDA-approved dose of 12 μg/kg daily for 5 days as first-line therapy, the rate of complete response (CR) or clinical complete response (CRc, defined as complete response in the marrow and lymph nodes/extramedullary sites with only microscopic disease remaining on skin biopsy) was 72% (95% confidence interval [CI], 53 to 87). The median time until response was 43 days (range, 14 to 131). The rate of complete, clinical complete, and partial responses (CR + CRc + PR) among the 29 therapy-naïve patients was approximately 90% ($n = 26$ of 29). About 45% of the treatment-naïve patients went to HCT (10 allogeneic, 3 autologous) after receiving tagraxofusp, all of whom were in a CR or CRc. The median OS for first-line treated patients was not reached (25 months follow-up), nor was the median duration of response (19 months follow-up). Two patients remained in CR on continued tagraxofusp without transplant for more than 1 year (>15 and >30 months), but with these small numbers of patients the long-term efficacy of tagraxofusp alone is not clear. In those with relapsed or refractory disease, treatment with tagraxofusp resulted in CR/CRc/CRi (complete response with incomplete count recovery) in 5 of 15 patients and an overall response rate (PR or better) of 67% (95% CI, 33 to 88). One patient with relapsed BPDCN achieved a CRc with tagraxofusp and went on to allo-HCT.

Tagraxofusp Side Effects and Management of Capillary Leak Syndrome

Grade 3 or higher thrombocytopenia and liver enzyme elevations (alanine/aspartate aminotransferases [ALT/AST]) were seen in about 40% of patients on the tagraxofusp trial, but these did not lead to clinical complications and resolved within 4 weeks of the first dose in nearly all patients. Approximately half of patients developed hypoalbuminemia or peripheral edema and 20% developed frank capillary leak syndrome (CLS). CLS is related to endothelial damage and manifests as one or more of: weight gain, hypoalbuminemia, edema, pleural or pericardial effusions, hypotension, and fever. CLS is a known side effect of diphtheria and pseudomonas toxin conjugate drugs and therefore, tagraxofusp should not be given to patients with baseline hypoalbuminemia or reduced cardiac function. Our practice is to follow the eligibility criteria from the registration trial and only give tagraxofusp to patients with baseline albumin of ≥ 3.2 g/dL (in the absence of exogenous supplementation with intravenous albumin) and a normal left ventricular ejection fraction.

The FDA approved dose of tagraxofusp is 12 μg/kg daily over 15 minutes for 5 days with cycles repeated every 3 weeks. However, dosing should be interrupted or halted in a given cycle if there are signs or symptoms of clinically important CLS, such as falling albumin concentration, weight gain, pulmonary edema, or hypotension. Specifically, if any of the following parameters occur, then no further tagraxofusp should be given during a cycle: albumin below 3.0 g/dL or ALT/AST greater than 5 times the upper limit of normal. Other clinical and lab abnormalities suggestive of CLS warrant holding tagraxofusp during a given cycle until the findings resolve: weight gain of more than 1.5 kg in 24 hours; albumin below 3.5 g/dL if baseline was 4.0 g/dL or higher, or any drop of more than 0.5 g/dL in 24 hours. In these situations, we recommend giving intravenous albumin, 25 g every 6 to 12 hours until albumin is greater or equal to 3.5 g/dL AND within 0.5 g/dL of baseline. Diuretics are recommended as tolerated for volume overload. For patients with CLS and signs of a systemic inflammatory response (fever, hypotension) consider giving corticosteroids, such as solumedrol 1 mg/kg daily, until resolution (Box 64.2).

Chemotherapy

An alternative to tagraxofusp for patients who are otherwise "fit" is intensive acute leukemia-type induction chemotherapy. Similar to tagraxofusp, if the patient is eligible for allo-HCT the goal of chemotherapy is to induce a complete remission and proceed to transplant. Given that there are no head-to-head comparisons of induction regimens, we recommend tagraxofusp as our first choice, as discussed previously. If unable to use tagraxofusp, we recommend induction chemotherapy. In retrospective studies and in our personal experience, less-intensive therapies (e.g., CHOP) appear to be inferior to conventional intensive acute leukemia-type regimens.[16] Among intensive induction regimens, ALL-type may be more effective than AML-type, although they have not been compared in randomized trials. Intensive induction therapies such as hyper-CVAD (cyclophosphamide, vincristine, doxorubicin (Adriamycin), and dexamethasone) have substantial response rates in BPDCN but the duration of response is often short with relapsed disease being difficult to treat and control. Another practical challenge is the advanced median age of patients with BPDCN who are, in most cases, unable to tolerate intensive induction chemotherapy, which is why tagraxofusp may be particularly useful in achieving remission. When tagraxofusp is not an option, our recommendation is for ALL-type intensive induction (e.g., hyper-CVAD or an L-asparaginase-containing induction regimen) for younger, "fit" patients. For older or "less fit" patients, we recommend age-adjusted ALL induction chemotherapy regimens or anthracycline-based lymphoma chemotherapy such as CHOP. Additional less intensive regimens with activity are discussed later.

Disease Response Assessment in Blastic Plasmacytoid Dendritic Cell Neoplasm

There are no formal standardized disease assessment criteria specifically for BPDCN, but most clinical trials are using the schema defined in the tagraxofusp registration trial. This has become the de facto standard in our clinical practice. Each disease compartment is assessed using criteria adopted from other hematologic malignancies: AML criteria for bone marrow biopsy and peripheral blood; lymphoma criteria for lymph nodes, spleen, and other extramedullary sites by CT or PET-CT scan; and the modified Severity Weighted Assessment Tool (mSWAT) for quantitative skin malignancy assessment originally designed for cutaneous T-cell lymphoma trials.[19] To be considered in a CR, a patient must have a CR in all three compartments. For patients who receive tagraxofusp, we usually assess for response after 2 cycles and then every 2 to 4 cycles based on the clinical situation. There are no data on the minimum number of cycles of tagraxofusp necessary prior to allo-HCT. Our practice is to proceed with allo-HCT once CR is achieved (here, we consider CR, CRc, or CRi acceptable to undergo allo-HCT), continuing tagraxofusp every 3 weeks with cessation of therapy immediately prior to the procedure. For patients receiving chemotherapy instead of tagraxofusp, we use these same response criteria and similar approach toward allo-HCT, with no minimum required number of chemotherapy cycles.

BOX 64.2 Management of Capillary Leak Syndrome During Tagraxofusp Therapy

A 65-year-old man with newly diagnosed blastic plasmacytoid dendritic cell neoplasm (BPDCN) involving skin and bone marrow is being treated with tagraxofusp. He is admitted to the inpatient hospital for cycle 1, days 1–6 (until at least 1 day after the last dose of tagraxofusp), as we recommend for all patients in the first cycle to provide close monitoring for tagraxofusp-associated capillary leak syndrome (CLS). On the fourth day of planned 5 days of therapy, he is found to have gained 2 kg from the prior day, his blood oxygen saturation is 91% on room air (down from 98%), he has new peripheral edema, and his albumin has dropped to 2.9 g/dL from 3.6 g/dL at baseline. The fourth and fifth doses of tagraxofusp in cycle 1 are cancelled. He is treated with intravenous albumin, 25 g twice daily, and intravenous furosemide for diuresis. Over the next 2 days, his weight returns to baseline and serum albumin recovers to 3.5 g/dL. He is discharged from the hospital and has no further signs or symptoms of CLS. Tagraxofusp is restarted in cycle 2 at the standard dose, with inpatient monitoring given prior CLS. He has no recurrence of CLS and future tagraxofusp cycles are administered in the outpatient setting.

Alternative Regimens for First-Line Therapy and Treatment of Relapsed/Refractory Disease

Clinical trials are preferred (Table 64.2). For those treatment-naïve patients unlikely to tolerate intensive induction, there are many regimens that have reported activity in BPDCN. None have been compared in randomized studies. These include lymphoma regimens such as CHOP, hypomethylating agent-based regimens with azacitidine or decitabine, pralatrexate, gemcitabine +/− docetaxel, bendamustine, and bortezomib-based therapy. In addition, BPDCN is dependent on the antiapoptotic protein BCL2 for survival and is sensitive to the BCL2 inhibitor, venetoclax.[11] Disease responses have been reported with single-agent venetoclax and in combination with hypomethylating agents or the hyper-CVAD regimen.[16,20,21] Mutations in *IDH1* and *IDH2* are present in 10% to 15% of BPDCNs and there are data demonstrating activity of enasidenib, an IDH2 inhibitor, in BPDCN with an *IDH2* mutation.[16] *FLT3* mutations are not common in BPDCN but are occasionally observed. Therefore, given that there are approved IDH1, IDH2, and FLT3 inhibitors for AML, it is reasonable to perform DNA sequencing to evaluate for these mutations and consider using them per AML treatment guidelines in patients with relapsed or refractory BPDCN.[22]

Radiation therapy is active against BPDCN cells and can be useful for emergent treatment of lesions with mass effect. Radiation has been used to treat skin-only disease, but most patients eventually progress with systemic disease and radiation is therefore not commonly used as part of curative-intent therapy.[23] CNS involvement is more frequent in the setting of relapsed/refractory disease and should be evaluated in any patients with symptoms. Lumbar puncture may be beneficial in all patients, including at initial diagnosis, to evaluate for asymptomatic disease. Active CNS BPDCN is associated with very poor outcomes and is commonly managed by intrathecal chemotherapy (methotrexate and/or cytarabine) or radiation, although there are very little data to guide treatment. Systemic corticosteroids can be useful as short-term palliative treatment for relapsed BPDCN or if needed acutely to control lesions with mass effect or symptomatic CNS BPDCN.

There are several additional therapies undergoing clinical evaluation in BPDCN, including other agents targeting CD123 and small molecule targeted therapies (Fig. 64.4).[22] Analysis of patient samples before and after tagraxofusp suggest that loss of CD123 is not a common mechanism of resistance, but instead, resistance is related to downregulation of the diphthamide synthesis pathway that is necessary for DT sensitivity.[24] Thus, clinical evaluation of sequential CD123-targeting agents is justified. Novel agents targeting CD123 include anti-CD123 antibody-drug conjugates, CD3 × CD123 bispecific T-cell engagers, and CD123-directed chimeric antigen receptor T cells (CD123 CAR-T).

Hematopoietic Cell Transplantation

Allo-HCT is recommended for all eligible adult patients with BPDCN in first complete remission (CR1). Long-term overall and disease-free survival are higher in patients with BPDCN who receive transplant compared to chemotherapy alone, although the data are

TABLE 64.2 **Selected Clinical Trials for Patients With Blastic Plasmacytoid Dendritic Cell Neoplasm**

Agent	Phase	Key Eligibility	Status	Clinicaltrials.Gov ID#
Venetoclax +/– azacitidine	1	Relapsed disease, or treatment-naïve but ineligible for standard therapy	Recruiting	NCT03485547
IMGN632 (anti-CD123 ADC)	1	Treatment-naïve or relapsed disease	Recruiting	NCT03386513
XmAb14045 (CD123 x CD3 bispecific T-cell engager)	1	Relapsed disease	Recruiting	NCT02730312
CD123 CAR-T cell (autologous)	1	Relapsed disease	Recruiting	NCT02159495
Combination chemotherapy (idarubicin, methotrexate, L-asparaginase, dexamethasone) followed by hematopoietic cell transplantation (auto- or allo- transplant)	2	Treatment-naïve	Recruiting	NCT03599960
Hyper-CVAD/mini-CVD + venetoclax + tagraxofusp	2	Treatment-naïve or relapsed disease	Recruiting	NCT04216524
Flotetuzumab (CD123 × CD3 bispecific T-cell engager)	2	Relapsed disease	Anticipated	NCT03739606

ADC, Antibody-drug conjugate; *CAR*, chimeric antigen receptor.

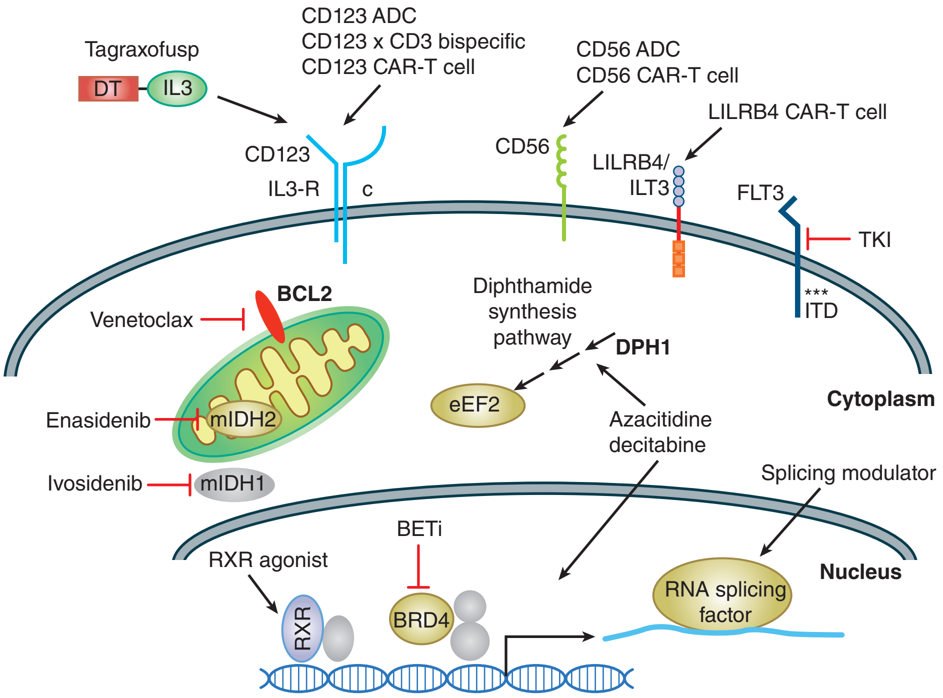

Figure 64.4 NOVEL TARGETS AND AGENTS UNDER INVESTIGATION IN BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM (BPDCN). Tagraxofusp is approved for treatment of BPDCN in the United States. Tagraxofusp is being combined with chemotherapy, including azacitidine, and/or venetoclax in clinical trials. Several additional CD123-targeting agents are in clinical trials. The other drugs listed are described as having activity in clinical case reports or supportive evidence via mutation profiling or pre-clinical models of BPDCN. *ADC*, Antibody-drug conjugate; *BETi*, bromodomain and extraterminal motif inhibitor; *CAR*, chimeric antigen receptor; *DT*, diphtheria toxin; *eEF2*, eukaryotic elongation factor 2; *IL3*, interleukin 3; *mIDH1* and *mIDH2*, mutant isocitrate dehydrogenase 1 and 2; *RXR*, retinoid X receptor; *TKI*, tyrosine kinase inhibitor; ****ITD*, internal tandem duplication mutation in *FLT3*. *(Image is from Figure 1 [page 590] of Lane AA. Novel therapies for blastic plasmacytoid dendritic cell neoplasm. Hematol Oncol Clin North Am. 2020;34:589–600.)*

retrospective and subject to inclusion and eligibility biases. Transplant in the setting of any residual active disease is associated with dismal prognosis. A meta-analysis of 128 adult patients (from four studies) who received allogeneic transplant for BPDCN reported approximately 50% (95% CI, 41 to 59) OS at 4 years. OS was 67% (95% CI, 52 to 80) in those who were transplanted in CR1 versus 7% (95% CI, 0 to 32) in those transplanted in any state less than CR or after first disease relapse.[25] The analysis also confirmed decreased relapse rates using myeloablative compared to reduced intensity conditioning (RIC; 18% vs. 40%, respectively). These results translated into higher OS of 55% for myeloablative compared to 44% for RIC. Based on these and results from a European Blood and Marrow Transplantation (EBMT) group study,[26] our practice is to offer allo-HCT, preferably with myeloablative conditioning (MAC), to all eligible adult patients in CR (including CRc and CRi).

In our practice we have observed complete regression of disease following rapid immunosuppressive taper in patients with relapsed disease after allo-HCT suggestive of a graft-versus-BPDCN immune effect. This observation supports the utility of RIC transplants in older and frailer patients who cannot tolerate MAC. In contrast, autologous transplantation relies on the high-dose chemotherapy effect. One study in a Japanese population reported 4-year disease-free survival of over 80% in 11 patients after auto-HCT.[27] However, a retrospective analysis in a North American population found that auto-HCT was associated with only 11% 1-year OS.[28] In our practice, we do not recommend autologous transplantation for BPDCN except in limited situations. It is reasonable to consider consolidation with auto-HCT for patients with chemosensitive disease in CR who are ineligible or decline allo-HCT.

Treatment of Blastic Plasmacytoid Dendritic Cell Neoplasm in Children (<18 Years of Age)

Response to therapy and disease-free survival are better in children than in adults with BPDCN.[3] A high-risk ALL-type induction chemotherapy regimen with screening lumbar puncture and prophylactic CNS-directed therapy per standard lymphoid leukemia practice is recommended. Given the relatively higher disease-free survival after achieving remission in children, allogeneic transplant is usually not recommended in CR1. Pediatric patients should continue on consolidation and maintenance chemotherapy regimens as used for high-risk ALL in CR1. Allo-HCT is recommended for children who experience relapse and achieve CR2. Published experience with tagraxofusp in children is limited to the relapsed/refractory setting. Tagraxofusp was approved by the FDA for ages 2 and up based on one report of safety and short-term efficacy in three patients with relapsed BPDCN.[29] However, we do not recommend tagraxofusp as first-line therapy in pediatric BPDCN (<18 years of age) given the absence of efficacy and survival data in treatment-naïve disease and because of the relatively favorable outcomes with conventional ALL-type chemotherapy.[30] Whether young adults benefit most from a pediatric or adult approach is not known. In our practice, we have treated patients 18 years of age and older with the adult algorithm outlined previously.

FUTURE DIRECTIONS

Progress in BPDCN research requires improved scientific understanding of the unique disease pathobiology and performance of disease-specific clinical trials. We recommend enrolling patients on clinical studies whenever possible and encourage investigators to design BPDCN-specific trials that evaluate response in all sites of disease involvement. Important questions that are unanswered include comparison of tagraxofusp with intensive induction chemotherapy, particularly in the first-line setting for younger patients. We must determine if combination therapy is superior to currently available treatments, including testing tagraxofusp with intensive or nonintensive chemotherapy, and adding venetoclax to tagraxofusp or to chemotherapy. We also need to determine if maintenance therapy in the setting of CR after chemotherapy or HCT (autologous or allogeneic) has clinical benefit and which agent(s) are most effective in the maintenance setting. Finally, a better understanding of how to assess measurable residual disease (MRD) in BPDCN may improve comparison of active therapies and should be incorporated into clinical trial endpoints, particularly in studies of maintenance therapy and after transplant.

CHAPTER 65

MYELODYSPLASTIC SYNDROMES AND MYELOPROLIFERATIVE NEOPLASMS IN CHILDREN

Elliot Stieglitz, Christopher C. Dvorak, and Benjamin S. Braun

Myelodysplastic syndromes (MDS) and myeloproliferative neoplasms (MPN) are a heterogeneous group of clonal stem cell disorders that result in ineffective hematopoiesis and an increased risk of developing acute myeloid leukemia (AML). Whereas in MDS ineffective hematopoiesis results in progressive cytopenias, in MPN ineffective hematopoiesis leads to excessive proliferation frequently characterized by increased peripheral blood counts. MDS and MPN are rare in children, and the only malignancy with overlapping features of both MDS and MPN in childhood is referred to as juvenile myelomonocytic leukemia (JMML). Chronic myeloid leukemia (CML), characterized by the Philadelphia chromosome (*BCR/ABL*-positive), is more common in adults and seen infrequently in children. However, other forms of MPN including polycythemia vera (PV), essential thrombocythemia (ET), primary myelofibrosis, chronic neutrophilic leukemia, chronic eosinophilic leukemia, chronic basophilic leukemia, chronic myelomonocytic leukemia, systemic mastocytosis (SM), and stem cell leukemia–lymphoma syndrome) are exceedingly rare in children. Additional information regarding disorders that are predominantly found in adults are referred to in Chapters 70–75. In contrast, two MPNs are uniquely pediatric: JMML and Down syndrome–associated transient abnormal myelopoiesis (TAM) will be the main focus of this chapter.

MYELODYSPLASTIC SYNDROMES

The MDS are a heterogeneous group of clonal disorders characterized by ineffective hematopoiesis, impaired maturation of hematopoietic cells, progressive cytopenias, and dysplastic changes in the bone marrow (BM).

Epidemiology

MDS is a common malignancy of adults, with an incidence of 50 cases per million in people older than the age of 60 years.[1] In contrast, MDS accounts for only 3% to 7% of all hematologic malignancies in children, with an unknown true incidence, owing in part to the inclusion of children with Down syndrome in some estimates. Several population-based studies have been performed with reported incidences of 4.0 cases per million in Denmark,[2] 3.1 per million in British Columbia (Canada),[3] and 1.35 per million in the United Kingdom.[4] The median age of presentation is 6.8 years with an equal sex distribution.[4–6] However, in a study of children with advanced or high-risk MDS, the median age of presentation was older, at 10.7 years with a 2:1 male-to-female ratio.[7]

Pathobiology

As in adults, MDS in children can be considered as primary (de novo) or secondary. In adults, two predominant patterns of primary, de novo MDS have been observed. In the first of these patterns, the disease is indolent in nature and is characterized by prolonged survival, little accumulated genetic damage, and a low probability of progression to AML. This group of diseases is best exemplified by the 5q− syndrome, an entity not seen in children. Far more common in adults is a disease characterized by the accumulation of genetic changes, progression to BM failure, and a high probability of developing AML. This form of the disease is characterized as a mutator phenotype.[8] The primary MDS seen in children appears to share this mutator phenotype.

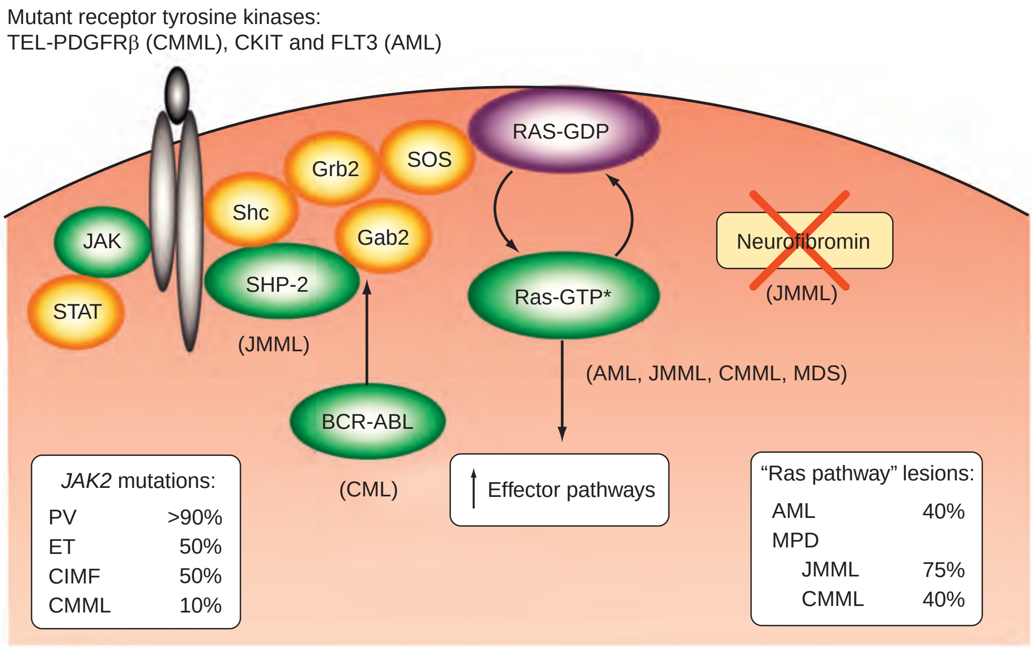
As in adults, secondary MDS in children can also arise as sequelae from exposure to chemotherapy and radiation, and from genetic conditions including Down syndrome, paroxysmal nocturnal hemoglobinuria (PNH), neurofibromatosis type 1 (NF1), Bloom syndrome, and Li-Fraumeni syndrome. However, MDS in children may often result from inherited constitutional BM failure syndromes including Fanconi anemia (FA), severe congenital neutropenia, Shwachman-Diamond syndrome, congenital amegakaryocytic thrombocytopenia, dyskeratosis congenital, Diamond-Blackfan anemia, and MonoMAC syndrome.

Ongoing studies are now defining the molecular pathogenesis and interrelationships among MDS, MPN, and AML.[8–10] Accumulating data suggest that aberrant signal transduction resulting from acquired somatic mutations encoding proteins, leading to hyperactivation of the Ras pathway, may stimulate proliferation without concomitant differentiation.[9] This has been clearly demonstrated in CML (*BCR-ABL*).[11,12] A number of other putative pathogenetic mutations have been identified in other myeloproliferative disorders, including *JAK2* V617F and *CALR* mutations in PV, ET, and primary myelofibrosis[13]; *KIT* D816V mutations in SM[14]; *FIPL1-PDGFRA* in chronic eosinophilic leukemia-SM[15]; *ZNF198-FG4FR1* mutations in stem cell leukemia–lymphoma syndrome[16]; *RAS/NF1/PTPN11* mutations in JMML (Fig. 65.1)[17–19]; and *GATA1* mutations in TAM.[20]

AML is the result of cooperating mutations in genes that confer a proliferative and survival advantage (e.g., activating mutations in receptor tyrosine kinases [FLT3, c-kit]), and genes that impair differentiation and apoptosis (e.g., loss-of-function mutations in transcription factors [CBF, AML/ETO]) (Fig. 65.2). This multistep model for the pathogenesis of AML is supported by murine models,[21,22] the analysis of leukemia in twins,[23–26] and the analysis of patients with familial platelet disorder with a propensity to develop AML (FDP/AML syndrome).[27]

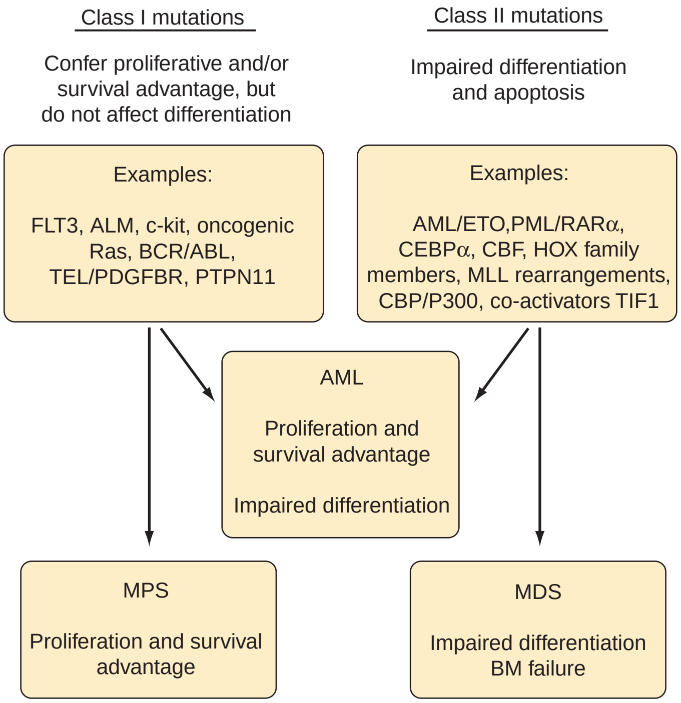
The patterns of genetic and karyotypic abnormalities in children with MDS are typically distinct from that of adults. Although a few karyotypic abnormalities are shared (e.g., 7/7q−), many that are common in adults are only rarely found in children (e.g., 5q−). Importantly, mutations in mRNA spicing genes are only rarely found in children with de novo and secondary MDS.[28–31] Mutations in epigenetic genes that control DNA methylation and histone function are also only rarely identified in children, making their role in MDS uncertain. For example, although mutations in *TET2* are identified in 20% to 25% of adults with MDS, only 1 out of 19 children with refractory cytopenia of childhood (RCC) had a mutation in *TET2*.[32] Instead, the genetic abnormalities in children with MDS are most often those associated with inherited BM failure syndromes and other genetic disorders (*FANC* member genes, *DKC*, *TERT*, *TREC*, *WAS*, *GATA-2*, *SBDS*, etc.).

Finally, three exceedingly rare familial forms of MDS/AML are associated with mutations in *RUNX1/AML1* (familial platelet disorder with a predisposition to AML), *CEBPα* (familial AML), and *GATA-2*.[31,33–35] Most recently, germline mutations in the genes *SAMD9* and *SAMD9L* have been shown to lead to Mirage and ataxia–pancytopenia syndrome, respectively. Patients with these disorders are at a higher risk of developing MDS compared to the general population and are frequently present with monosomy 7.



Mutant receptor tyrosine kinases:
TEL-PDGFRβ (CMML), CKIT and FLT3 (AML)
RAS-GDP
Grb2
SOS
Shc
JAK
Gab2
Neurofibromin
SHP-2
STAT
Ras-GTP*
(JMML)
(JMML)
(AML, JMML, CMML, MDS)
BCR-ABL
JAK2 mutations:
PV >90%
ET 50%
CIMF 50%
CMML 10%
(CML)
Effector pathways
"Ras pathway" lesions:
AML 40%
MPD
JMML 75%
CMML 40%

Figure 65.1 OVERVIEW OF RAS SIGNALING WITH MOLECULES HARBORING MUTATIONS IN PATIENTS WITH MYELOID MALIGNANCIES. *AML*, Acute myeloid leukemia; *CML*, chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *ET*, essential thrombocythemia; *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate; *JAK*, Janus-activated kinase; *JMML*, juvenile myelomonocytic leukemia; *MDS*, myelodysplastic syndromes; *MPD*, myeloproliferative disorder; *PV*, polycythemia vera.



Class I mutations
Confer proliferative and/or survival advantage, but do not affect differentiation
Class II mutations
Impaired differentiation and apoptosis
Examples:
FLT3, ALM, c-kit, oncogenic Ras, BCR/ABL, TEL/PDGFBR, PTPN11
Examples:
AML/ETO,PML/RARα, CEBPα, CBF, HOX family members, MLL rearrangements, CBP/P300, co-activators TIF1
AML
Proliferation and survival advantage
Impaired differentiation
MPS
Proliferation and survival advantage
MDS
Impaired differentiation
BM failure

Classification

Until recently, MDS in children was poorly defined, characterized, classified, and reported. In fact, MDS was not included in the International Classification of Childhood Cancer until 2005.[36] Also contributing to this lack of information was the use of classification and prognostic systems designed for adults that have had limited applicability to children. A number of classification systems for children and adults have now been proposed. Taken together, it may be useful to think about childhood MDS as primary or secondary in nature, with secondary MDS arising either from a known inherited BM failure syndrome, prior acquired aplastic anemia, or as a complication from prior chemotherapy or radiation therapy. A diagnosis of primary MDS would then apply to all other cases.

Historically, one of the most commonly used classification systems was the French-American-British (FAB) system, originally proposed in 1982.[37] This classification system recognized five forms of MDS in adults: refractory anemia (RA), RA with ringed sideroblasts (RARS), RA with excess of blasts (RAEB), RAEB in transformation (RAEB-T), and CMML. While RAEB and RAEB-T were commonly reported in children, RA and RARS were thought to be rare in children. However, a population-based study in the United Kingdom showed 25% of childhood MDS cases to be RA or RARS, suggesting inaccurate diagnosis or reporting of these subtypes in other pediatric studies. CMML has only rarely been reported in children.

Additional subtypes of MDS are now recognized that do not fit well into the FAB system, including hypoplastic MDS, therapy-related MDS, refractory cytopenias with trilineage dysplasia, MDS associated with myelofibrosis, and MDS associated with inherited disorders (congenital neutropenias, Shwachman-Diamond syndrome, FA), Down syndrome, NF1, and mitochondrial cytopathies.[38,39] Therefore, the World Health Organization (WHO) proposed changes to the FAB criteria to account for many of these subtypes.[40,41] Importantly, whereas adults commonly present with RA without cytopenias in the myeloid or platelet lineages, this is very rare in children since they more often have cytopenias in more than one cell line. Therefore, children with low-grade MDS are classified as having refractory cytopenia as opposed to RA. Thus in 2008 the WHO classification of pediatric MDS included the provisional category of RCC based on persistent cytopenia with <5% blasts in the BM and <2% blasts in the peripheral blood.[42] Under this classification, it is recommended that children with refractory cytopenia with multilineage dysplasia (RCMD) be classified as RCC until it is clarified whether the number of lineages involved is an important prognostic discriminator in childhood MDS. Under the 2016 revision of the WHO classification of myeloid and neoplasms and acute leukemia, RCC remains a provisional entry.[43]

Clinical Manifestations

Signs and symptoms of MDS are nonspecific and are usually attributable to pancytopenia (fever, infections, pallor, fatigue, bruising, and petechiae). Lymphadenopathy, hepatomegaly, and splenomegaly are uncommon presenting signs in children with MDS.

Laboratory Manifestations

Commonly accepted minimal diagnostic criteria for pediatric MDS include the absence of common de novo AML karyotypic abnormalities and at least two of the following: (1) sustained, unexplained anemia; neutropenia or thrombocytopenia; dysplastic morphology in the erythroid; granulocytic or megakaryocytic lineages (at least bilineage), and (2) an acquired, sustained clonal cytogenetic abnormality with 5% or more blasts in the BM.[8,44] Almost half of all children with MDS in one series presented with refractory cytopenia, most notably neutropenia and thrombocytopenia.[45]

Morphologically, the BM may be hypocellular, normocellular, or hypercellular. A diagnosis of MDS is made based on the presence of dysplastic changes in at least two cell lineages. The dysplastic changes in the granulocytes (hypogranulation, nuclear hyposegmentation, megaloblastoid maturation, and a left shift with an increased number of myeloblasts), megakaryocytes (micromegakaryocytes, abnormal megakaryocyte nuclei), monocytes (increase in BM monocytes, abnormal granulation with persistence of azurophilic granules, hemophagocytosis, abnormal nuclei, and giant forms), or erythroid lineages (megaloblastoid maturation, nuclear budding and multinucleated forms, and ringed sideroblasts) can be multiple and varied. Similar dysplastic changes can occur in the peripheral blood for each of these lineages. Although dysplastic changes in the BM are a common feature of MDS, it is important to remember that dysplasia, unto itself, is not diagnostic of MDS because dysplastic features are associated with other conditions, and can be found in normal BM donors.[46]

Flow cytometric analysis can serve as a useful addition to histopathology and to quantitate the number of blasts based on aberrant cell surface antigen expression and to exclude AML. It is also helpful in detecting populations of PNH-like cells.[47,48] However, while beneficial, flow cytometric findings are not generally diagnostic of MDS.

Cytogenetic abnormalities are seen in approximately half of children diagnosed with de novo MDS. Karyotypic abnormalities most commonly seen are −7, 7q−, and +8. Abnormalities in chromosomes 6, 9, 11, 12, and 13 are rare in children. Deletions of chromosome 20q can be seen in pediatric patients with SDS. Specific abnormalities seen in adults, including −5, 5q−, and −Y, are very rarely seen in children.

Differential Diagnosis

Although the history, physical examination, evaluation of the BM and peripheral blood, and cytogenetic analysis often make the diagnosis of MDS, other diseases should be considered. Congenital disorders such as Down syndrome, FA, Shwachman-Diamond syndrome, Diamond-Blackfan anemia, congenital dyserythropoietic anemias, and hereditary sideroblastic anemia should be considered. The differential should also include AML with a low blast count, mitochondrial cytopathies such as Pearson syndrome, rheumatic diseases including juvenile idiopathic arthritis, and myeloproliferative disorders. Specifically, PNH, although rare in children, should be considered. Deficiencies of vitamin B_{12} and folate can cause megaloblastic changes that resemble the dysplastic changes seen in MDS. Other nutritional deficiencies, including copper, iron, thiamine, riboflavin, and pyridoxine, should be considered. Infections caused by human immunodeficiency virus, parvovirus, Epstein-Barr virus, cytomegalovirus, and human herpes virus 6 can cause changes that resemble MDS. Finally, the differential diagnosis should include toxins (insecticides, chemotherapy agents, and arsenic), as well as cytokine exposure and radiation.

Hypoplastic MDS (RCC) can be difficult to distinguish from severe aplastic anemia and inherited BM failure (BMF) syndromes, especially when no chromosomal aberrations are detected. One interesting area of research that may help in differentiating between these diagnoses is the use of cytokine-based programs. In one preliminary study, thrombopoietin and IL-17 levels were useful in differentiating hypoplastic MDS from aplastic anemia.[49] When the diagnosis is unclear, prospective monitoring and serial BM examinations may serve as useful aids in making an accurate diagnosis.

Therapy

Although MDS is a heterogeneous, clonal disease of hematopoietic stem cells (HSCs) that can manifest different clinical courses, it is not readily curable by conventional chemotherapy, and requires allogeneic hematopoietic cell transplantation (HCT) to be cured in most cases. Some children with RCC and RCMD, who do not have life-threatening neutropenia nor require transfusions, may only require close observation (see box on Treatment Overview for Children With MDS). Although children with this disease may eventually develop progressive disease requiring HCT, they may have long periods when minimal treatment is required.[45] The use of AML-like chemotherapy for patients with RCMD with excess blasts (RCMD-EB) is controversial, but may serve to “debulk” patients with a high percentage of blasts before HCT.[6,50,51] However, this potential benefit may be offset by toxicities associated with AML-like chemotherapy. Finally, patients with advanced MDS (RAEB-T or t-MDS) should be treated like those with AML.

Prognosis

Although a number of methods have been developed to predict the outcome of adults with MDS, the systems now most commonly used in adults are the International Prognostic Scoring System[88], that uses percentage BM blasts, karyotype, and number of cytopenias to assign a score that is then used to predict outcome, and the WHO classification-based prognostic scoring system (WPSS) that includes more recently identified prognostic factors (e.g., transfusion dependency and multilineage dysplasia).[89] A recent study demonstrated that both systems “well represent” the prognostic risk for patients whose MDS is defined by the WHO classification criteria.[90] Although these are effective tools for adults, their value for children is very limited.[91]

Secondary Myelodysplastic Syndrome

Secondary MDS can develop in both children and adults after exposure to chemotherapy and radiation. Alkylating agents used to treat Hodgkin disease, non-Hodgkin lymphoma, and Ewing sarcoma are particularly concerning in children.[92–104] Interestingly, there is also evidence to suggest that the cardioprotectant dexrazoxane, a topoisomerase II inhibitor with a mechanism of action that is different from etoposide and doxorubicin, may have increased the incidence of secondary MDS and AML in children treated for Hodgkin disease.[105]

Treatment options for children with secondary MDS are limited. Although AML-like chemotherapy can induce a period of remission and reduction in BM blasts, it is not curative. As noted above, allogeneic HCT has curative potential, but outcomes remain poor, with only 20% to 30% of children surviving in the reported

TREATMENT OVERVIEW FOR CHILDREN WITH MYELODYSPLASTIC SYNDROMES

A multitude of agents have been studied for the treatment of myelodysplastic syndromes (MDS) in adults, but only rarely in children. These include low-dose chemotherapy (cytosine arabinoside, melphalan, hydroxyurea, etoposide, topotecan, 6-mercaptopurine, and busulfan), hormones (glucocorticoids and androgens), differentiating agents (13-*cis*-retinoic acid, all-*trans* retinoic acid), hematopoietic growth factors (granulocyte-macrophage colony-forming factor, granulocyte colony-forming factor, and erythropoietin), demethylating agents (decitabine, 5-azacytidine), proteasome inhibitors, antiangiogenic agents, and arsenic.[52–67] This has resulted in three drugs (lenalidomide, azacitidine, and decitabine) that are now approved by the US Food and Drug Administration for the treatment of MDS in adults. However, as there are currently no safety or efficacy data to support the use of these agents in children with MDS, these drugs are not approved for MDS in children.

In addition, a large number of agents are being tested in clinical trials in the broad categories of kinase inhibitors, deacetylase inhibitors and DNA methyltransferase inhibitors, altered cell metabolism, cytotoxics, cell cycle inhibitors, immunomodulators and immunosuppressive agents, apoptosis modulators, and others.[68]

The difficulty in assessing the safety and efficacy of new agents in children with MDS is illustrated by the Children's Oncology Group's recent prospective study of amifostine.[69] This prospective Phase II cooperative group study was unable to be completed because of lack of accrual. As a result, the safety and efficacy of amifostine in children with MDS remains uncertain. Despite a lack of successful prospective clinical trials in children with MDS, there are limited retrospective data on the use of the hypomethylating agent azacytidine in children with newly diagnosed MDS, and in the palliative setting, children with relapsed MDS. These children had refractory cytopenia of childhood (RCC), advanced and secondary MDS,[70] and prior to allogeneic hematopoietic cell transplantation (HCT).[71] These retrospective reviews suggest that azacytidine is tolerable and responses are possible, although the safety and efficacy in these various clinical settings have not been demonstrated in prospective clinical trials in children.

The utility of chemotherapy prior to allogeneic HCT for childhood MDS is controversial. One retrospective report suggested that use of pre-HCT chemotherapy was associated with poorer post-HCT survival; however, interpretation was limited by the lack of randomization, such that patients with more aggressive disease may have been the ones treated with chemotherapy.[72] Another report suggested less post-HCT relapse after pre-HCT chemotherapy in more advanced cases.[7] Rather than using traditional cytotoxic chemotherapy, a single-center report of non-random use of azacitidine pre-HCT decreased blast counts and improved survival post-HCT.[71] This approach has also been demonstrated to result in better outcomes after HCT for adults with MDS.[73,74]

Most children with MDS require allogeneic HCT for curative therapy. Although children have been included in published HCT studies for MDS that are largely focused on adult patients, several studies have focused specifically on children.[7,75–80] These studies suggested a probability of disease-free survival in about 50% of patients undergoing human leukocyte antigen (HLA)–matched related donor HCT. However, HCT outcomes have improved in recent years. A single-center report compared OS rates between the time-period of 1997–2007 (50%) and 2008–2017 (87%; $P = .006$).[81] The authors attributed much of this improvement to advances in haploidentical donor HCT.

Given the rarity of this disease in children, the best approach for HCT is not clear. A small single center report suggested that reduced intensity conditioning (RIC) was at least equivalent to fully myeloablative conditioning (MAC) for patients with RCC.[82] Another small single-center report also suggested high rates of EFS after RIC for patients with RCC.[75] Treosulfan, if available, may be an especially attractive agent to use in conditioning for patients with MDS, given low toxicity and relapse rates.[83,84] Conversely, patients with more advanced forms of childhood MDS, including RCC associated with monosomy 7, 7q−, or multiple genetic abnormalities, continue to have high rates of post-HCT relapse and probably should be treated with MAC.[7] Algorithms have been proposed to help guide this decision.[85] There are also single-arm adult trials which have attempted to prevent post-HCT relapse with the using of hypomethylating agents,[86,87] though these have been fraught with high rates of toxicity, and pediatric data is lacking.

series.[79,103,106,107] HCT has also been reported in children and young adults with secondary MDS, arising from hereditary BMF syndromes, as well as MDS secondary to chemotherapy exposure.[108–113] In the setting of hereditary BMF syndromes, careful evaluation of potential familial donors needs to be factored into donor choice.[113,114] HCT outcomes for MDS secondary to chemotherapy exposure have been poor, with both high rates of relapse and transplant-related mortality.[110,111] Current areas of investigation include the utility of monitoring hematopoietic chimerism after transplantation, and intervening with preemptive immunotherapy to try to prevent relapse.[115,116]

MYELOPROLIFERATIVE NEOPLASMS

Juvenile Myelomonocytic Leukemia

JMML is classified by the WHO as an overlap of MDS and MPN. It is an aggressive myeloid malignancy of young children with poor outcomes to conventional therapies. The diagnostic criteria are complex (Table 65.1), but recent advances in elucidating the molecular genetics of the disorder demonstrate that approximately 95% of children will harbor an alteration in one of several genes in the Ras pathway. Thus, there is now international agreement on the diagnostic criteria (see Table 65.1),[117] with an emphasis on incorporating these molecular criteria, as well as a recent definition of common response criteria.[118]

Epidemiology

The incidence of JMML in the United States has been estimated as 0.69 to 1.2 per million.[4,119] There is a male predominance with a median age of diagnosis of 1.8 years. The apparent incidence and demographic distribution may change in the coming years because of the refinement of diagnostic techniques such as molecular testing. In particular, mutation analysis may identify patients with less aggressive disease or at a younger age.

Pathogenesis

Early clonality studies suggested that JMML arose at the level of at least an immature myeloid precursor cell.[117,120–124] More recent data suggest that JMML may arise in a pluripotent stem cell with involvement of the myeloid, erythroid, and megakaryocyte lineages, as well as B lymphocytes and T lymphocytes.[117,125–128] This is supported by finding pathogenic mutations in immature hematopoietic cells identified by flow cytometry.[129]

Somatic mutations that augment signaling through the Ras pathway occur in approximately 90% to 95% of JMML patients. These include biallelic inactivation of *NF1* (15%),[18] activating mutations in *NRAS* or *KRAS* (25%),[130–132] mutations in the *PTPN11* gene (see Fig. 65.1) (35%), and mutations in *CBL* (10% to 15%).[133–136] Less frequent but more recently reported mutations occur in the genes *RRAS*, *RRAS2*, *RAC2* and *SH2B3*. This synopsis reflects decades of research, beginning with the seminal observation that JMML is associated with NF1. A rough comparison of incidence rates suggests that NF1 carries a 500-fold increased risk of acquiring JMML. At a molecular level, these children inherit a defective allele of the *NF1* gene, which encodes a negative regulator of Ras named *neurofibromin*. In JMML, the normal allele is lost as a somatic event in the initiating cell, most often by loss of heterozygosity in which the overall copy number remains unchanged (uniparental isodisomy). This completely ablates neurofibromin and thereby increases Ras activity.

Such interplay of inherited and somatic mutations is also relevant to the other JMML genes. Germline mutations in *PTPN11* cause Noonan syndrome (NS), a common genetic condition that overlaps

TABLE 65.1 **Diagnostic Criteria for Juvenile Myelomonocytic Leukemia**

Category 1 All of the Following:	Category 2 At Least 1 of the Following:	Category 3 At Least 2 of the Following:
Splenomegaly[a]	Somatic mutation in *RAS* or *PTPN11*	Circulating myeloid precursors
AMC >1000/μL	Clinical diagnosis of NF1 or *NF1* gene mutation	WBC >10,000/μL
Blasts in PB/BM <20%	Homozygous mutation in *CBL*	Increased Hgb F for age
Absence of the t(9;22) *BCR/ABL* fusion gene	Monosomy 7	Clonal cytogenetic abnormality excluding monosomy 7
		GM-CSF hypersensitivity

The diagnosis of juvenile myelomonocytic leukemia is made if a patient meets all of the Category 1 criteria and one of the Category 2 criteria without needing to meet the Category 3 criteria. If there are no Category 2 criteria met, then the Category 3 criteria must be met.

[a] For the 7%–10% of patients without splenomegaly, the diagnostic criteria must include all other features in Category 1 AND one of the parameters in Category 2 OR no features in Category 2 but two features in Category 3.

AMC, Absolute monocyte count; *BM*, bone marrow; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *Hgb F*, fetal hemoglobin; *NF1*, neurofibromatosis type 1; *PB*, peripheral blood; *WBC*, white blood cell.

From Chan RJ, Cooper T, Kratz CP, et al. Juvenile myelomonocytic leukemia: a report from the 2nd International JMML Symposium. *Leuk Res.* 2009;33:355.

phenotypically with NF1 and sometimes includes a mild JMML-like myeloproliferative syndrome. This finding led directly to the discovery of somatic *PTPN11* mutations in sporadic JMML, a lesion now recognized as the most common pathogenic mutation in this disease. Furthermore, rare germline mutations in *KRAS* have also been associated with related genetic syndromes including NS and cardiofaciocutaneous syndrome.[137–142] The *PTPN11* and *KRAS* mutations present in the germline generally have less severe biochemical consequences than those in sporadic cases. This suggests that strong signal activation is not tolerated during development. Accordingly, the most common NS-associated *PTPN11* alleles have relatively weak effects on signal transduction, and the myeloproliferative syndrome in these patients is usually transient.[143–145] However, a more recent and comprehensive analysis has suggested that a cohort of NS patients may inherit more deleterious mutations and develop fatal neonatal JMML.[146] Thus, cytoreductive therapy or HCT may be considered for select NS patients with severe disease.

Similar to *NF1*, mutations in *CBL* are most often heterozygous in the germline, with subsequent reduction to homozygosity in hematopoietic cells. However, recent reports demonstrate that JMML patients can harbor somatic *CBL* mutations, similar to adults with MPNs.[135] The more typical heterozygous germline mutations appear to cause a genetic syndrome with features that can overlap with NS, termed *CBL syndrome* or *NS-like disorder with or without JMML*. The phenotypic manifestations of NSLL are variable and incompletely penetrant, and they include cryptorchidism, hearing loss, and skeletal abnormalities. Importantly, major vascular abnormalities have been described in patients with *CBL*-mutant JMML, and this could also reflect an NSLL phenotype. As expected for a heterozygous mutation, transmission is autosomal dominant, although 50% of cases arise spontaneously.[134,136,147,148] In contrast to the loss of function mutations in *NF1*, the mutations in *CBL* selectively inactivate the ubiquitin ligase activity of the Cbl protein while leaving the molecule otherwise intact. When homozygous, this alteration eliminates the negative regulatory activity of Cbl while sparing positive signaling functions.[135]

These so-called *Ras pathway* or *driver* mutations are largely mutually exclusive, supporting the idea that each provides a similar function in JMML. However, patients with two such lesions (approximately 10% of patients have co-occurring Ras pathway mutations) or duplication of the mutant allele have been reported, typically co-occurring in the same cells.[149,150] This likely reflects clonal evolution and positive selection for increased Ras signaling even beyond that provided by the initiating mutation. Growing evidence demonstrates that negative feedback prevents the Ras pathway from being fully activated by a single lesion, leading to a dosage effect of mutant alleles on signaling outputs.[151] Consistent with predictions from model systems, cases with multiple Ras pathway mutations have a more aggressive clinical course.[150]

Genomic studies have also begun to address the question of whether mutations outside the Ras pathway contribute to the pathogenesis of JMML.[129,149,150,152] A wide variety of so-called secondary mutations have now been recognized. They are primarily associated with relapse of JMML after HCT, or with transformation to AML. However, they often can be detected at a low level in the blood or BM when JMML is first diagnosed. This suggests that clonal evolution depends on chemotherapy resistance and eventually leukemic transformation. This is supported by the striking observation that secondary mutations of any kind have a major prognostic impact, even when they are present in a very small proportion of hematopoietic cells at diagnosis.

In the few JMML cases in which clonal history has been inferred, mutations appear to be acquired sequentially, beginning with a Ras pathway lesion. This linear evolutionary path contrasts with the highly branched patterns typical of high-grade neoplasms. Thus, despite the discovery of a variety of secondary mutations in JMML, it remains a disease with much less genetic complexity than most cancers. This may have important implications for therapy, as any individual patient is likely to harbor a relatively small number of distinct subclones that need to be eradicated to achieve cure.

The cellular function of cooperating mutations in JMML is under active investigation. Most can be categorized into three groups. Some amplify signaling beyond the level provided by the initial Ras pathway mutation. As described earlier, some second mutations directly alter core Ras pathway genes. Janus-activated kinase (JAK)/signal transducer and activator of transcription (STAT) signaling is enhanced by activating mutations in *JAK3* or loss-of-function mutations in *SH2B3*, which encodes the negative regulatory adaptor protein LNK. Mutations in *RRAS*, *RRAS2*, and *RAC2* represent a novel signaling complex in JMML that is implicated in regulating the PI3K/Akt pathway.[150] Dominant point mutations in *SETBP1* remain somewhat unexplored, but may augment signal transduction by inhibiting the phosphatase PP2A, or regulate gene transcription and strengthen self-renewal programs. Other secondary lesions have broad effects on gene expression, through inactivation of the PRC2 polycomb repressor complex or alteration of spliceosome components. Many of these genes and cellular functions are also implicated in the pathogenesis of other myeloid neoplasms such as CMML or AML.

Several genome-wide studies have now been published documenting the role of altered DNA methylation as a predictor of the outcome in JMML.[153–155]

Patients with a hypermethylated profile are typically present at an older age, have higher levels of fetal hemoglobin, and more often have more than one somatic alteration in their JMML cells.

In multivariable analyses, DNA methylation has been the most significant predictor of outcome with hypermethylated patients experiencing the highest rates of relapse post-HSCT. In contrast, patients with a hypomethylated profile tend to be younger at presentation, have normal levels of fetal hemoglobin and invariably have only one somatic mutation. These patients are more likely to be cured with HSCT but of interest may also be the most likely to experience spontaneous resolution in the absence of transplant. International efforts are now underway to establish consensus definitions of altered DNA methylation and develop techniques to bring DNA methylation testing into the clinic in order to prospectively test the predictive nature of DNA methylation. The exact mechanism that altered DNA methylation plays in this disease has yet to be elucidated and is the focus of ongoing investigations.

Model Systems

Genetically engineered mouse models of JMML have been based on directed mutation of *Nf1*, *Kras*, *Nras*, *Ptptn11*, and *c-Cbl*. These are reviewed in detail elsewhere.[156,157] In general terms, these mice reproduce many key features of JMML, but penetrance and severity of disease vary across these models. In an alternative approach, induced pluripotent stem cells have recently been generated from germline and neoplastic cells from JMML patients.[158] These can be differentiated into myeloid progenitors that also recapitulate signal transduction and cell biology phenotypes characteristic of JMML. Most recently, several groups have reported the feasibility of generating patient derived xenograft models using a variety of immunocompromised mouse strains. Together, these systems provide a robust set of tools for investigating the biology of JMML and also enable preclinical testing of novel therapeutic strategies.

Clinical Manifestations

Children with JMML typically present with signs and symptoms attributable to a heavy burden of organ-infiltrating cells that results in hepatosplenomegaly, lymphadenopathy, and skin rash. As a result of the association with neurofibromatosis, patients may also have café-au-lait spots or juvenile xanthogranulomas. Death is usually the result of organ dysfunction caused by infiltrating cells, infection, or bleeding. Approximately 10% to 20% of children progress to a blast-like phase consistent with AML.

Laboratory Manifestations

Laboratory abnormalities may include an elevated white blood cell count with absolute monocytosis, anemia, and thrombocytopenia (Figs. 65.3 and 65.4). Monocytes, either circulating in the peripheral blood or in the BM, frequently appear dysplastic. The peripheral smear shows leukoerythroblastic changes, and there are often circulating nucleated red blood cells. Fifty percent of patients may also present with elevated fetal hemoglobin levels and hypergammaglobulinemia, which is of interest given that there are patients recently described with autoimmune lymphoproliferative syndromes who also harbor *RAS* mutations (see later). International criteria mandate that the BM have fewer than 20% blast cells at diagnosis. Other findings typical in the BM may include micromegakaryocytes.

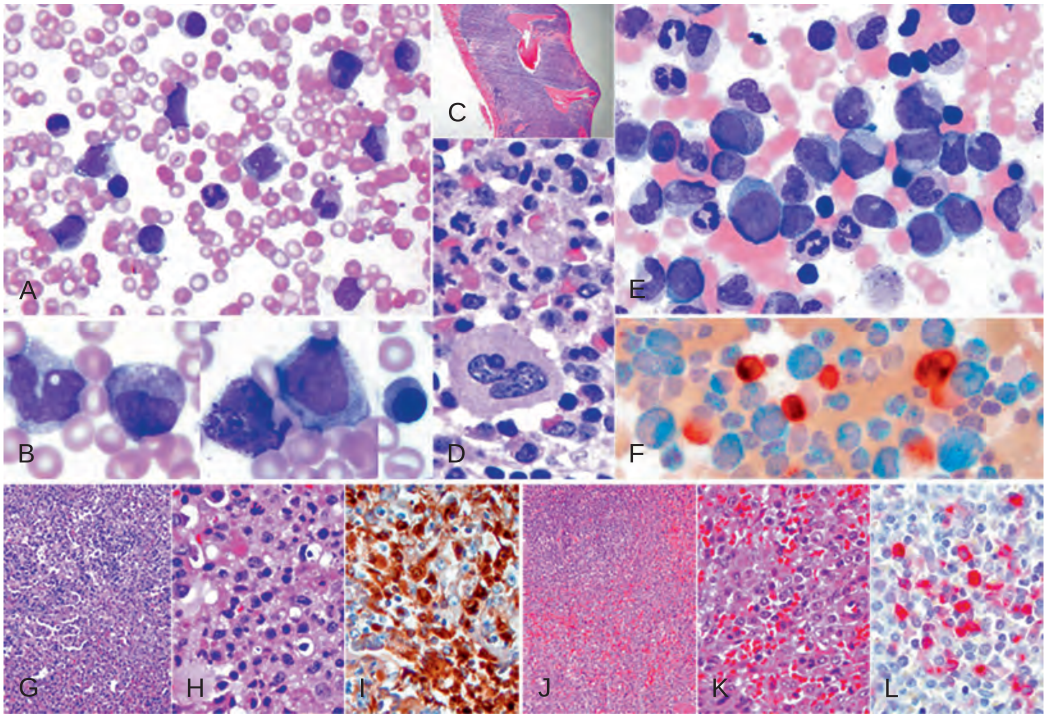

Figure 65.3 JUVENILE MYELOMONOCYTIC LEUKEMIA: BLOOD, BONE MARROW, LUNG, AND SPLEEN. The illustrations are from the case of a 3-year-old boy who was diagnosed with neurofibromatosis at birth. At 1 year of age, he presented with leukocytosis (58 K/μL). The peripheral blood (A and B) showed left-shifted granulocytes and increased monocytes (16%). A bone marrow biopsy (C and D) was hypercellular as a result of increased granulocytic and monocytic cells that could also be appreciated on the aspirate (E). Blasts accounted for only 4% of the bone marrow elements. A combined esterase reaction (F) illustrated the increased monocytes (α-naphthol butyrate esterase reaction positive; *orange/brown*) in the background of granulocytes (chloroacetate esterase reaction positive; *blue*). Cytogenetic analysis revealed monosomy 7. At age 2 years, the patient presented with respiratory distress, and a lung biopsy (G and H) demonstrated a monocyte infiltrate (lysozyme stain, I) consistent with involvement by juvenile myelomonocytic leukemia. This is not uncommon in such patients. At age 3 years, his blast count began to rise, and he underwent a splenectomy (which showed a marked infiltrate of immature and mature monocytes and granulocytic cells [J and K; lysozyme stain, L]). After the splenectomy the patient underwent a successful stem cell transplant.

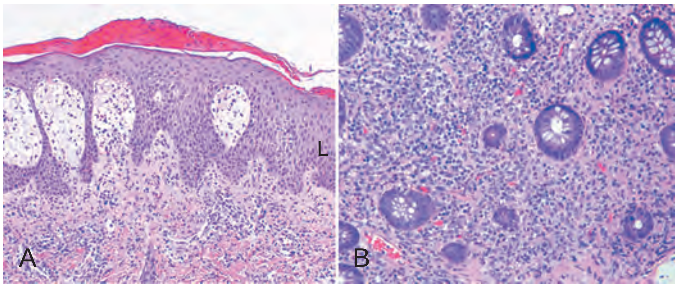

Figure 65.4 JUVENILE MYELOMONOCYTIC LEUKEMIA: SKIN AND GASTROINTESTINAL TRACT. Patients with juvenile myelomonocytic leukemia sometimes present with or develop skin nodules, which on biopsy show a myelomonocytic infiltrate in the upper and lower dermis (A). Involvement can also be seen in the gastrointestinal tract (B). *(The case was kindly provided by Dr. Elizabeth Hyjek, University of Chicago.)*

Differential Diagnosis

Traditionally, establishing a diagnosis of JMML was challenging because its clinical and laboratory presenting features can also be associated with other disorders, including Wiskott-Aldrich syndrome,[159] infantile osteopetrosis,[160] infections (Epstein-Barr virus, cytomegalovirus, human herpesvirus 6, histoplasmosis, mycobacterium, and toxoplasmosis), class I Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis, FA, Kostmann syndrome, Shwachman syndrome, and Down syndrome. However, with a confirmed molecular mutation, patients who exhibit the category 1 features are now more easily diagnosed.

Recently, the term "Ras-associated lymphoproliferative disorder (RALD)" has been coined to describe patients with autoimmunity and lymphoid proliferation with activating *RAS* mutations in the blood.[161] These mutations were initially thought to be in the germline, but later were established to be somatically acquired in the BM. These patients also exhibit splenomegaly and monocytosis, and they tend to meet clinical diagnostic criteria for JMML. At this time, there is no accepted method for distinguishing JMML from RALD, except to note that patients diagnosed with RALD have less fulminant myeloid disease and relatively more prominent immune dysregulation. Further study is needed to determine whether these diagnoses represent distinct clinicopathologic entities, or rather represent the spectrum of hematologic phenotypes specified by Ras pathway mutations. Along with reports of rare JMML patients who survive without chemotherapy despite persistent Ras pathway mutations, this idea has raised the controversial question as to whether or not select patients can be monitored without definitive therapy. However, given the difficulty of prospectively diagnosing RALD, its extremely low incidence, and the strong tendency of JMML to become more aggressive over time, most patients meeting JMML criteria should be treated as such.

Therapy

Children with JMML can have a variable course, with rare patients having a spontaneous remission and long-term survival without treatment, and others having a rapidly fatal course despite aggressive treatment.[162,163] The patients likely to do well without HCT are those with somatic *NRAS* or *KRAS* mutations, or germline mutations in *CBL*.[135,164,165] Older age, lower platelet count, and elevated hemoglobin F levels have been used to predict a more aggressive clinical course for patients.[4,166–169] Currently, the most adverse prognostic factors for outcome are the presence of >20% blasts, an AML-like gene expression profile,[166,168] or a hypermethylated DNA signature, which have survival rates of 10% to 20% even with allogeneic HCT.

A wide variety of agents have been used to treat children with JMML, including AML-like chemotherapy,[51,170–175] low-dose chemotherapy,[176,177] interferon-α (IFN-α),[178] and 13-*cis*-retinoic acid. Tipifarnib, a farnesyl transferase inhibitor, was tested in a Phase II window by the Children's Oncology Group (COG) where it produced some responses, but did not appear to impact long-term survival.[179] Azacitidine, a DNA hypomethylating agent has now been tested in a prospective clinical trial in Europe with promising results. Trametinib, an oral, MEK1/2 inhibitor is currently being tested through the COG for JMML patients with relapsed or refractory disease (NCT03190915).

Perhaps because the evaluation of these treatment regimens has been complicated by small patient numbers, a prior lack of consistent response criteria, and until recently, lack of assays to measure residual disease, the utility of chemotherapy prior to HCT is unclear. One report showed no difference in univariate post-HCT outcomes in patients who did or did not receive AML-like chemotherapy, but this was limited by the inclusion of patients with AML and the lack of multivariate analysis.[166] A report in patients undergoing umbilical cord blood transplant shows a trend towards better post-HCT EFS after receipt of AML-like chemotherapy.[167] Another report demonstrated trends to better EFS and lower relapse in patients who had normalization of WBC count and organomegaly prior to HCT.[179] With the advent of uniform response criteria[118] and the ability to follow molecular disease burden in patients with mutations in *PTPN11*, *NRAS*, and *KRAS*,[180] the role of pre-HCT chemotherapy has evolved. A single center report demonstrated that patients who achieved low levels of molecular disease burden pre-HCT had excellent post-HCT outcomes,[181] though this needs to be confirmed in larger datasets.

For most children with JMML, allogeneic HCT offers the only known potential for cure, with about half of transplanted children surviving disease-free.[166,167,182] Rapid withdrawal of immunosuppression appears to be important in this disease, as mounting evidence supports a graft-versus-leukemia effect.[181,183,184] A number of issues related to HCT for JMML remain uncertain. Among these are the value of pre-transplant splenectomy, and the optimal conditioning regimen and graft-versus-host disease prophylaxis. Splenectomy demonstrated a trend towards improved outcomes in patients undergoing umbilical cord blood transplant,[167] but no benefit in those getting transplants from other donors,[166,179] and can be associated with increased risk of overwhelming sepsis from encapsulated organisms. Triple alkylator-based conditioning appears to be associated with lower rates of relapse for patients with high disease burdens, either through direct anti-leukemic effects or via tissue-injury mediated induction of GVHD and GVL.[185] However, these very intensive regimens might not be needed for patients who enter HCT in molecular remission.[181] Radiation-containing preparative regimens, which have significant long-term risks in small children, have not shown benefit when compared with other published reports,[179] although they did decrease the risk of rejection in patients undergoing cord blood transplant.[167] JMML appears to be highly sensitive to a GVL effect.[181] As such, preemptive withdrawal of immunosuppression may be beneficial in the setting of low disease burden and donor leukocyte infusions may have some response.[184,186] While the most common cause of death after HCT is recurrent disease, a second HCT can be lifesaving for some children.[166,187,188]

Down Syndrome–Associated Transient Abnormal Myelopoiesis

Epidemiology

Down syndrome is one of the most common congenital disorders, affecting approximately one in every 800 to 1000 live births. A population-based study estimated that children with Down syndrome have a 10- to 20-fold overall increased risk of developing leukemia,[189] a 150-fold increased risk of developing AML, and a 500-fold increased risk of acute megakaryocytic leukemia. The median age of diagnosis of myeloid leukemia of Down syndrome (ML-DS), as defined by the WHO classification system, in children with Down syndrome is 2 years, and it is rarely diagnosed after age 4.[190] TAM, also known as *transient myeloproliferative disorder (TMD)* and *transient leukemia*, is thought to occur in at least 10% of children with trisomy 21 Down syndrome, although 7% to 16% of TAM cases have mosaic trisomy 21. It has also been suggested that when cases of TAM that develop and resolve in utero or result in death before delivery are taken into account, the incidence may be as high as 20%.[191] Currently, it is estimated that approximately 10% to 20% of children with TAM subsequently develop ML-DS, usually by 3 years of age.[192–194]

Pathobiology

The molecular pathogenesis of TAM and ML-DS in children with Down syndrome has provided valuable insights into myeloid leukemogenesis.[195] Current research suggests that the development of TAM and subsequent progression to ML-DS result from a three-step process: perturbation of fetal hematopoiesis by trisomy 21; an acquired *GATA1* mutation; and the acquisition of additional oncogenic mutations.[195,196]

It is increasingly clear that trisomy 21 results in genome-wide changes in gene expression that affect, directly or indirectly, most chromosomes.[197,198] This results in perturbed hematopoiesis with increased numbers and clonality of HSCs, increased frequency of megakaryocyte and erythroid progenitors, and reduced numbers of granulocyte- and macrophage-committed progenitor cells.[199,200]

Recent studies have shown that virtually all patients with TAM, and most patients with ML-DS, harbor mutations in exon 2 and, occasionally, in exon 3 of the hematopoietic transcription factor *GATA1*.[201–205] *GATA1* is a double–zinc finger DNA-binding transcription factor expressed primarily in hematopoietic cells. It is required for the development of red blood cells, megakaryocytes, mast cells, and eosinophils. A number of different mutations in *GATA1* have been identified, including insertions, deletions, missense mutations, nonsense mutations, and splice site mutations. All of these mutations lead to a block in the expression of the full-length 50-kd isoform of *GATA1* but allow for the expression of a smaller, 40-kd isoform (*GATA1s*).[206] This smaller isoform lacks the N-terminal transactivation domain, but retains both zinc fingers involved in DNA binding as well as interactions with its cofactor, friend of *GATA1* (*FOG1*).[201] Recent studies have shown that mutations that alter *GATA1-FOG1* binding in the N-terminal zinc finger or result in the expression of the *GATA1s* isoform uncouple megakaryocyte growth and differentiation.[207–209] Similar studies in cell lines derived from children with ML-DS have demonstrated that expression of *GATA1* led to erythroid differentiation whereas expression of *GATA1s* did not alter the characteristics of the cell line.[205] Taken together, current data suggests that the loss of *GATA1* and expression of *GATA1s* directly contribute to leukemogenesis. Importantly, TAM and ML-DS reflect an interaction between *GATA1s* and trisomy 21. This likely reflects the combined effects of multiple genetic interactions, with studies implicating various genes on chromosome 21 such as *ERG*, *ETS2*, *RUNX1*, *CHAF1B*, and mir-125b2.[195]

Although *GATA*1 mutations in the context of trisomy 21 may be sufficient to cause TAM, these mutations are not sufficient for the development of ML-DS, as evidenced by the latency period between resolution of TAM and the development of ML-DS, as well as the observation that not all children with TAM and *GATA1* mutations will ultimately develop ML-DS. Therefore, a multistep pathogenesis model is proposed in patients with Down syndrome in whom ML-DS develops in clones with *GATA1* mutations and additional cooperating mutations. This has been corroborated by genomic analyses of TAM and ML-DS cases.[198,210] These studies have revealed common molecular functions in genes mutated upon progression to ML-DS. One such class increases cytokine signaling, with typical lesions affecting genes in receptors (*MPL*. *CSF2RB*, *KIT*), associated kinases (*JAK2*, *JAK3*), and downstream signal transduction molecules (*NRAS*, *KRAS*, *NF1*, *SH2B3*). Another class of mutations disrupts the cohesin complex (*STAG2*, *RAD21*, *CTCF*, *SMC1A*). This multifunctional complex regulates sister chromosome pairing during mitosis and also participates in epigenetic regulation of gene expression in a broad fashion. Epigenetic regulation is also implicated by a third large class of mutations (*EZH2*, *SUZ12*, *KANSL1*, *DNMT3A*), often reducing function of the PRC2 complex and/or DNA methylation. Importantly, some of these same genes can be mutated in TAM, but without the same deleterious biochemical or functional consequences; thus, mutations of unclear functional significance must be interpreted with caution in TAM.[198]

Clinical Manifestations

Patients with Down syndrome typically present with TAM within 3 months after birth, although TAM can be manifest at birth. Some of these children present with hydrops fetalis, secondary to anemia and cardiac dysfunction. Although some patients may be asymptomatic, others can have myeloblast infiltration of the heart, liver, and spleen that can result in hepatosplenomegaly; hepatic fibrosis; pleural, pericardial, and peritoneal effusions; and disseminated intravascular coagulopathy. In some cases, organ dysfunction can be severe, with failure of the liver, heart, kidneys, and lungs. In the COGs prospective study, death occurred in 21% of patients, although only 10% died as a result of TAM-associated problems.[192]

Laboratory Manifestations

The complete blood count in infants with TAM typically demonstrates an elevated white blood cell count with myeloblasts present (Fig. 65.5). One difficulty that arises when evaluating a baby for TAM is that circulating blasts are present to some degree in almost newborns with Down syndrome. However, in a landmark study that included molecular analysis, *GATA1* mutations were found only in patients with peripheral blasts present at levels >10%.[211] Thus, some groups require *GATA1* mutation for diagnosing TAM (with a detection threshold of >5%); however, this may not be universally available, and the clinical significance of rare *GATA1* mutant clones (e.g., <1%) remains unclear. In the same study, deep sequencing revealed that 20% of babies lacking clinical or hematologic features of TAM had such small *GATA1* mutant clones. While these authors coined the term "silent TAM" for these patients and recommended close observation, a widely accepted standard of care has yet to be defined. Rarely, a neonate without stigmata of Down syndrome will present with similar features—in these cases, workup for either trisomy 21 mosaicism or a *PTPN11* mutation should be pursued.

Myeloblasts from TAM and ML-DS patients have an immunophenotype that is distinct from other types of AML in children.[212,213] Specifically, all TAM and ML-DS blasts express CD45, CD38, and CD33, but the majority of cases express CD36 and CD34. CD41 and CD61 also are expressed, consistent with megakaryocyte differentiation. CD14 and CD64 are usually negative. Most cases have

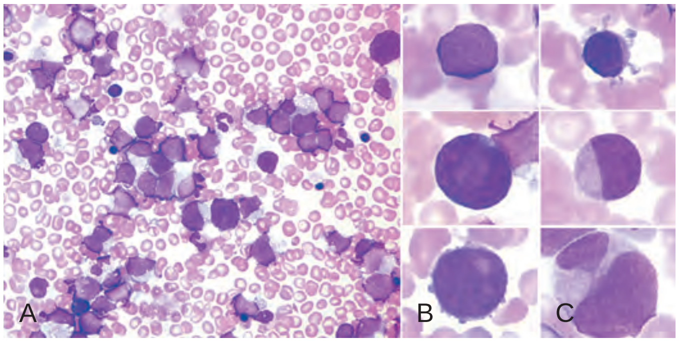

Figure 65.5 TRANSIENT ABNORMAL MYELOPOIESIS AND TRANSIENT LEUKEMIA OF DOWN SYNDROME. The patient was a premature newborn girl with trisomy 21 and a white blood cell count of 195,000/μL with 67% blasts (A). The blasts were CD34+, CD33+, and CD117+, and a portion exhibited CD41, a megakaryocyte marker. Morphologically, some of the blasts appeared to be megakaryoblasts (B), sometimes with slight differentiation toward megakaryocytes (C).

aberrant expression of CD7, a T-lineage antigen. Finally, regenerating BM in children with Down syndrome often demonstrates a population of nonmalignant CD34$^+$/CD56$^+$ precursors.[214]

Therapy and Prognosis

Supportive care is sufficient management for most babies with TAM.[192,215,216] In the COGs prospective study, peripheral blood blasts and TAM-associated symptoms resolved in 36 and 49 days, respectively, for observation patients.[192] However, approximately 25% of patients with clinically significant TAM exhibit life-threatening organ dysfunction, and these patients warrant urgent medical intervention. Risk factors for mortality have been defined by several studies (summarized in Box 65.1). Importantly, hepatopathy can be fatal after a protracted, indolent course that eventually leads to irreversible hepatic fibrosis. This represents one of the most common causes of death associated with TAM. Thus, liver dysfunction is an urgent indication for chemotherapy even when it appears to be physiologically well tolerated. By contrast, mild hepatomegaly with adequate function is not itself an indication for treatment unless it compromises the function of other vital organs. Guidelines for management of TAM that incorporate international studies have recently been published by the British Society for Haematology.[217] Though not part of these guidelines, prematurity (gestation <37 weeks) has also been noted as a recurrent risk factor for early death.[192,215,216]

A consensus has emerged that a short course of low-dose cytarabine (e.g., 1 to 1.5 mg/kg/day for 5 to 7 days) improves outcomes for babies with TAM at risk for mortality. In a non-randomized trial, the BFM group reported a substantial benefit of low dose cytarabine among infants with TAM and high risk features.[215] The overall survival was 76% in the treated patients versus 28% in the untreated patients. Similarly, the Japanese TAM-10 study demonstrated that patients with leukocytosis (>100 × 10^8/l) had survival rates of 78% if treated with cytarabine versus 39% if not.[216] While neutropenia is a common adverse effect of cytarabine, the benefits appear to greatly outweigh the risks for high risk TAM patients. Therapy should be initiated promptly for patients with these risk factors; supportive care is insufficient in patients with life-threatening symptoms.

Most patients with TAM lacking high risk features do well with supportive care. Approximately 10% to 15% of these patients die in early infancy.[192,216] However, the COG study reported that almost all of these deaths were attributable to causes unrelated to TAM. These patients must be closely monitored for resolution of TAM and possible development of life-threatening symptoms such as hepatopathy, or emergence of ML-DS. Failure to resolve hematologic abnormalities by 4 months of age is atypical and should raise consideration of potential transformation to ML-DS or MDS.

Therapy for ML-DS has been adapted from conventional AML protocols, after early studies noted that these patients had higher cure rates but also more severe toxicities. These observations have been attributed partly to an increase in cytarabine sensitivity in cells with trisomy 21. Subsequent studies have attempted to improve the risk-benefit ratio of chemotherapy by reducing intensity. AAAML0431 adapted standard AML therapy for ML-DS by (a) moving high-dose cytarabine earlier in the treatment regimen (from cycle 5 to cycle 2), and (b) reducing anthracycline exposure by 25%. This successfully preserved the excellent outcomes in ML-DS patients, with >90% having long term event-free survival.[218] Similarly, a European study, ML-DS 2006, was able to reduce etoposide exposure by ~50%.[219] The most recent North American study, AAML1531, attempted to reduce therapy further in low-risk ML-DS patients by eliminating a course of high dose cytarabine and asparaginase. However, relapse (and salvage) rates were unacceptably high in these patients. Thus, prolonged and intensive myelosuppressive chemotherapy is still considered essential for curing ML-DS. Interestingly, high dose chemotherapy is effective for ML-DS when it presents as MDS without excessive blasts in the marrow. This is distinct from sporadic MDS in the general population, for whom the benefit of chemotherapy is less clear.

BOX 65.1 Life-Threatening TAM Symptoms Indicating Need for Intervention[192,217]

Multi-organ failure
White blood cell count >100 × 10^8/L or leukostasis
Hepatopathy (conjugated bilirubin >83 μmol/L or >5 mg/dL, ascites or massive hepatomegaly)
Hepatosplenomegaly (beyond umbilicus or causing respiratory or feeding compromise)
Hydrops fetalis
Pleural or pericardial effusions
Renal failure
Disseminated intravascular coagulation/coagulopathy with bleeding

Chronic Myeloid Leukemia

Epidemiology

Nearly 1 in 500 adults will be diagnosed with CML in their lifetime. CML in children on the other hand is rare with an annual incidence of between one and two cases for every million children under the age of 18 in the United States.[220] Both children and adults can present in one of three phases: (1) nearly 90% present in the chronic phase which is the most common and indolent, (2) accelerated phase is more aggressive and (3) blast phase, upon transformation to an acute leukemia, either ALL or AML.[221] In general, children appear to have higher risk disease with more frequent presentation in accelerated or blast phase compared to adults.[222]

Pathogenesis

CML is an MPN that occurs in HSCs. In children, it always presents with the Philadelphia chromosome t(9;22)(q34;q11), leading to the fusion gene, *BCR-ABL1*.[223] This encodes for an oncoprotein, leading to a constitutively active tyrosine kinase as a result of oligomerization of the coiled coil region of BCR, and deletion of the inhibitory SH3 domain of ABL. Several downstream pathways are then activated including JAK2, RAS, and STAT1/5. Nearly 90% of patients present in the chronic phase of the disease, but the events leading to the more advanced accelerated phase and blast crisis are incompletely understood. Typically, cytogenetic changes involving the acquisition of additional oncogenes or loss of tumor suppressors is noted. The single most common alteration involves deletion of 17q, where p53 resides, but non-random changes involving chromosomes 7, 8, 9, and 22 are frequent. Patients who transform to acute lymphoblastic leukemia frequently present with loss of CDKN2A/B. In general, it is thought that constitutive activation of BCR/ABL1 leads to an unstable genome within the mutated HSC, which results in the increased likelihood of non-random changes involving genes with critical functions that are more likely to be tolerated due to impaired apoptosis.[224]

Clinical Manifestations

Children with CML frequently present with elevated white blood cell and platelet counts.[222] These can be detected in the asymptomatic patient but more frequently due to fatigue, malaise or weight loss. Patients can also present with concomitant infections due to nonfunctional neutrophils. Enlargement of the spleen is nearly universal at diagnosis and can cause abdominal discomfort. Bleeding due to thrombocytopenia, coagulation defects, or even thrombocytosis with an acquired von Willebrand's disease can be presenting symptoms.

Laboratory Manifestations

CML patients present with a median elevated white blood count of 250 × 10^8/l per an international registry study of nearly 200 pediatric patients with a median age of 12 years.[225] Owing to the myeloproliferative nature of the disease, nearly all types of myeloid cells will be visible on a peripheral blood smear, with basophilia and eosinophilia being nearly universal. Blasts are typically <2%, although it can be higher depending on the phase of presentation. A CBC and FISH, or RT-PCR for BCR/ABL, can be performed although a BM examination that rules out the more common diagnosis of AML is required. Cytogenetic culture is typically sent from the BM. Next-generation sequencing is more commonly sent at diagnosis to determine the presence of tyrosine kinase inhibitor (TKI) resistance mutations although the therapeutic utility of this approach has not been definitively documented.[226]

Therapy

As a poster child for precision medicine, the advent of TKIs demonstrated remarkable efficacy in CML, first in adults and later in children.[227] A paradigm shift occurred in adults, wherein CML became a chronic manageable condition in the setting of TKIs, of which several generations of increasingly potent drugs are now available. In pediatrics, whereas HSCT was indicated for nearly all patients in the pre-TKI era, it is now reserved for patients who present in an accelerated or blast crisis phase.[228] For the approximately 90% of pediatric patients who present in the chronic phase of the disease, monotherapy with a TKI is the standard of care. The choice between the several generations of TKIs including, but not limited to, imatinib (first generation), dasatinib or nilotinib (second generation), ponatinib or bosutinib (third generation) to name just a few, is mainly stylistic or resource-dependent, as there is no clear winner from the few randomized studies in pediatrics.[222] The goal with all treatment is to induce rapid molecular remission and prevent the development of mutations that cause resistance to TKIs. Studies have demonstrated that adult patients who achieve early and/or major molecular remissions can safely stop TKI therapy and maintain deep remissions. TKIs in children have been shown to affect growth among other side effects and, in pediatrics, there is great interest in safely discontinuing TKIs. Prospective studies testing this strategy in pediatrics are currently ongoing. In summary, TKIs have transformed CML, but the optimal TKI, duration, and the exact role of HSCT are still not defined in pediatrics.

Prognosis

There are several prognostic scoring schemas that accurately predict the outcome in adults in the context of a variety of therapies including TKIs. Prognostic include age, sex, spleen size, white count, basophil, eosinophil and blast count.[229] However, none of these prognostic models have ever been prospectively tested in pediatric CML. In general, early cytogenetic and molecular responses are associated with favorable outcomes in both adult and pediatric studies.

Other Myeloproliferative Neoplasms

Essential Thrombocythemia

ET has an estimated incidence of 1 to 1.25 cases per million in adults, but it is even rarer in children, with an estimated incidence of 0.09 cases per million.[230–234] ET is a genetically heterogeneous disease. Mutations in *JAK2* have been reported in adults with *BCR-ABL*–negative MPNs, including ET, PV, and idiopathic myelofibrosis (IM). It has been proposed that ET consists of several subtypes, with some children and adults having monoclonal disease but others having polyclonal disease. Further investigation into the mutational status of *JAK2* V617F also demonstrates mutation-positive (roughly 55%) and mutation-negative patients.[231,235] Another cause of ET was recently demonstrated to be mutations in CALR (calreticulin).[236] Studies suggest that a similar proportion of children with sporadic ET display polycythemia rubra vera-1 (PRV-1) RNA overexpression, *JAK2* V617F mutations, and monoclonal disease, as compared to adults with sporadic ET.[237] Rare cases of familial ET have been shown to be caused by dominant activating mutations in both *c-MPL*[237] and in *JAK2*.[238]

Patients with ET have thrombocythemia with an increased number of megakaryocytes in the BM. Platelet clumps on peripheral blood smears are common. Some patients have a concomitant increase in the number of peripheral blood granulocytes. The differential diagnosis includes familial ET, other forms of MPS, and increased platelets as a reactive process.

Although the clinical course can be uncomplicated, patients can develop thromboembolic complications, including deep venous thrombosis, and arterial thrombosis such as transient cerebral ischemia and peripheral vascular ischemia. The clinical course for children is typically less aggressive than in adults, with fewer thrombotic episodes.[237,239] Adult patients have a median survival of at least 10 years, with most deaths caused by thrombosis.[240,241] Progression to AML has been reported in adult patients, usually those with a prior exposure to chemotherapy agents.

Asymptomatic children do not require treatment. There is no clear association with platelet count and thrombotic events. As such, there is not a clear role for treatment with aspirin, which can increase the risk of paradoxical bleeding episodes.[242] Risk factors for thrombosis include leukocytosis and the presence of a *JAK2* V617F mutation.[243] A number of treatment approaches aimed at controlling thrombocytosis have been attempted for symptomatic patients, including hydroxyurea, IFN-α, and anagrelide.[244–246] The JAK inhibitor ruxolitinib may benefit some patients with ET, especially those with *JAK2* V617F mutations, although pediatric-specific data with this agent are lacking. The only potentially curative therapy for ET is allogeneic HCT.[247] Because ET is primarily a disease of older individuals, the data on its efficacy is mainly limited to adult patients with ET that had transformed to myelofibrosis or AML.[248–250] However, younger patients, and those with matched related donors, did especially well, suggesting that allogeneic transplant should be considered in the rare pediatric patient with symptomatic ET.

Idiopathic Myelofibrosis

Idiopathic MF is very rarely diagnosed in children[251] and should be differentiated from acute megakaryocytic leukemia; metastatic neoplasms; and connective tissue, metabolic, and bone diseases. It is characterized by BM fibrosis, megakaryocytes with bizarre morphology, splenomegaly, anemia, and extramedullary hematopoiesis. Idiopathic MF is a clonal disorder, with approximately half of adult patients having mutations in *JAK2* V617F.[252] Recent studies have suggested that angiogenic cytokines produced by megakaryocytes and monocytes and their receptors (platelet-derived growth factor receptors, vascular endothelial growth factor receptor-2, and fibroblast growth factor receptor) may be involved in the pathogenesis of the myelofibrosis.[253]

Treatment algorithms for adult MF have been proposed (Fig. 65.6).[254] Numerous treatment approaches have been attempted with variable degrees of success. These include splenectomy, splenic radiation, transfusions, androgens, corticosteroids, hydroxyurea, and IFN-α.[255–257] More recently, based on preliminary studies about the potential role of angiogenic cytokines and their receptors, newer approaches have been tested, including the tyrosine kinase inhibitor imatinib[258,259] and the antiangiogenic agent thalidomide.[260,261] Selective JAK inhibitors have been successfully used in patients with IM with a dramatic improvement in the quality of life, but without generalized reduction of the *JAK2* V617F burden allele.[262] In 2011, the United States Food and Drug Administration granted approval to the first of these agents, ruxolitinib, for adults with IM. However, the safety and efficacy of ruxolitinib in children is still unknown. Further trials are investigating the combination of JAK inhibition in combination with other therapeutic modalities, such as PI3K inhibition, mammalian target of rapamycin inhibition, histone deacetylase inhibition, and antifibrotic agents.[263]

Allogeneic stem cell transplantation in myelofibrosis. Biol Blood Marrow Transplant. 2017;23(9):1429–1436.)*

Retrospective adult studies suggest that MF patients who respond to JAK2 inhibitors have significantly improved post-HCT OS,[264,265] though a prospective trial was complicated by signs of ruxolitinib withdrawal, including cardiogenic shock and tumor lysis.[266] When used, it appears important to continue JAK2 inhibition until close to the start time of conditioning chemotherapy.

Allogeneic HCT is the only potentially curative option for MF, with resolution of BM fibrosis in donor-engrafted patients, but high rates of transplant-related complications, even with reduced intensity conditioning.[249,267–271] Risk-prediction models (assessing age, performance status, WBC and platelet parameters, mutation status, and donor type) have been built for adults undergoing HCT for MF, which identifies groups with 5-year survival rates as low as 22% and as high as 83%,[272] though whether this data is applicable to children is unknown. Algorithms to help determine whether adult patients should undergo HCT have been proposed (Fig. 65.7).[273]

Polycythemia Vera

PV has an incidence of three cases per 100,000 in adults but is very rarely seen in children, with fewer than 0.1% of PV patients diagnosed before 20 years of age.[270] PV in children is far more often the result of congenital or acquired causes of an increased red blood cell mass. These include primary familial polycythemia (characterized by specific mutations in the erythropoietic receptor gene)[274] and secondary polycythemias caused by abnormal hemoglobins, cardiac and pulmonary disease, excessive erythropoietin, and a relative polycythemia that is the result of decreased plasma volume.

PV in children and adults is associated with clonal hematopoiesis,[275] *JAK2* V617F mutations (in 95% of patients; with mutations in *JAK2* exon 12 representing 2% to 4%),[237,276–281] overexpression of PVR-1 RNA,[282,283] and endogenous erythroid colony growth.[284,285] In contrast to adults, children with PV may be less likely to have *JAK2* V617F mutations and endogenous erythroid colony growth,[237,286] such that the proposed revision to WHOs diagnostic criteria,[287] may be less helpful in the diagnosis of PV in children, although other reports suggest that the proposed WHO criteria are equally applicable to children.[288] The proposed criteria include: (1) a hemoglobin >16.5 g/dL in men or >16.0 g/dL in women; (2) a BM biopsy showing trilineage myeloproliferation and pleomorphic megakaryocytes; and (3) either a *JAK2* mutation or a serum erythropoietin level below the normal reference range.[289] Although the pathogenesis is currently unclear, patients also have abnormalities in tissue factor, endogenous anticoagulants mechanisms, hyperhomocysteinemia, and acquired von Willebrand syndrome.

Children with PV may present with signs and symptoms associated with an increased red blood cell mass such as headache, dizziness, fatigue, pruritus, night sweats, and a ruddy complexion. Mild splenomegaly may be present, but massive hepatosplenomegaly is rare. As a result of hyperviscosity of the blood, elevated platelet counts, and coagulation abnormalities, patients can develop thromboses and CNS ischemia, although the incidence of thrombotic events may be lower than that reported in adults.[237,286]

Many different agents have been used to treat patients with PV, including chlorambucil,[290] melphalan,[291] 6-thioguanine,[292] uracil mustard,[293] busulfan,[294] carboquone,[295] anagrelide,[296] imatinib,[297] hydroxyurea,[298] radioactive phosphorous,[299] and IFN.[300] Despite these efforts, the best approach to patients with PV remains unclear. Therefore, the British Committee for Standards in Haematology formulated recommendations for the initial management of PV.[301] Recommendations include phlebotomy to maintain a hematocrit level <45%;[302] low-dose aspirin unless contraindicated; and cytoreduction if there is poor tolerance to phlebotomy, symptomatic or progressive splenomegaly, evidence of disease progression, or thrombocytosis. For patients younger than 40 years of age, pegylated IFN was the recommendation for first-line cytoreduction, with hydroxyurea as the

second choice. However, the JAK inhibitor ruxolitinib was recently found to have excellent results in controlling the hematocrit and splenomegaly with minimal side-effects in an open-label phase III trial.[303] This may eventually supplant IFN and hydroxyurea as front-line therapy once pediatric-specific dosing is available. Finally, allogeneic transplantation has been successfully used to treat some adult patients with PV,[247–250] especially those with progression to myelofibrosis or AML. Younger patients, and those with matched related donors, did especially well, suggesting that allogeneic transplant should be considered in pediatric patients with PV, though data is currently limited to case reports.[288,304]

FUTURE DIRECTIONS

Although a clearer understanding of the biologic mechanisms underlying MDS in children is slow in coming, dramatic progress has been made in our understanding of the genetic and biologic mechanisms contributing to TMD, JMML, PV, ET, and IM. There exists a potential for targeted therapeutics for many of these disorders, with the first targeted agents now receiving approval for use in adults. However, the use of these approved agents in children remains investigational.

Progress for both MDS and MPN in children will require international cooperation. The rarity of these disorders and limitations in resources for pediatric cooperative cancer groups make clinical trials within each individual cooperative group increasingly difficult.
